The noise produced by air compressors is radiated from the filtered air inlet, the compressor casing, the interconnected piping and interstage cooler, as well as the motor or engine used to drive the compressor. The noise produced by air compressors can exhibit a distinctive duty cycle based on the demand for compressed air and is generally considered omnidirectional and broadband and absent prominent discrete tones. The air inlet noise of certain vacuum pumps sometimes includes high levels of low-frequency pulsating noise.

Noise-estimating procedures presented in this section are applicable to conventional industrial-, utility-, and construction-type air compressors without special noise abatement packages. Air compressors are often available from their manufacturer with special noise abatement packages that include various types of inlet mufflers, laggings, insulations, and enclosures that provide varying degrees of noise reduction. Acoustical data for these low-noise compressors should be obtained directly from the manufacturer's literature.

TABLE 16.1 Adjustments Used to Estimate A-Weighted and Octave-Band L_w[a]

Line	Equipment[b]	A-Weighted	31.5	63	125	250	500	1000	2000	4000	8000

[a] Subtract values shown from estimated overall L_w; except for transformers, subtract values from A-weighted sound level.

[b] RR: rotary and reciprocating; C: casing; S: small, L: large, CC: coal car; R: rotary car dumpers; BL: bucket ladder; CS: clamshell; T: transfer; C. coal; ND C: natural-draft cooling; MD C: mechanical-draft cooling; A-C: air cooled; D: diesel; C-C plant: inside combined-cycle power plant main building; SL: steam line.

The overall sound power level radiated by the casing and air inlet of rotary and reciprocating air compressors can be estimated using Eq. (16.1) (see also line 1 of Table 16.1). These relations for rotary and reciprocating compressors assume that the air inlet is equipped with a filter and small muffler as normally provided by the manufacturer:

$$\text{Rotary and reciprocating compressor, overall } L_w = 90 + 10\log(\text{kW}) \quad \text{(dB)} \tag{16.1}$$

where kW is the shaft power in kilowatts. The casing and unmuffled air inlet overall sound power levels for centrifugal air compressors in the power range of 1100–3700 kW can be estimated using Eqs. (16.2) and (16.3) (see also lines 2 and 3 of Table 16.1). The insertion loss of any muffler installed at the air inlet should be deducted from the calculated inlet power levels:

$$\text{Centrifugal compressor casing, overall } L_w = 79 + 10 \log(\text{kW}) \quad (\text{dB}) \qquad (16.2)$$

$$\text{Centrifugal compressor inlet, overall } L_w = 80 + 10 \log(\text{kW}) \quad (\text{dB}) \qquad (16.3)$$

The term $\log(x)$ represents the common logarithm to base 10 of the value of x.

Equations (16.2) and (16.3) do not include the noise radiated by the motor or engine used to drive the compressor. Sound power levels calculated for the driving equipment should be added to the calculated sound power levels for the compressor.

Mufflers, laggings, barriers, and enclosures have all been used with varying degrees of success to control the noise radiated from compressors to nearby workspaces or neighborhoods. However, it is suggested that it is often most practical to specify and purchase a reduced-noise compressor from the manufacturer.

16.2 BOILERS

Two procedures are provided to predict the noise from boilers; one is for relatively small boilers in the range of about 50–2000 boiler horsepower (one boiler horsepower equals 15 kg of steam per hour). Another procedure is provided for large boilers of the type that serve electric-power-generating stations in the range of 100–1000 megawatts (MWe).

Small Boilers

The sound power output of small boilers is only weakly related to the thermal rating of the boiler. The combustion air fans and the burners probably radiate more noise than do the insulated sidewalls of small boilers. The overall sound power level of small boilers can be estimated using Eq. (16.4) (also see line 4 of Table 16.1):

$$\text{Small boiler, overall } L_w = 95 + 4 \log(\text{bhp}) \quad (\text{dB}) \qquad (16.4)$$

Large Boilers

Noise levels measured in work spaces adjacent to large central-station boilers that are not enclosed in a building (open boilers) are often in the range of 80–85 dBA at the lower half and 70–80 dBA at the upper half of the boiler. Noise levels measured in the vicinity of enclosed boilers (generally found in areas with cold climates) are often about 5 dBA higher. The overall sound power output of large central-station boilers can be estimated by the relation given in Eq. (16.5) (also see line 5 of Table 16.1):

$$\text{Large boiler, overall } L_w = 84 + 15 \log(\text{MWe}) \quad (\text{dB}) \qquad (16.5)$$

The noise from boilers is essentially omnidirectional and broadband in character. However, the combustion air or forced-draft fans, induced-draft fans, gas recirculation fans, overfire air fans, and drive motors sometimes produce tonal noise and may increase the noise levels on their side of the boiler. A small number of boilers have also been found to exhibit a strong discrete tone, usually at a frequency between about 20 and 100 Hz during operation at particular boiler loads. This can be caused by vortex shedding from heat exchanger tubes that excite an acoustical resonance within the boiler that in turn causes coherent (rather than random) vortex shedding to occur at a boiler resonance frequency. The low-frequency tonal noise that radiates from the boiler sidewalls has caused strong adverse reactions from residential neighbors. Boiler operators have also expressed concern about possible fatigue failure of vibrating tube sheets. Installation of one or more large metal plates to subdivide the interior of the boiler volume and thereby change its resonance frequency has successfully corrected this problem. Additional information about this resonant condition and its control is provided in references 4 and 5.

The typical broadband noise radiated by boiler sidewalls has been successfully reduced with the use of a well-insulated exterior enclosure, which also serves as weather protection for equipment and workers. The noise produced by fans serving the boiler can also be controlled as described in Section 16.6.

16.3 COAL-HANDLING EQUIPMENT

A wide variety of noise-producing equipment, such as railcar, ship and barge unloaders, transfer towers, conveyors, crushers, and mills, are used to unload, transport, and condition coal for use at large industrial and utility boilers. The results of numerous noise-level surveys have been studied and condensed to prepare the following general noise prediction procedures for this equipment.

Coal Car Shakers

Coal car shakers vibrate coal cars during bottom unloading. The unloading operation of each car often occurs for about 2–5 min when the coal is not frozen. When frozen coal is located in the car, the shake-out operation can last for up to 10 min or longer. Car shakers are often located inside a sheet metal or masonry building with little or no interior insulation for sound absorption. Shaker buildings include large openings at both ends and sometimes smaller openings and windows along the sidewalls. They also include dust collection and ventilation systems with fans that produce noise. The overall sound power produced during a coal car shake-out can be estimated using the following relation (also see line 6 of Table 16.1):

$$\text{Coal car shake-out, overall } L_w = 141 \text{ dB} \qquad (16.6)$$

Noise produced by the dust collection and ventilation fans can be estimated using the relations provided in Section 16.6 and in Chapter 17.

The far-field noise produced by car shake-outs can be reduced by enclosing the operation inside a metal or masonry building or by reducing the openings in any existing building. In addition, modern car-shaking equipment is sometimes available that produces measured A-weighted sound levels about 10 dB lower than are estimated with Eq. (16.6). Careful train movements can reduce the impact noise associated with indexing the train through the shaker operation. Limiting the shake-out operation to daytime hours also reduces the community noise impacts.

Rotary Car Dumpers

Rotary car dumpers are often used to unload long unit trains equipped with special rotary couplings. It typically takes 2–3 min to unload unfrozen coal from each car. A 100-car unit train can be unloaded in about 3–5 h unless delays are encountered. The overall sound power produced during rotary car unloading cycles can be estimated using Eqs. (16.7) and (16.8) for open and enclosed facilities (also see lines 7 and 8 of Table 16.1). However, short-duration impact sounds can be as much as 10–25 dB greater than the equivalent values given by these relations:

$$\text{Rotary car open unloading, overall } L_w = 131 \text{ dB} \tag{16.7}$$

$$\text{Rotary car enclosed unloading, overall } L_w = 121 \text{ dB} \tag{16.8}$$

Noise abatement methods for rotary car dumpers are similar to those discussed previously for car shakers.

Bucket Ladder and Clamshell Bucket Unloaders

Bucket ladder and clamshell bucket unloaders are often used to unload coal delivered by ship or barge. This equipment is located outdoors along the dock line with the electric motors and speed reduction gears often inside metal enclosures for weather protection. Acoustical data studied to prepare the prediction relations provided here were obtained at bucket ladder unloaders with free-digging rates in the range of 1800–4500 metric tons per hour and clamshell unloaders with free-digging rates in the range of 1600–1800 metric tons per hour. The energy-averaged overall sound power level produced during operation of bucket ladder and clamshell bucket unloaders can be estimated using Eqs. (16.9) and (16.10) (see also lines 9 and 10 of Table 16.1):

$$\text{Bucket ladder unloader, overall } L_w = 123 \text{ dB} \tag{16.9}$$

$$\text{Clamshell bucket unloader, overall } L_w = 131 \text{ dB} \tag{16.10}$$

Noise control treatments for bucket ladder and clamshell bucket unloaders generally employ insulated enclosures for the drive equipment and limiting unloading operations to daytime hours.

Coal Crushers

Coal is sometimes conveyed to a crusher building where the chunks are reduced in size in preparation for firing in a power plant boiler. Noise produced during crushing operations is a composite of the crusher, metal chutes, conveyors, drive motors, and speed reducers. Coal crushing is usually an intermittent operation and the noise is often omnidirectional without major tonal components. The overall sound power level produced during operation of the crusher can be estimated in accordance with the following relation (also see line 11 of Table 16.1):

$$\text{Coal crusher, overall } L_w = 127 \text{ dB} \tag{16.11}$$

The far-field noise associated with coal-crushing operations can be reduced by using a well-insulated and ventilated building to enclose the operation.

Coal Transfer Towers

Transfer towers reload coal from one conveyor to another as the coal is relocated within the coal yard on its way to the plant. Transfer tower noise is comprised of coal impacts, local conveyors, drive motors, and dust collection and ventilation system fans. Coal transfer is usually an intermittent operation, and the noise is often omnidirectional without major tonal components. The overall sound power level produced during coal transfer in open buildings can be estimated in accordance with the following relation (also see line 12 of Table 16.1):

$$\text{Transfer tower, overall } L_w = 123 \text{ dB} \tag{16.12}$$

Coal transfer operations can be enclosed in a well-ventilated building to reduce the far-field community noise. In this case, the estimated far-field noise can be mitigated by the composite sound transmission loss of the exterior building walls. Fan noise associated with the ventilation system should be estimated with the relations given in Section 16.6 or Chapter 17.

Coal Mills and Pulverizers

Coal mills and pulverizers crush and size coal in preparation for burning in a boiler. The resulting noise is associated with internal impacts, drive motors, speed reducers, and fans. The noise is essentially broadband, omnidirectional, reasonably steady, and continuous while the plant is operating. The overall sound power level produced by a coal mill in a building with large openings can be estimated in accordance with the following relations for mills in the size ranges of 13–36 and 37–55 metric tons per hour (also see lines 13 and 14 of Table 16.1). When coal mills are located in a closed building, the estimated far-field noise can be reduced by the composite sound transmission loss of the exterior building walls:

$$\text{Coal mill, overall } L_w = \begin{cases} 110 \text{ dB} & 13\text{–}36 \text{ metric tons per hour} \quad (16.13) \\ 112 \text{ dB} & 37\text{–}55 \text{ metric tons per hour} \quad (16.14) \end{cases}$$

16.4 COOLING TOWERS

The sound power output of wet cooling towers is caused primarily by the water splash in the fill and in the basin as well as by the fans, motors, and gears used to provide draft in mechanical towers. The noise is usually continuous and somewhat directive for rectangular towers. The noise produced by a specific pair of large natural-draft hyperbolic cooling towers has been observed to include a modest low-frequency discrete tone associated with aerodynamic vortex shedding at the base of each tower.

Methods that can be used to estimate the sound power output of natural-draft and mechanical induced-draft cooling towers are provided below. Major tower manufacturers can provide additional useful information regarding noise estimates and noise abatement.

Natural-Draft Cooling Towers

The overall sound power radiated from the rim of large hyperbolic natural-draft wet cooling towers can be estimated with Eq. (16.15) (see line 15 in Table 16.1). Noise radiated by the top of the tower is usually not significant at ground elevations compared to the rim-radiated noise:

$$\text{Natural-draft cooling tower rim, overall } L_w = 86 + 10 \log Q \quad \text{(dB)} \tag{16.15}$$

where Q is the water flow rate in gallons per minute (one cubic meter per minute is equal to 264 U.S. gallons per minute).

Inlet mufflers and fan assistance have been installed to control rim-radiated noise for hyperbolic cooling towers in Europe when located near residential neighbors. However, noise abatement is expensive and not common for large hyperbolic towers.

Mechanical Induced-Draft Cooling Towers

The sound power produced by mechanical induced-draft wet cooling towers operating at full fan speed and at half fan speed can be estimated using the following relations (also see lines 16 and 17 of Table 16.1):

Mechanical-draft tower full speed, overall

$$L_w = 96 + 10 \log(\text{fan kW}) \quad \text{(dB)} \tag{16.16}$$

Mechanical-draft tower half speed, overall

$$L_w = 88 + 10 \log(\text{fan kW}) \quad \text{(dB)} \tag{16.17}$$

where kW is the full-speed fan power rating in kilowatts for both relations.

The above relations apply in all horizontal directions from round towers and most directions away from the inlet face of rectangular towers. For directions away from the enclosed ends of rectangular towers, the far-field noise is several decibels less than estimated above due to the effects of shielding by the solid closed ends. For a line of as many as 6–10 rectangular towers, the far-field noise from the enclosed ends could be as much as 5–6 dB less than estimated, based on omnidirectional radiation using Eqs. (16.16) and (16.17).

Reduced fan speed is a common method used to mitigate the noise from mechanical-draft cooling towers during evening and nighttime hours when excess cooling capacity may be available due to reduced ambient air temperatures. In multiple-cell tower installations, it is preferable to reduce the fan speed for all cells rather than to shut down unneeded cells; the fans' speeds should be properly selected to avoid introducing a strong acoustical beat. Another common noise control method is to install wide-chord high-efficiency fan blades that can provide the necessary fan performance at reduced speeds. In addition, mechanical-draft towers with centrifugal fans may be selected because they can sometimes be designed to produce less noise than towers with propeller fans, although at some energy cost. Mufflers have also been installed at the air inlet and discharge to reduce both the fan and water noise. However, the mufflers must be protected from the wet environment, can become coated with ice during freezing weather, and introduce an additional aerodynamic restriction that must be overcome by the fan. Barrier walls and partial enclosures have successfully shielded neighbors from cooling-tower noise; however, barrier walls that avoid excessive restrictions to the airflow often limit their acoustical benefit for protecting far-field locations.

16.5 AIR-COOLED CONDENSERS

The sound power output of air-cooled condensers (dry cooling systems) is caused primarily by the fans used to move air across the condenser with some additional noise contribution from the motors and gears. The noise is usually continuous and somewhat directive for rectangular installations. The sound power output of dry air-cooled condensers does not, of course, include the water splash noise associated with wet cooling towers.

The need to reduce water consumption is causing the increasing trend to install air-cooled condensers even at large industrial facilities. When installed at a moderate to large new combined-cycle power plant, the fans for the forced-draft air-cooled condenser can contribute approximately the same sound power output as the balance of equipment at the plant. Fortunately, low-noise fans are now readily available for air-cooled condensers that produce comparable airflow rates and 3–6 dBA less noise than do conventional fans. These low-noise fans include high-efficiency wide-chord blades operating at reduced tip speeds. For some installations, noise reductions greater than 6 dBA can be available.

To avoid water consumption, power consumption, and fan noise generation, air-cooled systems are installed in hyperbolic natural-draft towers.

The sound power produced by air-cooled condensers with low-noise fans operating at full speed can be estimated using the following relation (also see line 18 of Table 16.1):

$$\text{Air-cooled condenser full speed, overall } L_w = 84 + 10\log(\text{fan kW}) \quad \text{(dB)} \tag{16.18}$$

where kW is the full-speed fan power rating in kilowatts.

The above relation applies in all horizontal directions from a low-noise unit; a standard unit will produce greater noise. It is suggested that fan- and air-cooled condenser manufacturers be contacted to obtain useful information regarding noise estimates and noise abatement for specific applications. See also references 6 and 7 for information about air-cooled condenser noise generation and propagation. Summary comparisons of the operating performance of wet, dry, and parallel condensing systems are provided in reference 8.

16.6 DIESEL-ENGINE-POWERED EQUIPMENT

When machinery such as compressors, generators, pumps, and construction equipment is powered by a diesel engine, it is usually the diesel engine that is the dominant noise source.

Mobile construction and coal yard equipment powered by diesel engines, such as dozers, loaders, and scrapers, often produces in-cab A-weighted noise levels as high as 95–105 dB. Methods to retrofit and reduce in-cab noise levels for several loaders and dozers have been developed, field tested, and documented in references 9 and 10. Well-designed cabs and noise control features are now often available from major manufacturers when purchasing new diesel-engine-powered mobile equipment.

A simple relation for estimating the maximum exterior overall sound power level for naturally aspirated and turbocharged diesel engines used to power equipment is provided in Eq. (16.19) (also see line 19 in Table 16.1):

$$\text{Diesel engine equipment, overall } L_w = 99 + 10\log(\text{kW}) \quad \text{(dB)} \tag{16.19}$$

The above relation assumes that the engine has a conventional exhaust muffler in good working condition as typically provided by the engine manufacturer and further assumes that the engine is operating at rated speed and power. Noise associated with material impacts during equipment operation is not included.

Equipment used on construction sites often operates at part power. Measurements obtained at the operating equipment indicate that work-shift-long equivalent L_{eq} sound levels are therefore typically about 2–15 dB less than the maximum values provided by Eq. (16.19). It is assumed that the following values could be subtracted from the Eq. (16.19) maximum levels to obtain work-shift-long equivalent L_{eq} levels. When project-long equivalent L_{eq} levels are required, the estimated values can be further reduced to account for the percentage of time that the equipment will actually operate on the construction site [10 log(operating time/project time)]:

3–4 dB	Backhoes, rollers
5–6 dB	Dozers, graders, haulers, loaders, scrapers
7–8 dB	Air compressors, concrete batch plants, mobile cranes, trucks
12–13 dB	Derrick cranes, paging systems

When stationary diesel-engine-driven equipment is located inside masonry or metal buildings, it is necessary to consider the sound power radiated by the engine inlet, the engine casing, the engine exhaust, and the engine cooling fan as well as the driven equipment. It is also necessary to account for the attenuation expected from the building walls and openings, the inlet filter/muffler, the exhaust muffler, and mufflers to be installed at building openings that serve ventilation and cooling systems. Additional information about the propagation of noise from equipment located inside buildings and about muffler systems is provided in Chapters 9 and 17.

16.7 INDUSTRIAL FANS

The noise produced by industrial fans is caused by the dynamic interaction of the gas flow with rotating and stationary surfaces of the fan. Noise produced by shear flow is usually not considered important. Broadband fan noise results from the random aerodynamic interactions between the fan and the gas flow. The prominent discrete tones produced by centrifugal fans result from the periodic interaction of the outlet flow and the cutoff located directly downstream of the blade trailing edges. Tonal noise produced by axial-flow fans results from periodic interactions between distorted inflow and the rotor blades as well as the rotor wakes and nearby downstream surfaces, including struts and guidevanes. This tonal noise is usually most prominent at the harmonics of the passing frequency of the fan blade (number of blades times the rotation rate in revolutions per second). Detailed information about the noise associated with gas flows and fans is provided in Chapters 15 and 17.

The noise produced by new forced-draft fans can be controlled most easily with the use of ducted and muffled inlets. Sometimes the ducted inlet is extended to a location in the plant where warm air is available and additional ventilation is needed. To provide further noise reduction, acoustical insulation lagging should be considered for the inlet and outlet ducts and the fan housing. Open-inlet forced-draft fans can be located within an acoustically treated fan room that contains the fan and its noise. However, workers inside the fan room during inspections and maintenance will be exposed to high levels of fan noise and should wear ear protection.

Discharge noise of large induced-draft fans radiated from the top of the stack to residential neighbors has caused serious community noise problems. The fan and duct system design should include provisions to control this noise if residential areas are located within $\frac{1}{2}$–1 mile of the plant. Mufflers used for induced-draft fan service at boilers and furnaces should be of the dissipative, parallel-baffle, open-cavity type tuned to the harmonics of fan blade passing frequency. These mufflers are built to avoid fly-ash clogging and include erosion protection to ensure adequate long-term performance. They can usually be designed to introduce a pressure loss in the range of about 10–40 mm water gauge. Consideration should also be given to the noise attenuation that will be provided by any flue gas scrubbers, filters, or precipitators that are to be located between the induced-draft fan and its stack. Alternatively, variable-speed fan drives can be installed to reduce nighttime noise at cycling plants that shed load during nighttime hours. This has the added benefit of also reducing the power consumed by the fans and reducing the erosion rates and stresses of rotating components. When multiple fans are installed, they should be operated at the same speed to avoid acoustical beats between the fan tones. (see references 3 and 11).

When an induced-draft centrifugal fan discharges directly to a stack, it is not uncommon for the tonal fan noise to radiate relatively long distances from the top of the stack. This tonal noise is generated by the fluid dynamic interaction of the gas flow leaving rotating fan blades and the stationary cutoff of the fan. This noise propagates with little attenuation up the stack and radiates from the stack top. Some success in reducing the magnitude of this tonal noise at large industrial centrifugal fan installations has been achieved by modifying the geometry of the cutoff. The fabrication and installation of "slanted" and rounded cutoffs, as described in reference 12, have been shown to reduce the tonal noise level by about 3–10 dB with no observed loss in fan performance.

Well-designed and sized inlet and outlet ducts that properly manage the flow are essential to avoid excessive fan noise. Inlet swirl, distorted inflow, and excessive turbulence can result in high noise levels and reduced system efficiency. Useful design guidelines have been established by the Air Movement and Control Association (AMCA) for large industrial fan installations.

Procedures are provided in this section to estimate the overall sound power output of large industrial fans operating at peak efficiency conditions with undistorted inflow. Experience indicates that fans operating with highly distorted inflow or at off-peak efficiency conditions often produce sound power levels that may be 5–10 dB higher than indicated below. Centrifugal- and axial-flow fans produce less sound power when operating at low speeds and reduced working points than during full-load, high-speed operation. For part-speed operation, the sound power levels estimated below can be reduced by about 55 log(speed ratio). Additional information about fan noise generation and attenuation is provided in reference 13.

Centrifugal-Type Forced-Draft and Induced-Draft Fans with Single-Thickness, Backward-Curved or Backward-Inclined Blades or Airfoil Blades

The overall sound power level radiated from the inlet of forced-draft centrifugal fans and the outlet of induced-draft centrifugal fans (with single-thickness, backward-curved or backward-inclined blades or airfoil blades) can be estimated with the relationship provided in Eq. (16.20) (also see line 20 of Table 16.1):

$$\text{Centrifugal fan, overall } L_w = 10 + 10\log Q + 20\log(\text{TP}) \quad \text{(dB)} \qquad (16.20)$$

where Q is fan flow rate in cubic meters of gas per minute and TP is fan total pressure rise in newtons per square meter at rated conditions.

To account for the tonal noise, 10 dB should be added to the octave bands containing the fan blade passing frequency and its second harmonic. For multiple-fan installations, the estimated sound power levels should be increased by 10 log N, where N is the number of identical fans.

The overall sound power level radiated from the uninsulated casing of centrifugal fans can be estimated with the relationship provided in Eq. (16.21) (also see line 21 of Table 16.1). To account for the tonal noise, 5 dB should be added to the octave band containing the fan blade passing frequency:

$$\text{Centrifugal fan casing, overall } L_w = 1 + 10\log Q + 20\log(\text{TP}) \quad \text{(dB)} \qquad (16.21)$$

where Q and TP are as defined for Eq. (16.20).

The sound power radiated by the uninsulated discharge breaching is about 5 dB less than the sound power estimated using Eq. (16.21) for the fan casing.

The overall sound power level radiated from the casings of radial-blade centrifugal fans with ducted inlets and outlets, such as are sometimes used for gas recirculation and dust collection service, can be estimated with the relationship provided in Eq. (16.22) (also see line 22 of Table 16.1):

$$\text{Radial fan casing, overall } L_w = 13 + 10\log Q + 20\log(\text{TP}) \quad \text{(dB)} \qquad (16.22)$$

where again Q and TP are as defined for Eq. (16.20).

To account for the tonal noise, 10 dB should be added to the octave bands containing the fan blade passing frequency and its second harmonic.

Axial-Flow Forced-Draft and Induced-Draft Fans

The overall sound power level radiated from the inlet of forced-draft axial-flow fans and the outlet of induced-draft axial-flow fans can be estimated with the following relation:

$$\text{Axial-flow fan, overall } L_w = 24 + 10\log Q + 20\log(\text{TP}) \quad \text{(dB)} \qquad (16.23)$$

where Q and TP have been defined in Eq. (16.20).

To account for the tonal noise, 6 dB should be added to the octave band containing the fan blade passing frequency and 3 dB should be added to the octave band containing its second harmonic. For multiple-fan installations, the above estimated values should be increased by 10 log N, where N is the number of identical fans.

Ventilation Fans

The sound power output of industrial ventilation fans can be estimated using Eq. (16.20) for centrifugal ventilation fans or Eq. (16.23) for axial-flow ventilation fans; also see Chapter 17.

16.8 FEED PUMPS

It is common for the noise radiated by a pump motor set to be dominated by the motor noise. One exception is the relatively high-flow, high-head pumps used for boiler and reactor feedwater service in large modern power-generating stations that operate in the United States. These feed pumps are usually driven by an electric motor, an auxiliary steam turbine, or the main turbine-generator shaft. Midsize pumps generally produce broadband noise without strong tonal components. The larger pumps, however, commonly produce both broadband noise and strong midfrequency tonal noise. Feed pump noise is omnidirectional and continuous during plant operation.

A high-performance thermal-acoustical blanket insulation, described in reference 14, has been developed and evaluated at field installations specifically for use with equipment such as noisy feedwater pumps, valves, and turbines. This thermal-acoustical insulation provides far better noise attenuation than conventional blanket insulations. It is also easier to remove and reinstall during maintenance and inspections than most rigid insulations. It has been successfully used as a retrofit insulation at installed pumps, turbines, valves, and lines and has been used by equipment manufacturers at new installations requiring reduced noise levels. The use of flexible thermal-acoustical insulation to control noise avoids the mechanical, structural, and safety problems associated with the large rigid enclosures that have sometimes been used at boiler feedwater pump installations. Note that experience in Germany indicates that it is possible to design and operate boiler feedwater pumps that produce relatively low noise levels without external means for controlling the noise.

The overall sound power level radiated by boiler and reactor feedwater pumps can be estimated using the information provided below for pumps in the power range of 1–18 MWe:

Rated Power (MWe)	Overall Sound Power (dB)
1	108
2	110
4	112
6	113
9	115
12	115
15	119
18	123

Octave-band and A-weighted sound power levels for boiler and reactor feedwater pumps can be estimated by subtracting the values provided in line numbers 24 and 25 of Table 16.1 from the overall power level estimated above.

16.9 INDUSTRIAL GAS TURBINES

Industrial gas turbines are often used to provide reliable, economic power to drive large electric generators, gas compressors, pumps, or ships. A prediction scheme for the combustion noise of flightworthy gas turbine engines used in aircraft operations (turbojet, turboshaft, and turbofan engines) is provided in Chapter 15. The noise produced by industrial gas turbine installations is radiated primarily from four general source areas: the inlet of the compressor; the outlet of the power turbine; the casing and/or enclosure of the rotating components; and various auxiliary equipment, including cooling and ventilating fans, the exhaust-heat recovery steam generator, poorly gasketed or worn access openings, generators, and electric transformers. Each of the above areas should receive considerable attention if an industrial gas turbine is to be located successfully near a quiet residential area.

Operation of unmuffled industrial gas turbines of moderate size would produce sound power levels of 150–160 dB or greater. Because the resulting noise levels would be unacceptable, essentially all industrial gas turbine installations include at least some noise abatement provided by the manufacturer. Noise abatement performance requirements may call for reducing the sound power output to levels as low as 100 dB for installations located near sensitive residential areas.

Noise radiated from the compressor inlet includes high levels of both broadband and tonal noise, primarily at frequencies above 250–500 Hz. This mid- and high-frequency noise is controlled with the use of (a) a conventional parallel-baffle or tubular muffler comprised of closely spaced thin baffles and (b) inlet ducting, plenum walls, expansion joints, and access hatches that are designed to contain the noise and avoid flanking radiation.

Noise radiated by the casings of rotating components is typically contained with the use of thermal insulation laggings and close-fitting steel enclosures that include interior sound absorption and well-gasketed access doors. It is not uncommon for the enclosure to be mounted directly on the structural steel base that supports the rotating components. This encourages the transmission of structure-borne noise to the enclosure and can limit its effective acoustical performance at installations requiring high degrees of noise reduction. Off-base mounting of the enclosure can be considered for installations where noise abatement performance must be improved. In addition, many large industrial gas turbines are being installed within a turbine-generator building that provides weather protection and additional reduction of noise radiated through the enclosure from the rotating components.

Noise radiated from the power turbine outlet includes high levels of both broadband and tonal noise at low, mid, and high frequencies, with the low-frequency noise being the most difficult and expensive to control at simple-cycle installations (without heat recovery boilers) located near residential areas. The wavelength of sound at about 30 Hz is on the order of 15–20 m in the gas stream at the back end of the power turbine, thereby increasing the required size of the discharge mufflers. Furthermore, low-frequency exhaust noise has caused significant community noise problems when the sound level in the 31-Hz octave band exceeded about 70 dB at sensitive residential areas. This low-frequency exhaust noise might be best controlled by the manufacturer with improved gas management designs behind the power turbine. The outlet noise is typically controlled with the use of (a) conventional parallel-baffle or tubular mufflers that include thick acoustical treatments; (b) additional dissipative or reactive muffler elements tuned to attenuate low-frequency noise; and (c) outlet ducts, plenum chamber, expansion joints, and access hatches that include adequate acoustical treatments to avoid flanking along these paths and their radiation of excessive noise.

At combined-cycle and cogeneration plants, heat recovery steam generators (HRSGs) are installed downstream of the power turbine to absorb waste heat from the exhaust stream. The HRSG also serves to attenuate the stack-radiated turbine exhaust noise, often by as much as 15–30 dBA, depending on the configurations and sizes of the gas turbine and HRSG. The HRSG can eliminate, or at least reduce, the performance requirements of the exhaust muffler. Also, the HRSG reduces the exhaust gas stream temperature, the wavelengths of the exhaust sounds, and the required size of an exhaust muffler. It is necessary to consider and account for the noise radiated from the surfaces and various steam vents of the HRSG. It is suggested that most HRSG manufacturers can provide technical information describing the noise radiated from their equipment. See also references 15–19 for additional information.

Noise produced by auxiliary cooling and ventilation fans can be controlled effectively with the use of high-performance low-speed fan blades, mufflers, or partial enclosures, depending on specific site and installation requirements. The control of transformer noise, if required for a specific installation, is discussed in Section 16.11. The control of noise radiated from the sidewalls of heat recovery steam generators can be accomplished with large barrier walls or an enclosing building.

Combined-cycle gas turbine power plants produce relatively steady noise as well as relatively brief intermittent loud noises often associated with steam venting and steam bypass operations. Noise levels of 75–80 dBA or greater at 300 m are not uncommon; however, these intermittent sources can usually be reduced 5–10 dBA or more. Further information about such intermittent loud noise from power plants is provided in reference 20.

Sound-power-level prediction procedures are not provided here specifically for industrial gas turbines because of the rather wide range of noise control treatments available within the industry. Many manufacturers offer their machines with a variety of optional noise abatement treatments, ranging from modest to highly effective. For example, 50–100-MWe installations, with or without heat recovery boilers, are readily available with noise abatement treatments resulting in A-weighted noise levels in the range of 50–60 dB at 120 m. Installations with lower noise levels are available from certain manufacturers and can be designed by several independent professionals who have specialized in the control of noise from industrial gas turbines. Combined-cycle plants in the range of 500–600 MWe have been designed and constructed to meet 43 dBA at 300 m.

The overall sound power level of the combined-cycle equipment located within the main power building, including the combustion turbine, HRSG, steam turbine, generators, and support equipment can be estimated with the following relation (also see line 26 of Table 16.1):

$$\text{Inside main power building, overall } L_w = 96 + 10\log(A) \qquad \text{(dB)} \qquad (16.24)$$

where A is the wall and roof area of the building in square meters.

This relationship is based on field measurements obtained near the outer wall and roof areas at numerous combined-cycle and cogeneration power plants. Equation (16.24) assumes that the interior surfaces of the building have sound absorption, with a resulting average sound level of 85 dBA at the outer wall and roof areas. For buildings without significant sound absorption treatment, the estimates should be increased by 5 dB. The interior sound level and the building shell transmission loss will determine the amount of noise that radiates to the outdoors from the main plant equipment. For additional discussion on these plants, see reference 21.

One early but important step in the design of a new gas turbine installation is the preparation of a reasonable and well-founded technical specification by the buyer or buyer's acoustical consultant that fully describes the site-specific noise requirements. Methods and procedures for preparing gas turbine procurement specifications that describe expected noise-level limits are included in ANSI/ASME B133.8-1977 (R1996). If residential neighbors are near the site, the reader is cautioned to consider fully the site-specific needs when planning control of the low-frequency exhaust noise. Several independent consultants with many years of gas turbine experience have suggested that the noise-level threshold of complaints resulting from low-frequency noise in the 31-Hz octave band is about 65–70 dB, measured at residential wood-frame homes. Higher levels of low-frequency noise can sometimes vibrate the walls and rattle the windows and doors of wood-frame homes and result in varying degrees of annoyance. Gas turbine manufacturers, however, correctly indicate that low-frequency noise control treatments are expensive and that many industrial gas turbines are operating that produce higher levels of low-frequency noise in residential areas without causing complaints.

16.10 STEAM TURBINES

Two procedures are provided to predict the sound power radiation from steam turbines; one is for the relatively small turbines in the power range of 400–8000 kW that operate at about 3600–6000 rpm and are often used to drive auxiliary equipment at a plant where steam is readily available. Another procedure is provided for large steam turbine generators in the range of about 200–1100 MWe used at central electricity-generating stations. Thermal-acoustical blanket insulation that has been developed to control noise radiated from equipment including steam turbines is discussed in Section 16.8 and reference 14.

Auxiliary Steam Turbines

The overall sound power output of auxiliary steam turbines, with common thermal insulation installed, can be estimated using Eq. (16.25) (see also line 27 of Table 16.1). This noise is considered to be omnidirectional, generally nontonal, and continuous when the driven equipment is operating:

$$\text{Auxiliary steam turbine, overall } L_w = 93 + 4 \log(\text{kW}) \qquad (\text{dB}) \qquad (16.25)$$

Large Steam Turbine-Generators

The overall sound power output of large steam turbine-generators can be estimated using Eq. (16.26). This includes the noise radiated by the low-pressure, intermediate-pressure, and high-pressure turbines as well as the generator and shaft-driven exciter. The turbine-generator produces both tonal and broadband noise. The tonal components produced by the generator are typically most noticeable at 60 and 120 Hz for 3600-rpm machines and 30, 60, 90, and 120 Hz for 1800-rpm machines:

$$\text{Large steam turbine-generator, overall } L_w = 113 + 4 \log(\text{MW}) \qquad (\text{dB}) \qquad (16.26)$$

Octave-band and A-weighted sound power levels for large steam turbine-generators can be calculated by subtracting the values provided in line 28 of Table 16.1 from the overall sound power level estimated using Eq. (16.26).

Most major manufacturers of large steam turbine-generators will provide their equipment with additional noise abatement features that reduce the noise by about 5–10 dBA, when required by a well-written purchase specification. The reverberant noise inside a turbine building can also be reduced through the proper selection of the building siding. The use of building siding with a fibrous insulation sandwiched between a perforated metal inner surface and a solid exterior surface will provide improved midfrequency sound absorption and thereby reduce the reverberant buildup of noise within the turbine building. It can also reduce the noise radiated to the outdoors.

16.11 STEAM VENTS

Atmospheric venting of large volumes of high-pressure steam is probably one of the loudest noise sources found at industrial sites. The overall sound power produced during steam line blow-outs at large central stations prior to starting a new boiler can be estimated using Eq. (16.27) (see also line 29 of Table 16.1).

This noise is broadband and only occurs for a few minutes during each blow-out for the first few weeks of boiler operation:

$$\text{Steam line blow-out, overall } L_w = 177 \text{ dB} \qquad (16.27)$$

The actual sound power level produced during the venting of high-pressure gas is, of course, related to various factors, including the conditions of the flowing gas and the geometry of the valve and pipe exit. However, the above relationship will provide a reasonable estimate of the noise associated with the blow-out of steam lines at large boilers used for utility service.

Large heavy-duty mufflers are sometimes purchased or rented that reduce the noise by about 15–30 dB during steam line blow-outs. The noise produced by the more common atmospheric vents and commonly encountered valves can be estimated using prediction procedures available from many valve manufacturers and their representatives. Many manufacturers offer valves with special low-noise trims, orifice plates, and inline mufflers that effectively reduce noise generation and radiation. The low-noise trim can also reduce the vibration and maintenance that are sometimes associated with valves used in high-pressure-drop service.

16.12 TRANSFORMERS

The noise radiated by electrical transformers is composed primarily of discrete tones at even harmonics of line frequency, that is, 120, 240, 360, ... Hz when the line frequency is 60 Hz and 100, 200, 300, ... Hz when the line frequency is 50 Hz. This tonal noise is produced by magnetostrictive forces that cause the core to vibrate at twice the electrical line frequency. The cooling fans and oil pumps at large transformers produce broadband noise when they operate; however, this noise is usually less noticeable and therefore less annoying to nearby neighbors. The tonal core noise should be considered omnidirectional and continuous while the transformer is operating. The broadband fan and pump noise occurs only during times when additional cooling is required.

The technical literature includes numerous relations and guidelines for the prediction of noise produced by transformers. Reference 22 reports the results of measurements obtained at 60 transformer banks and indicates that the space-averaged A-weighted sound level produced by the core of the average transformer (without built-in noise abatement) at an unobstructed distance of about 150 m is well represented by the relationship given in Eq. (16.28). Ninety-five percent of the A-weighted noise data reported in reference 22 lies within about ±7 dB of this relation for transformers with maximum ratings in the range of 6–1100 MVA:

Average A-weighted core sound level at 150 m,

$$L_p = 26 + 8.5 \log(\text{MVA}) \qquad (\text{dBA}) \quad (16.28)$$

where MVA is the maximum rating of the transformer in million volt-amperes.

The space-averaged sound pressure levels of the transformer core tones at 120, 240, 360, and 480 Hz at 150 m can be estimated by adding the following values to the A-weighted sound level of Eq. (16.28):

120	240	360	480
17	5	−4	−8

Another relation for transformer A-weighted sound levels versus distance, extracted from reference 23, is

$$\text{Space-averaged far-field sound level } L_p = L_n - 20(\log\ d/S^{1/2}) - 8 \qquad \text{(dBA)} \tag{16.29}$$

where L_n = circumferential average sound pressure levels measured at National Electrical Manufacturers Association (NEMA) close-in measurement positions (A-weighted or tonal)
S = total surface area of four sidewalls of transformer tank
d = distance from transformer tank (in units that are compatible with tank sidewall area), must be greater than $S^{1/2}$

Equation (16.29) can be used if L_p and L_n represent the A-weighted sound levels or the sound pressure levels of the discrete tones produced by the transformer tank. The octave-band sound pressure levels of the transformer core noise can be obtained directly from the sound pressure levels of the discrete tones estimated above. The octave-band sound pressure levels of the total transformer noise with the cooling fans operating can be estimated by subtracting the values provided in line 30 of Table 16.1 from the A-weighted sound level estimated with Eq. (16.29). This applies to conventional cooling-fan systems with motors in the power range of about 0.15–0.75 kW operating at about 1000–1700 rpm with two- or four-bladed propeller fans. Further information about special low-noise cooling systems should be obtained from the manufacturer. Excess attenuation should be considered (see Chapter 5) when estimating sound levels at distances beyond about 150 m.

NEMA has published standard tables of close-in noise levels for transformers; see reference 24. Experience indicates that the noise near most operating transformers is often equal to or somewhat less than the NEMA standard values, and the noise near new high-efficiency transformers can be significantly less than the NEMA values. However, the noise produced by converter transformers operating at AC-to-DC converter terminals can include discrete tones at frequencies up to about 2000 Hz and can be about 5–10 dB greater than the NEMA standard values. This additional high-frequency noise has been found to be unusually noticeable and disturbing to residential neighbors when the converter transformer is located in quiet rural-suburban areas.

Two basic methods are available for reducing the far-field noise produced by transformers. First, manufacturers are able to respond to custom noise requirements and produce transformers with reduced flux density that generate noise levels as much as 10–20 dB lower than the NEMA standard values. New high-efficiency transformers with low electrical losses usually produce core noise levels that are less than the NEMA standard values. For the quieted-design transformers, reductions of the higher frequency tones (e.g., 480 and 600 Hz) are typically 1–3 dB more than the reductions of the lower frequency tones (e.g., 120, 240, and 360 Hz). High-efficiency low-speed cooling fans and cooling-fan mufflers are also available from some manufacturers when needed for special siting applications. In some cases, the cooling fans are eliminated from the transformer tank and replaced with oil-to-water heat exchangers.

Second, barrier walls, partial enclosures, and full enclosures can be provided to shield or contain the transformer noise. They are usually fabricated with masonry blocks or metal panels. The interior surfaces of the barrier or enclosure walls should usually include sound absorption that is effective at the prominent transformer tones. Care must be used to ensure adequate strike distances and space for cooling-air flows. If the fin-fan oil coolers are to be located outside of the enclosure, some attention should be given to the structure-borne and oil-borne noise from the core that can be radiated by the coolers. Space and provisions must be provided for inspections, maintenance, and transformer removal. It is also important to ensure that the enclosure walls are structurally isolated from the transformer foundation to avoid radiation of structure-borne noise resulting transformer-induced vibration. Further information about the control of transformer noise is available from most major transformer manufacturers as well as from reference 25. And a promising passive means of canceling tonal noise radiated from transformer sidewalls by means of an attached mechanical oscillator is discussed in reference 26.

As energy efficiency becomes increasingly important, new transformers are being purchased with low electrical losses reducing operating costs. Experience at numerous large electrical facilities indicates that new high-efficiency low-loss transformers also often produce core noise levels 5–10 dB less than the NEMA standard values.

Instead of, or in addition to, reducing the noise radiated from a transformer substation, it is sometimes possible to site a transformer far from residential neighbors or within an existing noisy area, such as close to a well-traveled highway, where the ambient sounds partially mask the transformer noise.

16.13 WIND TURBINES

The installation of modern wind energy systems is growing rapidly throughout many areas of the world. Installed capacity by 2001 exceeded 30,000 MWe as the reliability and efficiency of modern wind turbines increased and the costs declined. It has been estimated that wind turbines will generate more than 10% of the world's energy, more than 1200 GW, by year 2020. Wind turbine capacity is generally rated based on rotor diameter, rotor swept area, or generator capacity in watts. Small-capacity wind turbines are generally rated at less than about 5 kW, medium turbines at about 5–300 kW, and large wind turbines at about 500 kW and above. Large turbines are now available rated at up to 1–5 MW, and with multiple turbines on a single tower, ratings can continue to increase. Wind turbine parks or farms are being developed onshore and offshore with rated capacities of 50–150 MWe and greater. The development of wind turbine rotors to operate with low wind speeds will increase the available resource area and will bring development closer to more people.

The main types of noise from wind turbines are aerodynamic, mechanical, and electrical. The principal sources of noise include the rotor blades, the gearbox, and the generator. Additional sources include the brakes, the electronics, and the tower. Earlier wind turbine installations produced both prominent tonal noise from the gear box and a strongly modulated "thumping" noise most often associated with the rotor blades passing through and interacting with the turbulent tower wake flow at downwind machines. Fortunately, the manufacturers of modern wind turbines have learned to avoid what were these most noticeable and annoying aspects of wind turbine noise.

Considerable progress in reducing noise generation and radiation continues to be made by the equipment manufacturers with ongoing technical support from research organizations (reference 27). Noise abatement for modern wind turbines includes increasingly efficient rotor blade profiles, variable-speed and variable-pitch rotors, advanced electronics, and low-noise gearboxes, as well as vibration isolation mounts and sound absorption within turbine nacelles. Noise from modern wind turbines is generally dominated by broadband rotor noise that is directly related to tip speed. Information about aeroacoustical noise generation is provided in Chapter 15.

Modern wind turbines are generally available that produce broadband noise without strong tonal components. The midfrequency aerodynamic rotor noise generally includes some noticeable time-varying amplitude modulation at the passing frequency of the rotor blade (number of blades times the rotation rate in revolutions per second). For a three-blade constant-speed turbine operating at 25 rpm, this is 1.25 Hz. For variable-rotor-speed turbines, the modulation frequency will often be in the range of 0.5–1 Hz.

The approximate A-weighted sound power level of modern medium to large wind turbines can be estimated with the relationships provided in Eq. (16.30) or (16.31), although the sound power level of some turbines will be as much as 10 dBA greater:

$$\text{Wind turbine, A-weighted sound power level} = \begin{cases} 86 + 10 \log D \quad (\text{dBA}) & (16.30) \\ 73 + 10 \log \text{kW} \quad (\text{dBA}) & (16.31) \end{cases}$$

where D is the rotor diameter in meters and kW is the rated turbine power.

Alternatively, the approximate footprint area surrounding a modern wind turbine within which the A-weighted sound level equals or exceeds 40 dBA can be estimated with the relationship provided in Eq. (16.32):

$$\text{Wind turbine 40 dBA footprint area in square meters} = 800 \times \text{kW} \quad (\text{m}^2) \qquad (16.32)$$

The operating characteristics, including noise generation under specific conditions, of most modern wind turbines have been certified in accordance with national and international standards. The special requirements associated with reliable measurements and specification of wind turbine noise are defined by International Standard IEC 61400-11, 1998, "Wind Turbine Generator Systems—Part 11: Acoustic Noise Measurement Techniques."

16.14 SUMMARY

The machinery noise prediction procedures and relations presented in this chapter are based primarily on extensive field measurement data collected by the authors and their colleagues during many years of consulting projects. The results obtained when using these relations should be useful for many engineering applications. The reader is cautioned, however, that site-specific installation conditions and individual equipment characteristics can cause noise levels to be somewhat higher or lower than predicted, and detailed knowledge of these exceptions can be important for critical applications. Also, many items of equipment can be purchased with reduced noise, can be installed so as to reduce noise, or can be fitted with effective noise control treatments.

The authors continue to add to and update their library of equipment noise emission data used in the preparation of this chapter. Readers with access to new or useful data or information on equipment noise characteristics or control and wanting to share their information are encouraged to send copies to the authors.

CHAPTER 17

Noise Control in Heating, Ventilating, and Air Conditioning Systems

ALAN T. FRY

Consultant
Colchester, Essex, United Kingdom

DOUGLAS H. STURZ

Acentech, Inc.
Cambridge, Massachusetts

This chapter provides guidelines, recommendations, and design tools useful in assessing and controlling noise and vibration stemming from mechanical systems serving buildings. Discussed are the transmission of noise along duct systems, airflow velocities at various points in duct systems that are consistent with particular noise goals, fan noise, terminal box noise, and special design features for especially quiet heating, ventilating, and air conditioning (HVAC) systems. Sound isolation for mechanical rooms and special consideration for the application of vibration isolation for mechanical equipment in buildings are also addressed. Further discussion and additional detailed design information can be found in references 1–5, and in Chapters 9–15 of this book.

17.1 DUCT-BORNE NOISE TRANSMISSION

It is of significant practical interest to predict the noise that transmits via a ducted system from a source to a receiver space to achieve a desired noise goal. This is typically done by starting with the noise of a known source (typically and primarily a fan) and subtracting from this the attenuation provided by each of the various duct elements that the noise encounters as it propagates along the duct path. Thus, from a known noise source level, one can predict the noise level that reaches the occupant of a space and can engineer any special attenuation treatments that may need to be incorporated in the duct system to help achieve a desired result. Alternatively, one can work backward from a desired noise goal in the receiving space to determine the permissible sound power level of a fan serving the system (or other source in the system). There are many acoustical complexities that are difficult to model precisely without exhaustive knowledge of the duct construction and the nature of the sound field entering a duct element, and such details are generally not well known. The prediction procedure is really a guide to make decisions in order to achieve designs that are in the correct neighborhood of the goal, and generally the procedure is a good guide in the moderately lower frequency range that is of greatest interest for ventilation systems. There are many aspects of ducted systems which are strongly frequency dependent in the higher frequency range, and the precision of the calculations may be questionable for extensive systems in this frequency range. Fortunately, in designing noise control for ducted systems, when the lower frequencies are suitably controlled, the predicted noise levels at higher frequencies are dramatically lower than the goal and there is no need to make precise predictions in this higher frequency range. The following presents some of the data necessary to assess attenuation in the path of sound propagation from source to receiver. Considerations for some relevant noise sources are presented later.

Sound Attenuation in Straight Ducts

Even the attenuation of sound propagating in simple, straight ducts is quite complex. The sound attenuation in straight ducts of uniform cross section and wall construction is usually given in attenuation per unit length, decibels per meter or decibels per feet, assuming that every unit of duct length provides the same amount of attenuation. This is a considerable simplification because the attenuation is a function of the character of the sound field entering the duct section and the character of the sound field is constantly changing along the length of even a straight-duct run. At frequencies high enough for the duct to support higher order modes, these higher order modes are much more rapidly attenuated by duct attenuation treatments than the plane-wave fundamental mode. Attenuation of sound along a duct is a function of the sound dissipation when the sound wave interacts with the walls of the duct and this is determined by the impedance of the duct wall. Sound attenuation in lined ducts and silencers is treated in detail in Chapter 9. At high frequencies, energy loss due to sound transmission through the bare sheet metal duct walls yields only very little sound attenuation for the duct path. However, with sound-absorptive lining of the walls, high-frequency sound attenuation along the ducts can be quite high. At low frequencies, a substantial portion of the sound attenuation along the duct path is provided by energy transmission through the sheet metal walls of the duct—breakout. Form, stiffness, and surface weight control the low-frequency sound attenuation. Consequently, unlined form-stiff round ducts yield much less sound attenuation (and also much higher breakout sound transmission loss) than do ducts with rectangular or oval cross section and with large aspect ratio. The sound attenuation values represented herein are for typical duct construction within the range of constructions typically allowed by the Sheet Metal and Air Conditioning National Association (SMACNA) for low-pressure ductwork.

Estimation of the attenuation provided by unlined and lined ducts of round and rectangular duct constructions typically found in the field is presented in Tables 17.1–17.6.

TABLE 17.1 Sound Attenuation in Unlined Rectangular Sheet Metal Ducts

Duct Size, in. × in.	P/A, ft^{-1}	Attenuation by Octave-Band Center Frequency, dB/ft

Sound Attenuation by Duct Divisions

When sound propagating along a duct encounters a duct branch, the acoustical energy divides into the two branches according to the fraction of the area that each represents to the total area leaving the division. This is probably a reasonable approximation of what happens at lower frequencies, but at higher frequencies there are likely to be directional effects for which this simple model does not account. Fortunately, for most practical HVAC noise control concerns, the low-frequency range is of the greatest interest. The attenuation in decibels that occurs at a duct division is given by

$$\text{Attenuation} = 10 \log \left(\frac{A_1}{A_T}\right) \quad \text{dB} \tag{17.1}$$

where A_1 is the area of the duct leaving the division on the path being studied and A_T is the total area of all branches leaving the division.

Sound Attenuation by Duct Cross-Sectional Area Changes

Sound propagating along a duct is reflected back if it encounters a sudden cross-sectional area change. The strength of reflection at low frequencies, where only the fundamental plane wave can propagate in the duct, depends only on the ratio of the cross-sectional areas. Whether the sound is coming from the duct of the larger or smaller cross-sectional area, the resulting sound attenuation is given by

$$\text{Attenuation} = 10 \log \left\{0.25\left[\left(\frac{A_1}{A_2}\right)^{0.5} + \left(\frac{A_2}{A_1}\right)^{0.5}\right]^2\right\} \quad \text{dB} \tag{17.2}$$

[a] Add to attenuation of bare sheet metal ducts.
Source: 1999 ASHRAE *Applications Handbook*, © American Society of Heating, Refrigerating and Air Conditioning Engineers, Inc., www.ashrae.org.

Equation (17.2) yields an attenuation of only 0.5 dB for a cross-sectional area change of $A_1/A_2 = 2$ or $A_2/A_1 = 0.5$ and that of 2 dB for a 1 : 4 or 4 : 1 change. Since large abrupt changes in duct cross-sectional area do not occur very often for aerodynamic reasons, the attenuation attributable to duct cross-sectional area changes usually encountered in HVAC duct design is very small.

Sound Attenuation by Elbows

When sound propagating along a duct encounters an elbow, some of the sound is reflected back in the direction from which it was coming, some is dissipated, and some continues to propagate along the duct path. The fraction of sound energy that is reflected or dissipated determines the attenuation. The attenuation is a function of frequency and size of the elbow. The attenuation is also impacted by the type of elbow (mitered, mitered with vanes, and radiused) and the presence (or absence) of sound-absorbing lining in the duct (or on the turning vanes). Mitered elbows with vanes and radiused elbows tend to transmit more higher frequency energy around the bend than mitered elbows without vanes and so they provide less attenuation for the duct path. However, they yield lower pressure drop and therefore are commonly used. Tables 17.7–17.9 present the estimated sound attenuation for various elbow types.

Prefabricated Sound Attenuators

Prefabricated sound-attenuating devices (duct silencers) are available from a variety of manufacturers in a variety of styles, configurations, and constructions to fit virtually every HVAC system application and to meet every sound attenuation requirement. The sound-absorptive media may be conventional dissipative materials such as glass fiber, mineral wool, or nylon wool covered by a perforated metal facing sheet to provide physical protection for the fibrous sound-absorbing material from erosion by the turbulent flow. For low-velocity flows the sound-dissipating material may be protected only by a thin surface layer of flow-resistive facing such as applied on the surface of duct liners. For special applications, to prevent any fibrous material from getting into the air stream, the fill material can be sealed in thin plastic bagging. This typically will slightly increase the acoustical attenuation at specific low and midfrequencies and diminish it substantially at high frequencies compared to unfaced fill. Special construction details are typically required to prevent the film from sealing the holes in the perforated metal protective facing and to avoid chafing of the film on sharp edges formed on the back of the perforated metal in the punching process. Detailed information on the design and prediction of dissipative silencers is given in Chapter 9. There are also silencers without traditional dissipative fill but with special acoustically reactive surfaces lining the air channels which remove acoustical energy from the air stream.

Basic silencers have a straight-through air path with aerodynamic inlet and discharge geometry to help minimize pressure losses which are greatest at the flow transition points. Silencers are also available with special flow configurations for special applications. For HVAC system applications, elbow configuration silencers are particularly notable since these can help to avoid difficult flow conditions that could otherwise exist or even be caused by aerodynamically poor application of a straight silencer.

Manufacturers' information should be used for the prediction of the sound attenuation, pressure drop, and flow-generated noise. For a given application there are typically several silencers that might be able to provide the desired acoustical performance. The noise control and HVAC design engineers must select one that also yields a suitably low pressure drop and trade-offs will need to be considered between the length and the resistance class of the silencer. For most typical HVAC system applications the pressure drop across the silencer should be limited to about 0.30 in. water gauge (wg). The pressure loss can be higher, but the designer needs to be sure the extra pressure loss will not have undesirable impacts on the system. The energy consumed to overcome the pressure drop of the silencer should be considered in deciding what pressure loss is acceptable. Over the lifetime of the system, significant energy cost savings will result from having a silencer that has a particularly low pressure drop. The savings may be much more than the extra initial cost of the lower pressure drop model. Silencers should not be placed in the duct just upstream of a fan to avoid having the turbulent flow from the tail end of the baffles interact with the fan blade, which will increase the fan's broadband and blade passage tone noise.

Ideally, the airflow entering and leaving the silencer should be straight and smooth to approach the conditions under which the sound attenuation, pressure drop, and flow noise of the silencer are tested in accordance with ASTM E-477 or ISO 7235. In the field, such ideal conditions seldom occur, and there is some degree of excess pressure drop beyond the catalogued value for the application due to system effects. The system designer needs to consider these when making pressure drop predictions. To the extent that the silencers are placed in positions where the inflow is distorted and turbulent, there will be extra pressure drop. Figure 17.1 presents some common flow configurations and the associated extra pressure drop multiplier to be applied to the catalogued silencer pressure loss.

Because of the high velocity flows through the narrow silencer channels and the imperfect conversion of velocity pressure to static pressure at the discharge, turbulence is generated in the flow through silencers and this creates flow noise. The manufacturers typically tabulate the flow-generated noise of their silencers at various face velocities. The total flow-generated sound power is a function of the face velocity and the area of the silencers, and the noise generated by the silencer will typically be published for various face velocities and for a specific cross-sectional area. This data must be adjusted for the cross-sectional size of the silencer actually used when one predicts the flow-generated noise by adding $10 \log A_1/A_0$ to the published data (where A_1 is the actual silencer area and A_0 is the area that is the basis for the presented data, in consistent units). The noise generated by the silencer becomes another source of noise that propagates along the duct and needs to be addressed. The closer the silencer is placed to the receiving space and the quieter the receiving space, the more care needs to be taken in controlling flow-generated noise because there is less opportunity to attenuate it before it reaches the receiving space. For duct systems serving spaces where the noise goal is moderate (perhaps NC-35 to NC-40; NC = noise criterion) silencers located near the occupied space (such as on the room-side of a terminal box) typically need to be sized for less about 0.10 in. wg pressure drop. Where the noise goal is more stringent, the pressure loss through the silencer

needs to be commensurately lower. When silencers are located near the fans, at the beginning of systems, the noise of the fan on the building side of the silencer will often still be substantially higher than the flow-generated noise of the silencer (if selected for reasonable pressure loss), so that flow noise is not of concern. The lower the noise goal, the more carefully this needs to be checked.

Poorly selected and positioned silencers, which produce excessive pressure drop, can cause more noise problems than they solve.

Sound Attenuation by Plenums

Plenums in duct systems can often provide significant sound attenuation for the ducted path. The extent of the attenuation depends upon the size of the plenum compared to the connecting ducts, the orientation of the inlets and outlets, and the absorptivity of the inner walls. Equations (17.3)–(17.5) as applied to Fig. 17.2 provide a method for estimating the attenuation provided by plenums:

$$\mathrm{TL} = -10\log_{10}\left[S_{\text{out}}\left(\frac{Q\cos\theta}{4\pi r^2} + \frac{1-\alpha_A}{S\alpha_A}\right)\right] \tag{17.3}$$

where (refer to Fig. 17.2)

where TL = transmission loss, dB

S_{out} = area of outlet section of plenum, ft^2

S = total inside surface area of plenum minus inlet and outlet area, ft^2

r = distance between centers of inlet and outlet sections of plenum, ft

Q = directivity factor, which may be taken as 4

α_A = average absorption coefficient of the plenum lining

θ = angle of vector representing r to long axis l of plenum

The average absorption coefficient α_A of the plenum lining is

$$\alpha_A = \frac{S_1\alpha_1 + S_2\alpha_2}{S} \tag{17.4}$$

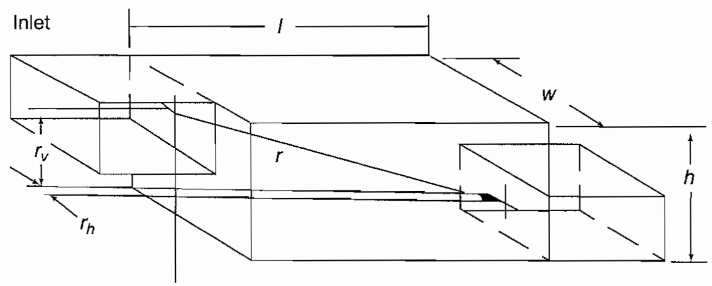

FIGURE 17.2 Schematic of plenum chamber. *Source*: 1999 ASHRAE *Applications Handbook*, © American Society of Heating, Refrigerating and Air Conditioning Engineers, Inc., www.ashrae.org.

where α_1 = sound absorption coefficient of any bare or unlined inside surfaces of plenum

S_1 = surface area of bare or unlined inside surface of plenum, ft^2

α_2 = sound absorption coefficient of any acoustically lined inside surfaces of plenum

S_2 = surface area of acoustically lined inside surface of plenum, ft^2

The value of cos θ is obtained from

$$\cos\theta = \frac{l}{r} = \frac{l}{(l^2 + r_v^2 + r_h^2)^{0.5}} \tag{17.5}$$

where l = length of plenum, ft

r_v = vertical offset between axes of plenum inlet and outlet, ft

r_h = horizontal offset between axes of plenum inlet and outlet, ft

The precision of plenum insertion loss predictions is generally not considered to be very good, and research is being conducted currently to improve the accuracy of the predicted attenuation of these duct elements. The results of the above equations are only valid where the wavelength of sound is small compared to the characteristic dimensions of the plenum. Equation (17.3) is not valid below the cutoff frequency of the entering and exiting ducts, given as

$$f_{\text{co}} = \frac{c_0}{2a} \quad \text{for rectangular ducts}$$

and

$$f_{\text{co}} = \frac{0.586c_0}{d} \quad \text{for circular ducts}$$

where f_{co} = cutoff frequency, Hz

c_0 = speed of sound in air, m/s

a = larger cross-sectional dimension of duct, m

d = diameter of duct, m

End-Reflection Loss

When sound propagating along ducts reaches an abrupt change in cross-sectional area (such as the termination of a duct system at a diffuser or grille) and there is no disturbance of the sound field as it makes the transition, some low-frequency sound reflects back from the point of the abrupt change and does not propagate on toward the receivers of concern. The end-reflection loss is a function of the size of the termination compared with the acoustical wavelength and the specific location of the duct termination within the room. Typical values of end reflections are given in Table 17.10. Note that these are for idealized conditions. If there is a grille or diffuser at the termination of the duct system or if the grille or diffuser is not in the middle of a large plane (like the ceiling) but is in a two- or three-dimensional corner of the room, the end reflection will be lower. For each factor that deviates

from the ideal case, one might consider the effective duct emitting area to be 4 times the actual duct size when entering the chart.

Note that end-reflection losses are not limited to the duct terminations but can be a useful technique within a ducted system to get low-frequency attenuation, for instance where a duct abruptly enters a large highly sound absorptive plenum volume.

Room Effect

Room effect is the translation of the sound power emitted into the room from the duct system to the sound pressure level that results in the space at a given location. The process of predicting the sound pressure level from the sound power level is treated in detail in Chapter 7.

The classical method to relate the sound pressure that results in a room to the sound power emitted from a source is modeled by a point sound source for small-size sources, such as round or rectangular diffusers, and by a line sound source in the case of strip diffusers or duct breakout. Note that the amplitude of the reverberant sound field, which dominates at large distances from the source, is independent of the nature of the source. However, the amplitude of the direct sound, which dominates in the vicinity of the sound source, strongly depends on how the sound energy spreads from the source.

For a point sound source radiating into the room the sound pressure level at a distance r (resulting from the power-based addition of the direct and reverberant fields) is given in the equation

$$L_p(r) = L_w + 10 \log_{10}\left(\frac{Q}{4\pi r^2} + \frac{4}{R}\right) \tag{17.6}$$

where L_w = source sound power level, dB re 10^{-12}W
L_p = sound pressure level, dB re 2×10^{-5}N/m^2
R = room constant, = $S\alpha_A/(1-\alpha_A)$, m^2
S = total room absorption, m^2
α_A = average absorption coefficient of room surfaces
r = source–receiver distance, m
Q = inverse of fraction of sphere to which sound energy radiates

For a case where there is only one source of concern for design, using this equation is simple and sufficient. However, where there are multiple noise sources such as various diffusers or grills with close to the same noise emission level and producing close to the same noise level at the receiver position, some way to adjust the room effect for the multiple diffusers is needed. This might be done by adjusting the room effect by 10 log N decibels, where N is the effective number of outlets contributing to the sound at the critical receiver location. Other, more sophisticated, methods based of sound propagation modeling in rooms presented in Chapter 7 may be used when dealing with special situations.

17.2 FLOW NOISE IN DUCTED SYSTEMS

The noise generated by flow in duct systems is a concern for noise transmission inside the duct along the duct path and that radiated from the outside surface of the duct. Noise generated at particular fittings or duct elements can be estimated in accordance with the methods presented in Chapter 15. Flow-generated noise propagates down the ducts just like noise from any other sources in the duct system. It is typically in the mid- and higher frequency range and thus is relatively easily attenuated by dissipative treatments such as silencers or lining. When attenuating elements do not exist in the ductwork between the source and the occupied space, this noise can become a concern.

TABLE 17.11 Recommended Airflow Velocities in Lined Duct Systems[a,b]

	Airflow Velocities (fpm) Consistent with Indicated Noise Criterion (NC) through Net Free Area of Duct Section or Device							
	NC 15		NC 20		NC 25		NC 30	
Duct Element or Device	Supply	Return	Supply	Return	Supply	Return	Supply	Return
Terminal device[c] ($\frac{1}{2}$in. minimum slot width)	250	300	300	360	350	420	425	510
First 8–10 ft of duct	300	350	360	420	420	490	510	600
Next 15–20 ft of duct	400	450	480	540	560	630	680	765
Next 15–20 ft of duct	500	570	600	685	700	800	850	970
Next 15–20 ft of duct	640	700	765	840	900	980	1080	1180
Next 15–20 ft of duct	800	900	960	1080	1120	1260	1360	1540
Maximum within space[b]	1000	1100	1200	1320	1400	1540	1700	1870

Note: Fan noise must be considered separately. Reduce duct velocities (not diffuser/grille velocities) by 20% if ductwork is unlined.

[a] All ducts with 1-in.-thick internal sound absorptive lining.

[b] Above mineral fiber panel ceiling. Lower velocities 20% if open or acoustically transparent ceiling.

[c] No dampers, straighteners, deflectors, equalizing grids, etc. behind terminal devices.

The following guidelines are offered for duct sizing based on the location, type, and class of ductwork:

- <3000 feet per minute (fpm) velocity in round ducts in mechanical rooms and shafts,
- <2500 fpm velocity in rectangular ducts in mechanical rooms and shafts,
- <2000–2500 fpm velocity in the ceiling of occupied spaces with mineral fiber ceiling for NC-35 to NC-40 goal,
- <1500–2000 fpm velocity in the ceiling of occupied spaces with open or acoustically transparent ceiling for NC-35 to NC-40 goal,
- <1500 fpm velocity in larger final distribution ducts serving NC-35 to NC-40 spaces,
- <a friction rate (pressure loss rate) of 0.10 in. wg/100 ft of duct run in smaller final duct distribution for NC-40, and
- <a friction rate (pressure loss rate) of 0.08 in. wg/100 ft of duct run in smaller final duct distribution for NC-35.

Airflow velocity guidelines for the design of special low noise spaces (typically NC-30 and lower) are presented in Table 17.11 for lined duct systems.

17.3 SYSTEM DESIGN FOR ESPECIALLY QUIET SPACES

The lower the noise goal for a particular space, the more carefully the duct arrangement needs to be considered from the air balance and aerodynamic

standpoints. In particular, the duct system needs to be designed to be as naturally balanced as possible. That is, if the system is turned on, the airflow naturally delivered from each outlet would match the desired airflow with little or no damper throttling to control the flow. Creating systematically branching duct arrangements to an array of diffusers or grilles is typically a good approach. There should be suitably long straight ducts between the branches for the flow to straighten out and divide, as desired at the next branch. However, not all buildings and conditions can accommodate this design concept. Often there is a need to have a series of diffusers or branches to diffusers off the side of a large main duct. Having at least a modest length (a duct diameter) of straight duct run out to the diffuser is always preferred to improve the airflow presentation to the back of the diffuser and to create a more desirable position for a damper that can be used to control the flow at a point that is away from the diffuser. For these cases, it is often best to have the main duct that feeds the diffusers remain a constant size so that the pressure drop along the main "header" duct becomes small and the flow distribution is controlled by the pressure drop of the runouts. To achieve a naturally balanced design, it is generally best to have the diffusers and grilles be in a reasonably cohesive grouping rather than be widely spaced out.

It is recommended to avoid having a tight cluster of diffusers serving a critical space and then a long "tail" duct extending downstream, because to balance the system, it will be necessary to throttle dampers near the diffusers serving the critical space, and this will cause noise to be generated.

Dampers should be provided in duct systems as needed to control the flow, but they must be located sufficiently far from the terminal devices so that the turbulence and noise they generate can be sufficiently attenuated before it reaches the occupied space. For especially quiet systems, dampers should not be placed at or near the face of the diffusers and grilles. It is essential to use dampers well back in the duct system to adjust for major deviations from a natural air balance design.

The airflow velocity near diffusers and grilles needs to be appropriately slow to avoid excessive noise generation. As one moves back in the duct system away from the critical space, flow velocities can progressively increase. Ideally, the velocities would step down in moving toward the critical space in a manner that is consistent with the desired systematic branching pattern. The best correlation between airflow velocities and the noise resulting in the space of interest is for noise from grilles and diffusers in the room and for the ducts closest to the room. The correlation between noise reaching the space of interest and the flow velocity becomes less direct as one moves further into the duct system, away from the receiving space. Thus, there is not much room for compromise in velocities close to the occupied space, but there may be room for compromise from an ideal design at greater distances from the occupied space.

Table 17.11 presents suggested velocities in duct systems serving quiet spaces to help ensure achieving particular noise goals with acoustically lined ductwork. These suggested flow velocities generally assume that the duct configuration will be only average in terms of its aerodynamics. If very desirable airflow geometry is achieved, somewhat higher velocities can be allowed. The suggested velocities through the net free area of the diffusers and grilles, given in Table 17.11, assumes a nominal slot width of about 1/2 in. To the extent that wider slot widths are used, higher velocities can be allowed for a given noise goal. Typically, there might be an allowable increase in slot velocity of 15–20% for each doubling of the nominal slot width up to about 2-in.-wide slots. Special nozzle-type diffusers are available to operate more quietly so that they can throw the air further for a given noise level. The manufacturer's noise data should be reviewed for special diffuser applications, being sure that the noise generation is adjusted from the conditions under which the devices are tested to the actual conditions of use. Because, at the indicated velocities, it is difficult to blow the air very far, for quiet systems, supply air is often delivered using a distributed array of diffusers at the ceiling rather than from the sidewalls of a space. This is not to say that sidewall blow applications need to be avoided; they just need to be limited to covering a small zone at the sides of the space rather than trying to condition the entire space from this position. Using a combination of ceiling diffusers and sidewall blow diffusers can be a useful technique to divide the main ducts into smaller pieces that will fit through the building more easily than handling all the airflow in fewer large ducts. Note that to help fit ducts into buildings it is often better to avoid having diffusers or grilles directly off the sides of a main duct because the entire airflow in the main duct will have to run at a very low velocity and this duct will be very large. However, in applications where there is ample space for large ducts or where ducts are exposed, this may be a simple, neat, and clean approach to the design. Developing the duct distribution in a systematic branching pattern naturally allows the ducts that have the large airflow quantity to be sized at a higher velocity, which helps them fit in the building more easily. For quiet systems, the space required to handle the airflow at the desired velocities can be considerable and this can translate into requiring more building volume in which to maneuver the ducts. Considering the system design concept and velocities early in the design can allow the building to be more economical from the standpoint of the sheet metal that is used and the building volume that is constructed. Not considering the duct system requirements early in the design may result in an undesirable compromise in the design and/or the noise levels that can be achieved.

Note that about a 20% change in velocity is generally associated with a 5-NC point change in noise level in the occupied spaces. Thus, a compromise of increasing the airflow velocities in a project design by 20% will generally increase the noise by about 5 NC points. Also, lowering the noise level by about 5 NC points requires about 20% lower velocities; this translates into only about 10–15% increase in the dimensions and surface area of round and (reasonably square) rectangular ducts. Increasing the noise goal by 5 NC points will only save about 10–15% of the sheet metal cost.

The airflow velocity guidelines in Table 17.11 assume that there will be lining in the duct system, and this is generally recommended to control the noise generated by flow in the ducts at fittings and unexpected flow obstacles in systems that are to be especially quiet. For lower noise goals, more things need to be

done properly in the implementation of the design and there is less margin for error. If the ductwork does not have lining, it is suggested that the velocities in the ductwork (not at the diffusers and grilles) be about 20% lower than indicated to allow about a 5-dB margin for the lack of attenuation in the duct path.

17.4 DIFFUSER AND GRILLE SELECTION

The airflow velocities for low-noise spaces presented in Table 17.11 are only guidelines which include a number of assumptions, including that the nominal slot width is about 1/2 in. and the ductwork leading to the diffuser is only nominally configured. This also includes assumptions regarding the room effect and the number of diffusers that are contributing to the sound field at the receiving position. Note that the larger the room, the more likely it is that diffusers will be more numerous (and hence there will be more sources of noise), but in this case, it is also more likely that the diffusers will be further from the receiver and hence the room effect will be larger. These two factors tend to counter each other so that a single velocity guideline chart can cover a wide range of applications.

Manufacturers often provide data for the noise generated by their diffusers and typically these are boiled down to a single NC rating for the diffuser at a particular flow. Be careful in applying manufacturers' data because they are generated under ideal flow conditions and often include very favorable room effects so that the reported noise levels are as favorable as possible. Also, they typically are reported for one diffuser or for a short section of a linear diffuser where the application may have many more such elements contributing to the noise level at a receiver location. It is necessary to account for the sum of the noise that is generated by multiple diffusers/grilles which reach the receiver as well as to make other adjustments to correct the assumptions in the presented data to match the actual conditions of a project. It is also essential to make adjustments to the ideal flow condition used as the basis for the data to get to the actual applied flow condition. For especially quiet spaces, use of the velocity guidelines may be a preferable approach for establishing the selection parameters for the diffusers and grilles.

The noise produced by dampers needs to be assessed separately from diffuser and grille noise, but having two flow turbulence-producing devices closely spaced in series may add to the noise each device produces by itself.

Displacement ventilation systems which deliver air to the occupied zone through diffusers at the floor can often be very quiet. This is largely because air is introduced to the space in small quantities at any one location and the flow velocity at the diffuser needs to be particularly low for comfort reasons. The result can be a system with little diffuser-generated noise and this can be a favorable design approach for spaces that need to be very quiet.

17.5 NOISE BREAKOUT/BREAK-IN

When ducts containing high levels of noise pass though spaces with low or moderate noise goals, it is necessary to consider whether the noise that transmits out through the surface of the sheet metal duct (called the breakout noise) is suitably controlled. Similarly, when a duct in which the sound field inside has been quieted passes near a noisy piece of mechanical equipment prior to penetrating the mechanical room wall, noise may break into the duct and travel down the duct to a receiving space of concern. To minimize concern for noise breakout/break-in, it is usually best to position the high-insertion-loss elements in the duct system (the silencer) at or very near the penetration of the mechanical room boundary. However, it is not always possible to achieve this goal along with the goal of achieving good aerodynamics for the application of the silencer. Special elbow (or other configuration) silencers can help achieve the goal of the desired position of the silencer for breakout/break-in considerations while avoiding poor flow. This is a very good use of special silencers.

The noise that breaks out of and into ducts can be predicted using Eqs. (17.7) and (17.8), respectively:

$$L_{w(\text{out})} = L_{w(\text{in})} - \text{TL}_{\text{out}} + 10 \log \left(\frac{S}{A}\right) - C \tag{17.7}$$

$$L_{w(\text{in})} = L_{w(\text{out})} - \text{TL}_{\text{in}} - 3 \tag{17.8}$$

where $L_{w(\text{out})}$ = sound power level of sound radiated from outside surface of duct walls, dB
$L_{w(\text{in})}$ = sound power level of sound inside duct, dB
S = surface area of outside sound-radiating surface of duct, in.^{2}
A = cross-sectional area of inside of duct, in.^{2}
TL_{out} = duct breakout transmission loss, dB
C = correction factor as follows for values of $\Delta = \text{TL}_{\text{out}} - 10 \log(S/A)$

Δ	C
$> +10$	0
$+8$ to $+5$	1
$+4$ to $+2$	2
$+1$ to -1	3
-2 to -3	4
-4	5
-5	6
-6	7
-7	8
-8	9
<-9	$-\Delta$

Note: These breakout and break-in equations should not be used where $\Delta < -10$. Also, where Δ is a negative number, the precision of the result is questionable. The value of Δ tends to go negative with relatively long duct sections. This approach does not take into account any dissipative attenuation along the duct path, but at the low frequencies principally of concern for breakout and break-in issues, dissipative attenuation is usually small along the duct path in the length of duct sections for which the approach should be used.

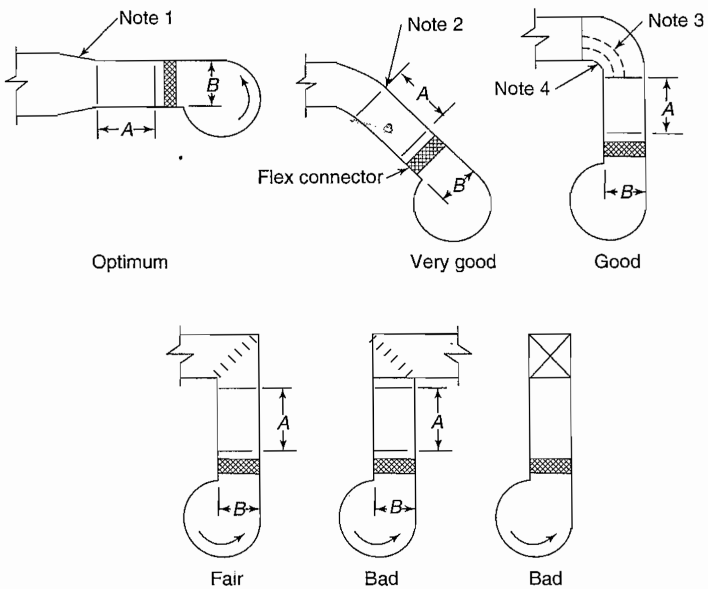
The noise breakout formula can further lead to prediction of the sound pressure level in a receiving space by applying an appropriate room effect and including the sound isolation of any intervening construction. The noise break-in equation will determine the sound power that can then be used as a source level and the propagation of this noise can be traced along the duct system. Treatments for noise breakout/break-in typically include increasing the surface weight of the duct construction, stiffening the duct, applying a flexible mass barrier material on resilient backing (such as a glass fiber mat or foam), or enclosing the duct in gypsum board using a variety of possible details. Prediction of the insertion loss achieved by various types of wrappings is given in Chapter 13. The further the enclosing mass layer is from the duct surface and the heavier the enclosure material, the better this will control low-frequency sound, which is most typically the concern. Circular ducts are inherently stiffer than rectangular ducts made of flat metal sheets, and for this reason, distribution systems using circular ducts are often less prone to breakout/break-in noise problems. Note that there is a particular concern for breakout/break-in noise when glass fiber panel or other acoustically transparent ceilings are used in occupied spaces in buildings. Where there is a solid gypsum board ceiling, breakout noise is naturally less of a concern than where there is a conventional mineral fiber acoustical ceiling.

Ducts that drop out of the bottom of rooftop air-handling units into the ceiling plenums above occupied spaces are a classic case where duct breakout noise is a problem, and this typically is worst when the supply duct discharges directly down into the ducts rather than into a plenum within the unit. Elbow silencers with high-transmission-loss casings can be a convenient method of addressing this problem. If a straight silencer is used and is located well away from the elbow that turns in the ceiling space, there can be a significant amount of duct wall which can radiate noise to the occupied space and may need to be treated. This is discussed further under the rooftop unit section (Section 17.10). Most of the duct enclosure treatments to address this concern are very difficult to install, especially when there is limited space and the building is finished. Whenever possible, designs should be developed which avoid the need for this sort of treatment.

17.6 FANS

Fans are typically the major source of noise emission into duct systems. The various fan types have differing noise spectrum and magnitude characteristics and this is also a function of the duty. Certain fans are aerodynamically better suited for particular flow and pressure applications. This needs to be considered for the full operating range of the application. Many older references, such as older editions of the ASHRAE handbooks, include generic methods to predict the noise generated by fans, and such sources can provide useful guidance in the absence of more specific data from the manufacturer for the fans that are planned. If such data are used, remember that, due to changes in manufacturing methods, modern fans may not be made the same way as the fans used as the basis for the generic prediction methodology. Often new fans are made more economically and produce more noise that older fans. It is best to obtain the noise data for the fan from the prospective manufacturer, tested in accordance with the most current applicable standards. These data should be used as a guide in the selection of the fan and as a point of comparison between candidate fans for an application. In addition, the quietest of the reasonable fans should be selected for a given application. Such a process should help avoid selecting a particularly noisy fan, which could lead to unexpected noise problems or noise control treatment which could unduly burden the system.

The manufacturer's noise emission data for fans are based on a standard test which may or may not closely match the conditions of a particular field



Notes:
1. Slopes of 1 in 7 preferred. Slopes of 1 in 4 permitted below 200 fpm.
2. Dimension *A* should be at least 1.5 times *B*, where *B* is the largest discharge duct dimension.
3. Rugged turning vanes should extend the full radius of the elbow.
4. Minimum 6-in, radius required.

FIGURE 17.3 Various outlet configurations for centrifugal fans and their possible rumble conditions. *Source*: 1999 ASHRAE *Applications Handbook*, © American Society of Heating, Refrigerating and Air Conditioning Engineers, Inc., www.ashrae.org.

application. The noise radiated by the fan into the duct will vary with the particular acoustical impedance of the connected ductwork. Consequently, the actual sound power of the fan that is emitted into a duct system may differ from the manufacturer's data.

Particular care should be given to the inlet and outlet flow conditions for fans. Poor inlet flow can unbalance the flow over a fan wheel, causing performance problems and excess noise generation at the anticipated speed for the application. The fan speed may need to be increased to compensate for unexpected pressure losses and thus generate more noise than expected. Inlet vanes or substantial flow distortion due to flexible connections protruding into the flow can easily cause an increase of noise on the order of 6 dB across the full frequency spectrum. The local airflow velocities on the discharge of fans can be quite high in some regions and probably will not be uniform over the outlet area. This needs to be taken into account in the system design and arrangement. It is often not possible to create ideal flow conditions, but it is important to create at least reasonable flow conditions and to avoid poor flow conditions which can create severe noise problems. Figure 17.3 illustrates some favorable fan discharge conditions as well as conditions that need to be avoided. It is always necessary to consider the flow arrangement on the discharge of a fan or air-handling unit to be sure that the duct and fan geometry work together as well as possible for the condition and, most essentially, to avoid poor conditions. Poor flow conditions at the fans can lead to low-frequency noise generation, either by the fan or due to large-scale turbulence in the ductwork which will drum the duct walls, causing a low-frequency noise problem that can be very difficult to solve.

17.7 TERMINAL BOXES/VALVES

Many HVAC systems serving buildings include a variety of terminal boxes or valves to control the amount of air delivered to the occupied zone. Some boxes are used to vary the airflow to the room in accordance with thermal load. Others provide a constant amount of flow to assure ventilation rates and control zone pressurization. Some boxes incorporate fans to mix plenum air with a variable amount of main system air to maintain a minimum amount of air movement while delivering variable heating/cooling. All of these boxes and valves have in common that they produce a pressure drop from the higher pressure in the main duct system to a low pressure in the final distribution ductwork on the room side of the box. In throttling the pressure from the main to the final distribution ductwork, noise is generated and this noise needs to be considered in the design to meet desirable noise levels in the occupied spaces. The greater the airflow quantity through the box, the greater the noise that is generated. However, the most significant factor is that the noise boxes generate is a strong function of the pressure drop across the valve. Boxes on a system that are near the fans naturally see a higher pressure in the main duct than boxes near the ends of the system, and boxes close to the beginning of the system will generate more noise than comparable boxes located toward the end of the system. Excess static pressure in the main ducts can be a significant factor in noisy systems as the terminal boxes in the system are throttling hard (have large pressure differential across them) to control the excess pressure.

The manufacturers of terminal boxes generally provide noise data for their boxes rated at various flow rates and pressure losses, and these data can be used for noise analysis of the ducted system just as fan noise propagation down the ducts is done. In such an analysis, the pressure loss that is of interest in determining the noise of the box is the actual pressure drop that the box is expected to produce in the field, not the minimum pressure at which the box will satisfactorily control flow or some arbitrary pressure loss that is assigned. Because of airflow control considerations, the boxes in many applications have inlet flow conditions that are reasonably close to the ideal flow condition under which the terminal box is tested for flow and noise. However, if there are adverse flow conditions, the noise generated by the boxes may be higher than the manufacturer's rating.

Noise radiation from the casings of the boxes can also impact the occupied spaces near them, and to enable assessment of this, manufacturers also publish casing radiated noise data. For fan-power boxes, these data include the noise that radiates from the fan out of the plenum air inlet and this can be a significant issue. In some cases it is necessary to provide attenuation for the plenum air inlet to the box. Most moderate-size terminal boxes operating at nominal pressures can be located in the ceilings of occupied spaces where the noise goal is NC-35 or higher when there is a conventional mineral fiber ceiling. Where boxes are in the ceilings of spaces with noise goals more stringent than NC-35, where system pressures are anticipated to be high, and/or where ceilings with lower transmission loss are used, special consideration should be given to the issue of casing radiated noise. In particular, be cautious of exposed box applications or where glass fiber, perforated, or open-slat ceilings are used.

The manufacturer's noise data should be reviewed for verification, but typically the frequency band of concern for flat-plate damper boxes is the 250-Hz octave band; for pneumatic-style boxes, the 500-Hz octave band; and for plunger-style valves, the 1000-Hz octave band. The type of noise control treatments that are applied in the duct systems should ideally be selected to treat the particular noise spectrum that is expected based on the box/valve type that is used.

For systems that utilize terminal boxes/valves it is usually a good idea to try to conceive the main duct system to be able to deliver the design airflow with the minimum overall pressure loss and the minimum differential in pressure arriving at the various boxes in the system. Consider gradually reducing the flow resistance in the main duct as the duct proceeds toward the end of the run and the magnitude of air being handled is reduced. The overall velocity in the duct system is often a significant factor determining the pressure drop from beginning to end, and the design velocities should be as low as reasonably possible. Use aerodynamically favorable fittings. Try to avoid particularly long duct runs by using more vertical shafts in the building to minimize the length of duct runs on the floors served. Where it is possible and acceptable to create ring ducts fed from both ends to serve the floor plate of a building, this can favorably reduce the pressure that is needed in the system. Consideration of these design features can help avoid noise problems and/or minimize the magnitude of attenuation treatments that are needed.

Always be sure that the final setup and balancing have the system operating at the lowest pressure that is consistent with delivering design airflow. This includes making sure that the system pressure cannot be further lowered without jeopardizing the required flow at the extremes of the duct system and making sure that the fan is operating at the lowest speed that will deliver design flow. If there are inlet vanes on the fan to control capacity, they should be nearly fully open when the system is demanding full design flow. The inlet vanes should not be constricting the airflow when the demand is full; if they are, the fan can probably be slowed, which should reduce noise emission.

17.8 MECHANICAL PLANT ROOM SOUND ISOLATION AND NOISE CONTROL

Good space planning is the best way to avoid sound isolation and noise problems at mechanical rooms. Avoid a common wall with a noise-sensitive space that would require a substantial and expensive wall construction. Very high sound isolation walls typically require discontinues in or special protection of the flanking structural paths; such treatments can be cumbersome and expensive. Having a common wall also invites penetration of that wall with ducts and pipes. Since creating a sufficiently tight seal around a single wall that is penetrated can often be difficult and risky, these should be avoided. Creating a buffer zone of less critical space between a mechanical room and noise-sensitive space allows simpler and less costly constructions to provide the desired isolation, and this minimizes the risk of noise leaks at penetrations. It is good practice to position particularly noisy equipment in mechanical rooms away from critical sound-isolating walls to avoid exposure of critical constructions to unnecessarily high levels of noise. Especially avoid locating equipment extremely close to walls where the sound has no opportunity to lose intensity owing to spreading losses.

Building constructions that provide a good deal of sound isolation can be constructed well, but there is always a door into the space, which is a weak sound isolation condition, and the location of doors needs special planning. Certainly it is necessary to avoid doors to mechanical rooms directly from noise-sensitive rooms. To the extent that it is possible to naturally create a double-door entrance vestibule ("noise-lock") to the mechanical room, such as by accessing the room off of a back-of-the-house corridor that is separated with another door from more public space, this is a good idea since good isolation can be reliably achieved with ordinary door construction.

Mechanical plant rooms often contain equipment which radiate relatively high levels of low-frequency noise, and it is necessary to have heavy constructions, such as masonry walls, surrounding the room. Lighter constructions such as gypsum board on stud can be used, but double-wall constructions with a substantial air space between the two sides of the wall will likely be required. Hence, light weight wall construction alternatives may take up more floor space. To the extent that there is auxiliary equipment associated with the main plant equipment that is wall mounted, it is often wise to have a double-wall construction so that minor vibration and structure-borne noise that might get coupled to the inner wall of the mechanical room will not get strongly transmitted to the side of the wall construction in the occupied space that is to be protected.

Creating an air-tight seal, as is always necessary for sound isolation, at the heads of walls can be particularly problematic. Necessary firestopping can be achieved for walls with fibrous packing and coating with intumescent material, but this is not a suitable seal for sound control purposes where the basic construction needs to close within a typical caulk joint of the abutting construction. Closing concrete block construction to the underside of fluted metal deck and beams can be very difficult. It is also difficult to create a seal when concrete block comes up under roof constructions that are sloped for drainage or need to accommodate structural deflection. The seals that are needed under these conditions need to be considered early in the design, and practical methods to accomplish the necessary seal in the field need to be detailed.

Floating concrete floors are sometimes required to separate mechanical spaces from noise-sensitive spaces that are above or below the mechanical room. Prediction of the insertion loss of floating floors is provided in Chapter 11. These constructions consist of a concrete slab (typically 4 in. thick) which is supported above the structural floor on resilient mounts. Systems to accomplish this are available from the various isolation product vendors. These constructions can and do provide effective control of sound transmission through floors, but they take up space that needs to be allocated from the start. They also require careful coordination and implementation in the field in order to function as planned. Floating floors are not generally designed as part of a vibration isolation scheme for plant equipment; their primary use is for airborne sound isolation. Concentrated loads such as from equipment can be accommodated on floated floors with appropriate planning and design of the floated floor, but it can also be acceptable to have such loads supported on small structural piers (housekeeping pedestals) that penetrate through the floated floor. To avoid a sound isolation concern at support points that penetrate the floors, these need to be kept as small as practical and typically complete housekeeping pads are not used. The sizes and positions of support piers need to be carefully coordinated in the field. Rather than use floating floors to provide high-level sound isolation to spaces above or below mechanical rooms, it is sometimes necessary to have special sound-isolating ceilings above or below the mechanical spaces. These can be complex to implement and require special coordination of the building services to avoid or minimize penetrations for supports through the ceiling. The timing of construction of the ceiling relative to installation of the building services needs forethought since it typically cannot follow the usual sequence.

17.9 VIBRATION ISOLATION CONSIDERATIONS FOR BUILDING MECHANICAL SYSTEMS

Technical aspects of isolation of vibration sources are treated in detail in Chapter 13. This section will provide some practical guidance regarding the application of vibration isolation systems and devices to building mechanical systems.

Numerous references, such as the sound and vibration control chapters of the ASHRAE *Applications Handbook*,[1] and vibration isolation equipment vendors provide guidance regarding the application of isolation devices for building equipment, and the reader is referred to such sources for specific isolation selections based on the type of equipment, the speed of the equipment, the location in the building, and the sensitivity of the application. For application to building equipment, the selection of vibration isolators is reduced to identifying the deflection of the isolation element under the static load. The deflection of the isolator under load is related to the natural frequency (the frequency at which resonance occurs) of the isolation system by the equation

$$f_n = 3.13 \left(\frac{1}{d}\right)^{0.5} \tag{17.9}$$

where f_n = isolator natural (resonance) frequency, Hz
d = isolator deflection, in.

Generally, to provide effective isolation, the natural frequency of the isolation system needs to be no more than 0.30–0.10 times the drive frequency (RPM/60) of the equipment. At ratios greater than 0.30 isolation efficiency will be minimal, and at a ratio of 0.70 there is theoretically no isolation at all. Clearly, it is necessary to avoid having the equipment operate at or near the natural frequency of the equipment. There is generally little point in an isolation system that has a ratio of isolation system natural frequency to equipment drive speed smaller than 0.10 since little additional effectiveness is gained for practical installations and the stability of the equipment on the isolation system can be marginal.

Many pieces or equipment are equipped with variable-speed drives and, in this case, it is generally appropriate to select the isolation system for the normal full speed of the equipment. As the equipment slows down and operates closer to the natural frequency of the isolation system, the isolation system will provide less isolation efficiency, but fortunately, the magnitude of the machine vibration force will be reduced at approximately the same rate. So, there are generally no problems with this. The natural frequency of the isolator should typically be no more than about half of the lowest operating frequency of the equipment to prevent operation too close to resonance, but for more difficult applications, this might be as high as 0.7. If it is not feasible to select large deflection springs, sometimes it is necessary to limit the operating range of the equipment to avoid operating too close to the isolation system natural frequency. This possibility should be considered early in the design. In some cases it might be worthwhile to judiciously increase the deflection of the springs to lower the natural frequency to avoid impacting equipment operation and efficiency. However, an isolation system should not be so flexible that it creates instability or operational problems such as with alignment or stress transfer.

Inertia bases are used with many pieces of equipment to lower the center of gravity and to reduce the vibratory movement of the equipment when it is resiliently supported. Movement due to starting torque, resistance to forces created by the static pressure a fan develops, and turbulent flow in large fan systems are also reasons such bases are recommended for equipment. The inertia bases only reduce the motion of the equipment on the isolation system. They do not change the inherent unbalanced forces of the equipment, even though the magnitude of vibratory movement of the equipment on the base will be lower. The vibratory displacement of the base and that of the equipment rigidly mounted on it will be lower because the mass that the forces are now acting on is the combined mass of the equipment and the inertia base compared with the mass of the equipment alone. Note that the inertia base does not change the vibration forces that are transmitted to the building assuming that the deflection of the isolation system remains the same. This is because, for the same static deflection, the springs need to be stiffer to support the additional weight of the equipment plus its inertia base.

In theory, the weight of the inertia base would be determined by the desired reduction of the magnitude of the vibratory movement, but the magnitude of the motion of the equipment is not well known, so it is difficult to tell what mass ratio to use. In practice, the weight of the inertia base for building mechanical equipment is often determined by the weight of concrete fill in a steel frame that approximates the rectangular outline of the equipment footprint (with allowance for fastening), and the depth is determined by the need to make the base suitably stiff. The depth of the base is often related to the length of the base and is typically about $\frac{1}{10}$ to $\frac{1}{12}$ the longest dimension. Experience indicates that for many pieces of mechanical equipment, the base weight that results from this methodology is sufficient to control excessive movement and prevent undue forces from being transmitted to connected pipes and appurtenances.

Spring isolators most typically are manufactured to achieve rated deflections of approximately 1, 2, 3, and 4 in. This means that when the full design load for the spring is applied, the spring will approximately deflect this rated distance, and at this condition, the spring will also achieve other desirable design features such as for lateral stability, horizontal stiffness, and deflection reserve to bottoming out. The rated deflection has nothing to do with the deflection actually achieved in the field under the actual equipment load applied. For example, a spring that has a rated deflection of 1 in. for a 1000-lb load will only deflect 0.10 in. if it is supporting 100 lb. The only thing that is important in terms of the isolation efficiency of the mounting is the actual static deflection that results under the applied load and, in the case of this example, the natural frequency would be determined by 0.1 in. deflection. Isolation devices need to be properly selected to achieve the desired minimum static deflection and hence the desired isolation

efficiency. Underloading an isolator can result in achieving less than the desired isolation efficiency and overloading can cause the spring to collapse (bottom out) so that it provides no isolation at all. If a spring is specified to achieve 1 in. minimum deflection under load, there is only one load that will exactly satisfy the requirement if a spring is selected from a 1-in. rated series of springs, and that is the maximum load that the mount can support; lower loads will achieve less than 1 in. deflection and will not meet the required minimum deflection, and greater loads will overload the spring. To achieve the required minimum deflection in this case, a 2-in. rated deflection spring would need to be used so that as long as it is loaded between half and full load, it will achieve the required minimum deflection. This can cause unnecessary expense for isolators that have substantially more capacity than needed. To clarify the performance desired and to avoid unnecessarily costly springs, it is often better to specify spring deflections of 0.75, 1.5, 2.5, and 3.5 in., as expected from 1,2, 3, and 4-in. rated static deflection springs, respectively, so that there is a reasonable selection range available.

For applications where the weight of the isolated equipment may vary substantially from time to time, such as for a cooling tower or chiller if the water is drained for maintenance, the isolation devices that are used need to incorporate some method to restrain the upward movement of the equipment as the weight is removed because this can put excessive stress on connecting pipes. Equipment that is located outdoors may be exposed to wind and exhibit lateral movement which needs to be restrained. Special travel-limited isolators have been developed for this application which will snub the movement of the equipment under such conditions, typically at about 1/4 in.

Many pieces of equipment need to be specially restrained to avoid damage to the equipment or the building if a seismic event occurs. This applies to many pieces of equipment, whether resiliently mounted or not, but clearly, equipment that is resiliently supported could easily fall off its mounts if there is a seismic event. Seismic restraint of equipment is an entirely separate issue from vibration isolation; it is essentially a structural issue. Isolation and seismic restraint become related because so many pieces of equipment that are resiliently supported need restraint. There are seismic restraints available from vendors which are completely separate devices from vibration isolators. In some cases it is convenient to incorporate seismic restraint into the isolators, and products that do this are available from vibration isolation vendors, but it may not be necessary to use combination devices. Where the equipment has no other point of attachment but the mounting points at which suitable support and restraint can be achieved, a combination device is necessary. It is essential that the seismic restraint not compromise the performance of the vibration isolation system, and this is not an easy task considering the relatively tight installation tolerances that are required for both seismic restraints and vibration isolators. Often isolators with combined seismic restraint can help achieve the desired level of installation more reliably, and this is another benefit that such devices provide.

Electrical connections to vibration isolated equipment need to be made flexible to avoid creating a problematic vibration transmission path to the building structure. These are typically made with either a section of flexible conduit or a special flexible electrical coupling. For small-size equipment and conduits, practical lengths of flexible conduit are effective and sufficient. As the size of the equipment and the connecting conduit increase, the flexibility of these systems may diminish and it may be necessary to use special flexible electrical couplings. The flexible connections should be installed in whatever manner creates a slack condition.

Piping that connects to isolated equipment also needs to avoid creating a vibration transmission path to the building. There are flexible pipe connections available for many applications, but because vibration can travel through the fluid in the pipes (which is often highly incompressible), vibratory energy is often not stopped sufficiently by them. Such connections are best used (or not) based on considerations other than vibration control (e.g., thermal expansion/contraction or alignment). To control vibration transmission to the building via pipes, it is usually necessary to resiliently support the pipes for some prescribed extent, but that extent is not easy to describe and could vary substantially from project to project. Many schemes have been devised to describe the scope of pipe isolation in buildings, such as a prescribed length of pipe or a certain multiple of the pipe diameter, and this is somewhat dependent on the designer's philosophical approach. The fixed length of pipe isolation from a vibration source approach does not account for variations of pipe stiffness based on size. Clearly, a 1-in. pipe for a particular duty is much more flexible over a given distance than a 12-in. pipe for a similar duty. Prescribing the length of isolation in pipe diameters partly addresses this issue, but this approach can be difficult to work with in the field. In practice, there needs to be some compromise between a practical scheme that can be implemented in the field, a system that makes sense economically, and a scheme which will provide the isolation that is needed for the size of pipes and the vibration sources involved. There are many possible approaches to this specification depending upon what is workable and cost effective. There may be a generic scheme that is appropriate for many applications, but this should be carefully considered for each project before finalizing the scheme. The designer should keep in mind that a resilient connection between a pipe and the building structure provides a reduction of the vibratory force only if the local impedance of the supporting structure is high compared to the impedance of the isolation device. Little isolation will be gained if a moderately stiff isolator like a neoprene pad is used to resiliently support a pipe from a lightweight and flexible gypsum board on stud wall.

Classic vibration isolation theory assumes that isolators sit on supports that are infinitely stiff and massive. This is reasonably the case for support conditions at slab-on-grade floors, but this may not be the case for support conditions at all structures above grade. Most isolation application guides take this into account and provide recommendations for a variety of less than perfect support conditions such as on above-grade structures. The implications of structural flexibility on vibration isolation for most above-grade support conditions are rather modest where the structure is reasonably massive (such as a concrete floor) and is suitably strong to support mechanical service equipment. This accommodation involves only slightly softer isolators than would be used on grade, but the isolators are still within the range of conventional products that are economically available. When the supporting structure is particularly lightweight, such as wood frame construction or a simple metal deck roof, special attention needs to be given to the support condition, and it may be necessary to create special load transfer schemes to transfer the load to more substantial points of structure such as columns.

17.10 ROOFTOP AIR CONDITIONING UNITS

Many HVAC systems employ a variety of types of packaged rooftop air conditioning units with circulating fan systems and sometimes with integral compressor/condenser sections. Because such equipment is often noisy and typically supported on a lightweight structure directly above occupied space, this equipment is one of the most common sources of noise problems in buildings. Because of space limitations and the magnitude and frequency of excess noise that results, problems with this equipment are often very difficult and expensive to address, especially once the equipment is installed. Sometimes it is not practical and economically feasible to fully resolve the problems presented by this equipment at the initially chosen location and major system changes are needed. The best way to address noise from this equipment is to have it installed at the outset according to a well-conceived noise and vibration control scheme. The necessary installation features to control noise and vibration may be new and unusual to some installers, and it is wise to take the extra steps to clearly document all the necessary details so they can be properly implemented.

The roof construction needs to extend fully under the equipment and needs to close tightly around any penetrating elements such as pipes and ducts. The roof construction needs to be appropriate to control airborne sound transmission to the occupied space, including sound that might transmit both through the roof deck directly under the unit and off to the side of the unit (for some distance from the unit). If concrete is used in the roof deck, this is very good and can help to address, in a simple manner, both airborne noise and vibration isolation issues. Concrete is not always necessary and lighter weight sound isolation alternatives can be conceived, but they may be unfamiliar to some installers.

Having the supply fan discharging directly down into the supply duct entering the ceiling of an occupied space is often a problem and does not allow easy opportunities to incorporate silencing devices. If possible, it is usually much better to have the fan discharge horizontally within the unit, into a discharge plenum (also in the unit), before the air is delivered to the duct system. The discharge plenum presents an opportunity to incorporate sound attenuation treatment before the air stream enters the duct in the ceiling of the occupied space. In some cases it is acceptable to run the ductwork across the roof before penetrating the roof, and this is always a favorable noise control approach since it allows space for turbulent airflow to smooth out, allows room for substantial silencing treatments before the ductwork gets into the ceiling of the occupied space, avoids what are often poor duct flow geometries at the fan discharge which occur when the duct drops directly out of the bottom of the unit, and allows low-frequency fan and duct rumble noise in the initial duct sections to dissipate outdoors rather than radiate in the ceiling of occupied space. However, such ducts may present practical and aesthetic design issues. The return/relief air path associated with rooftop units can present similar issues as discussed for the supply air path, but typically conditions at the return are not as severe because the flow conditions are not as bad and there is less fan noise. Similar noise control treatments might be considered for the return as for the supply.

Be sure that the duct geometry on the discharge of the supply fan is as reasonably advantageous as possible and avoid poor geometries as discussed above.

Silencers are often needed in the supply and return ducts and this attenuation should ideally happen before the ducts enter the occupied space, but if the ductwork from the unit drops directly into the ceiling and then has to turn into the horizontal ceiling plane, there is no aerodynamically appropriate location to put the silencer close to the unit discharge. Often, an elbow silencer can work well for these applications. When the silencer is moved away from the roof penetration, it is often necessary to encase the ductwork between the roof penetration and the silencer in a special noise barrier construction. The silencers for these applications also often need to have special high-transmission-loss casings or be encased along with the adjacent ductwork. All of these details are awkward, expensive, and difficult to construct within the limited ceiling space that typically exists. Sometimes, special curbs are created under the units to allow the return air to flow back to the units within the curb space, such as shown in Figure 17.4. With appropriate design and detailing, this can facilitate very good and practical ways to incorporate noise control treatments for both the supply and return paths.

Vibration isolation of packaged rooftop HVAC equipment can present problems, but this most often results when the units have integral compressor/condenser sections. When the unit just has basic supply and return/relief fans in the cabinet, vibration isolation can usually be satisfactorily accomplished with conventional, suitably soft, spring isolation for the fans within the unit. In this case, such units can externally be rigidly supported to the building in whatever manner is desired based on other considerations. When a unit has a compressor/condenser section, there is a concern for vibration isolation even though the compressor may be "internally" isolated. This is because the refrigerant piping within the unit is typically not adequately internally isolated, allowing vibration transmission to the equipment casing and hence to the building. In this case it is necessary to externally vibration isolate the entire unit with a spring isolation system. This is done in either of two ways, depending upon how the unit is intended to be supported and how the building designer plans to transfer the load to the building structure. There are special curb isolation devices available for equipment that requires curb support and closure of the space below the unit,

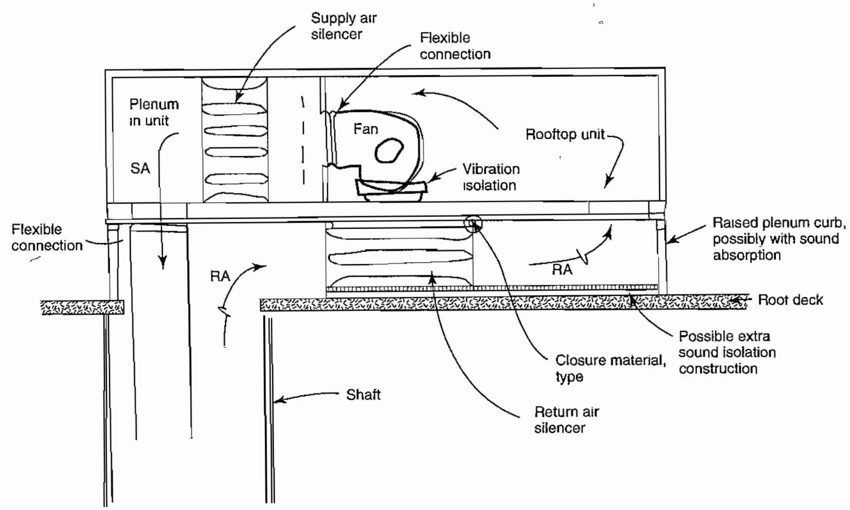


FIGURE 17.4 Rooftop unit with curb plenum return air. RA = return air, SA = supply air.

and some of these products can accommodate the aforementioned in-curb return airflow path scheme. If the load is to be transferred to the roof via a structural system raised above the roof, then point isolators are used. If the unit is intended for curb support but is raised above the roof in this manner, it may be necessary to mockup a structural curb for the unit to transfer its load to the point isolators.

17.11 OUTDOOR NOISE EMISSIONS

Many local authorities have noise regulations to control noise impact on neighboring properties and generally throughout the community. These need to be uncovered as part of the code searches at the outset of a building project so that they can be addressed in the mechanical system concept for the building. Typically, either fixed noise limits for specific receivers are established or the allowable noise level is based on the existing ambient noise level in the impacted area. If the noise requirement is based on the existing ambient noise condition, the existing noise has to be measured. Where neighbors are close by, requirements are stringent, and/or the receivers look down on the noise sources, meeting the noise requirements can be quite challenging.

Many pieces of equipment that are particularly economical (such as many air-cooled devices) are quite noisy and may not easily conform to noise regulations. Fortunately, equipment and mechanical schemes that produce less noise are often available, and, although they may be more expensive at the outset, they often provide some energy payback in the long run. Quieting the noise at the source is almost always the best approach to controlling outdoor noise emissions. Evaporative cooling equipment is usually quieter than air-cooled equipment. Equipment incorporating centrifugal fans is usually much quieter for a given duty than comparable equipment with propeller fans. Propeller fans can be quieted by using larger and/or slower moving fan blades, even if more fans are required for the duty. There are several degrees of propeller blade technology available (particularly for moderate to larger blade size applications) which can provide worthwhile noise reduction at an affordable cost. Typically, propeller blade noise reduction is achieved by having more aerodynamically efficient blades with wider chords so that they move more air with each rotation and can move a given quantity of air with lower fan speeds. Some equipment can be equipped with variable-speed drives so that when the demand on the equipment is low, the equipment (typically fans) can operate more slowly and therefore with lower noise emission levels. This is of course statistical noise reduction and will not produce noise reduction when full speed is required. However, this is particularly useful for equipment such as cooling towers where the heat rejection requirements at night are lower than the design condition and it is easier to reject heat to the cooler nighttime environment. The noise reduction that results with variable-speed drives often works naturally with the typical diurnal noise cycle which has lower noise conditions at night. It is best to avoid equipment which has a noise emission spectrum that is particularly tonal since many regulations prohibit or more strictly limit tonal sounds. Tonal sounds are typically judged to be more annoying than an equivalent level of broadband sound, so the likelihood of avoiding a noise complaint is better with broadband sources than with tonal sources. For a given level of satisfaction with the noise level achieved, a greater degree of noise control will need to be applied to tonal sources.

Sometimes equipment cannot be purchased suitably quiet within practical or economical limits, and it is necessary to apply noise control treatments. For many pieces of equipment and systems this can be reasonably and economically accomplished, such as with silencers or by building a noise barrier to block sound emissions in a particular direction. However, some pieces of equipment are not well suited to having noise control applied and treatments (such as barriers) can inhibit airflow. For instance, propeller fans produce dramatically lower airflow when working against even small degrees of extra pressure loss, and it is difficult to apply silencing devices to such equipment without degrading mechanical performance. Heat rejection equipment such as cooling towers and condensers need to avoid having the hot discharge air be recirculated back into the inlet because this can reduce efficiency and limit the mechanical capacity of the unit. Providing high levels of noise control to such equipment is often not possible and alternate equipment selection may become essential. The ability to adapt noise control treatments to equipment, if required, is a factor that should be considered in selecting the basic equipment and mechanical scheme. For small amounts of excess noise (typically less than about 10 dBA) it may be possible to create a noise barrier with sound-attenuating louvers which can allow some airflow to help mitigate the adverse airflow due to the barrier.

CHAPTER 18

Active Control of Noise and Vibration

RONALD COLEMAN AND PAUL J. REMINGTON

BBN Technologies
Cambridge, Massachusetts

18.1 INTRODUCTION

The term active noise and vibration control (ANVC) refers to systems that use externally powered actuators to generate sound and/or vibration to reduce responses caused by unwanted disturbances. These systems consist of a set of reference sensors that monitor the source and a set of control, or residual, sensors that monitor system response. In some cases (e.g., feedback control) the reference and control sensors are the same. The signals from these sensors are inputs to an electronic controller, which filters the sensor signals to generate drive signals for the actuators. In a well-designed system the actuators excite a structure and/or sound field in such a way as to interfere with the disturbance and reduce the unwanted noise and/or vibration. The advent of modern digital signal processing hardware and software has allowed the controller in the system to be extremely flexible and even to adapt to changing conditions.

While ANVC has become a powerful tool for the noise control engineer, it is not a "silver bullet," and careful consideration must be given to passive mitigation approaches in any noise and vibration control problem. At low frequencies where the offending source consists of a small number of discrete frequencies and where the system to be controlled has only a small number of degrees of freedom, ANVC can be very cost effective. Passive treatments can also be utilized successfully on tonal sources at low frequency, but because the acoustic and structural wavelengths can be very long, the weight and size of the treatments must often be quite large to be effective.

Broadband sources of noise and vibration at high frequency, the other extreme, are often best controlled using passive techniques because many passive approaches are broadband in nature. In addition, because the acoustic and structural wavelengths in the system to be controlled are short, the treatments need not be large and heavy to be effective. On the other hand, active systems are usually less effective against broadband sources, and higher frequencies can place considerably higher demands on the controller hardware.

As the above discussion indicates, ANVC can be effectively employed against narrow-band disturbances at low frequencies where the system to be controlled has a small number of degrees of freedom. The term *degrees of freedom* refers to the number of ways that the system to be controlled can respond. The number of modes contributing significantly to the response of a system is an example of the number of degrees of freedom. It is important in ANVC because, as will be discussed later, the number of degrees of freedom corresponds to the number of actuators needed to provide effective control. As the number of input and output channels to the controller, the frequency range for control, and the performance goals increase, so do the risks associated with the stability, robustness, and costs of the resulting control system. In general, one wants to employ the system of minimum complexity to achieve the design goals. In many cases the use of a hybrid system employing both passive and active components is the best approach and the most likely to succeed.

This chapter is designed to provide the practicing noise control engineer with an overview of the technology currently employed in the application of ANVC. Enough detail is included in the hope of allowing readers to assess the applicability of the technology to their problem and to allow them to lay out an approach to the solution of that problem appropriate for ANVC. We begin with a brief discussion of some basic issues underlying ANVC technology, including conceptual overviews of several types of ANVC systems. Modern-day ANVC systems rely on digital signal processing technology, and the heart of digital signal processing technology is, of course, the digital filter. These are discussed in Section 18.3. The design of digital filters is a rich topic that has seen many years of development. Here we can only scratch the surface and hope to give the reader some appreciation of the power of the technology. Sections 18.4 and 18.5 deal with feedforward and feedback control architectures, respectively. The chapters compare the two architectures, provide guidelines for design of optimal controllers, including adaptation, and discuss system identification issues. For feedback a suboptimal heuristic design approach is also presented. The next section deals with practical design considerations. The topics include the determination of the number and location of actuators and sensors, selection of control architecture and hardware, performance simulations, and controller implementation and testing. The final section provides a detailed discussion of three ANVC systems that have been successfully implemented.

18.2 BASIC PRINCIPLES

Placement and Selection of Control Sources/Actuators

The basic concept behind active noise control is illustrated in Fig. 18.1. There a loudspeaker has been placed a distance L from an unwanted source of sound. The intent is to create sound from the *control* loudspeaker that will be out of phase with and will cancel the sound from the *disturbance* source. Ideally it would be desirable to control the sound radiation in all directions (global cancellation),

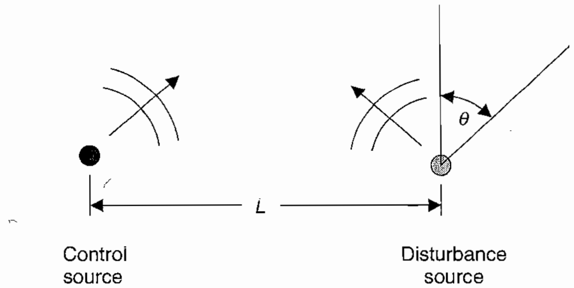

FIGURE 18.1 Disturbance source and control source.

and if the distance between the control source and disturbance source is small compared to a wavelength of sound, excellent global cancellation is possible. This comes about because the phases of the sound fields surrounding the two sources are very nearly the same at every location. Consequently, if one source is out of phase with the other two, the sound fields will cancel everywhere. On the other hand, if the separation distance is large compared to a wavelength, the two sound fields will have very different phases with the differences depending on location. As a result, the two sound fields will in some locations cancel and in others reinforce one another. This is illustrated in Fig. 18.2, where the change in the sound radiation from the disturbance source is shown as a function of angle θ. For $k_0L = 0.1$ in the figure, where k_0 is the acoustical wavenumber and L the distance between the disturbance source and the control source, the change is a reduction of 20 dB or more for all angles. However, as the frequency increases and k_0L increases, the global reductions decrease. For example, in the figure, for $k_0L = 1$ the reductions are limited to a small range of angles around $\pm 90°$ and for $k_0L = 10$ there is a 6-dB increase for most angles. The figure clearly shows that it is desirable to locate the control source as close as possible to the disturbance source. In some cases, however, when the physical dimensions of the source are comparable to or larger than a wavelength at the frequencies of interest, the control source cannot be located close enough to the disturbing source. Figure 18.3 shows the effect of source separation on the overall radiated acoustic power (the integral over all angles in Fig. 18.2). The figure shows that for separation distances greater than one-quarter of an acoustic wavelength the total radiated power will actually increase. This is a fundamental limitation on ANVC that can only be overcome through the use of additional control sources. The use of multiple sources in a prototype system for controlling locomotive exhaust noise is discussed in Section 18.7 under MIMO Feedforward Active Locomotive Exhaust Noise Control System with Passive Component.

One of the earliest demonstrations of active noise control was carried out by Conover[1] and Conover and Ringlee[2] of General Electric in the early 1950s to control the noise from a high-voltage transmission line transformer. Using a single loudspeaker, he utilized the electrical line signal to drive the speaker and

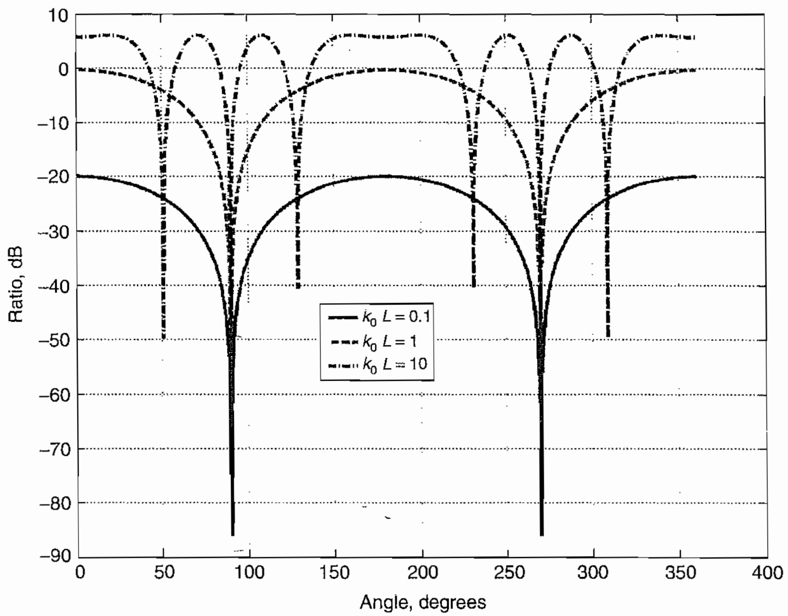

FIGURE 18.2 Change in the ratio of the controlled to the uncontrolled sound pressure level as a function of frequency and angle.

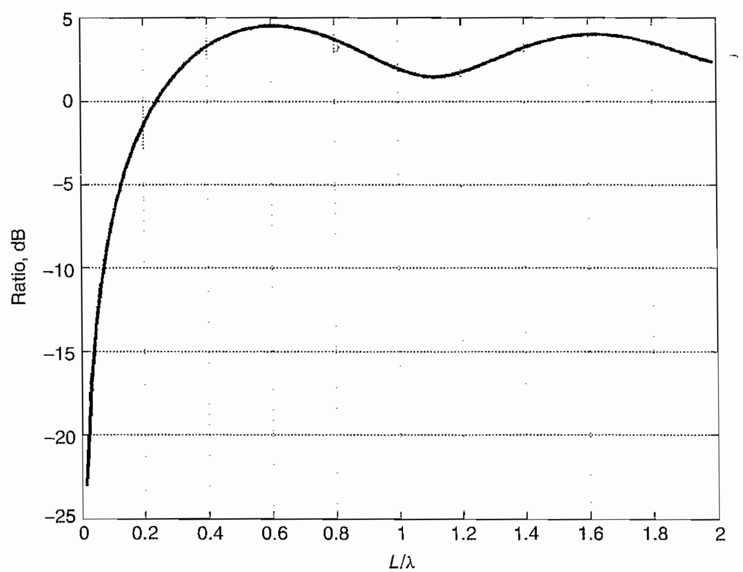

FIGURE 18.3 Change in the overall radiated output power as a function of the separation between sources.

appropriately amplified and phase shifted the harmonics of the line frequency to achieve the desired control. Because the system was not adaptive, occasional manual adjustment was required to correct for changes in sound propagation at the test site. In addition, because of the large size of the transformer, even at the low frequencies he was concerned with (120 Hz), he could not achieve global cancellation but had to be satisfied with ~10 dB of cancellation over a beam width of about 23°, corresponding to a point somewhere between the curves for $k_0L = 1$ and $k_0L = 10$ in Fig. 18.2. Remarkably, Conover was able to achieve this level of performance using purely analog hardware. Digital hardware did not come into use until the 1970s. Among the first to employ digital electronics were Kido[3] and Chaplin and Smith.[4] Kido used digital hardware to implement an active system to control transformer noise similar to Conover's and Chaplin and Smith developed a digital system for controlling tonal exhaust noise.

While the above discussion has focused on acoustical sources, similar principles apply to structural systems. Consider, for example, a plate with a point force disturbance applied as illustrated in Fig. 18.4 with a control actuator located as shown. In this example the plate is 10 × 5 ft and $\frac{1}{2}$-in-thick steel with a loss factor of 10% and the disturbance force and control actuator are about 1.4 ft apart. Because the plate in this example is finite in size, there will be resonant modes, which will add further complications to the selection of the number and location of the actuators. In this example, the control actuator is applying a force to the plate, the amplitude and phase of which is designed to control the first mode. Figure 18.5 shows the contribution of each mode to the plate response with and without activating the control actuator. Comparing the two plots in the figure, one can see that activating the control actuator has suppressed the first mode, and, in addition, the second and third modes have also been reduced. Higher

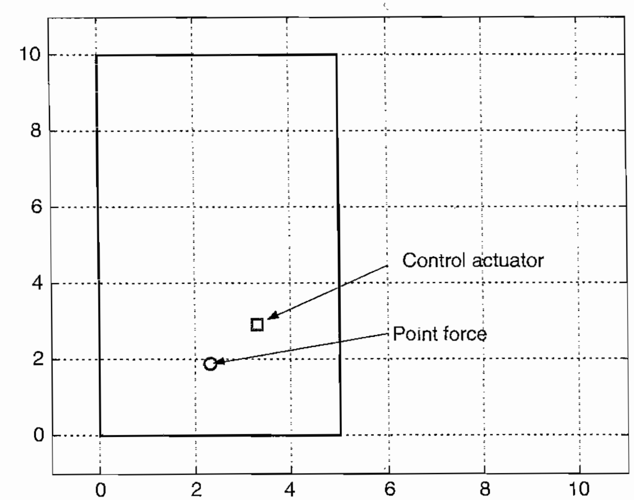

FIGURE 18.4 Plate with disturbance force and control actuator.

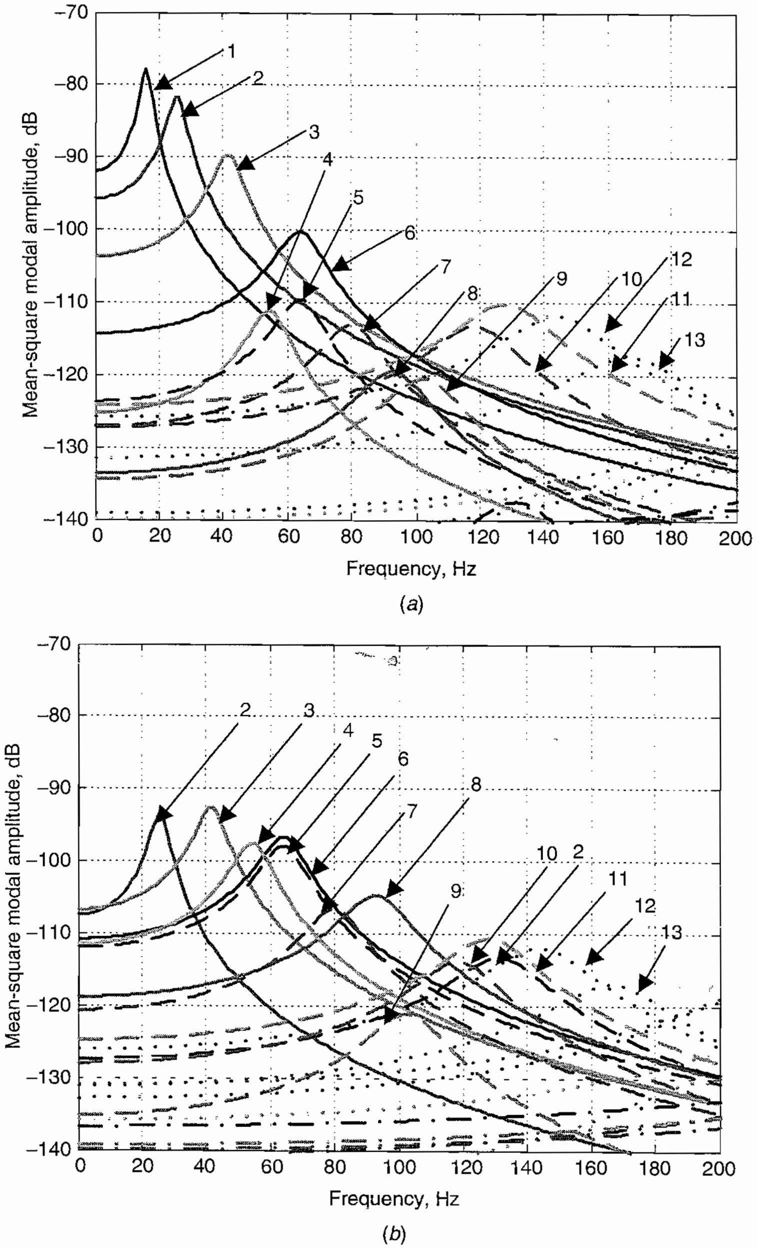

FIGURE 18.5 Modal amplitudes: (*a*) uncontrolled; (*b*) controlled.

order modes, however, have generally increased in amplitude. This increase in the amplitude of uncontrolled modes is referred to as *modal spillover*. Modes that are not targeted to be controlled can increase in amplitude. We can overcome this problem by moving the control actuator closer to the point of application of the disturbance force or we can add additional actuators, one for each mode that we wish to control. In general, placing the actuator as close as possible to the disturbance source will result in the best reduction in vibration. For example, in Fig. 18.6 the mean-square plate displacement averaged over the area of the plate is shown uncontrolled and controlled with a single actuator 1.4 ft away from the disturbance force and 0.28 ft away. When the actuator and disturbance are 1.4 ft apart, the vibration below 40 Hz is well controlled, but above about 50 Hz the control actuator increases the plate vibration due to modal spillover. When the control actuator is moved closer, spillover is virtually eliminated in the frequency range shown.

We can also increase the number of actuators, which will enable us to control additional modes and increase the frequency range over which the control will be effective. As an example consider the four control actuators located as shown in Fig. 18.7. These will be used to control the first four modes.* The result is shown in Fig. 18.8. While spillover has not been eliminated at all frequencies,

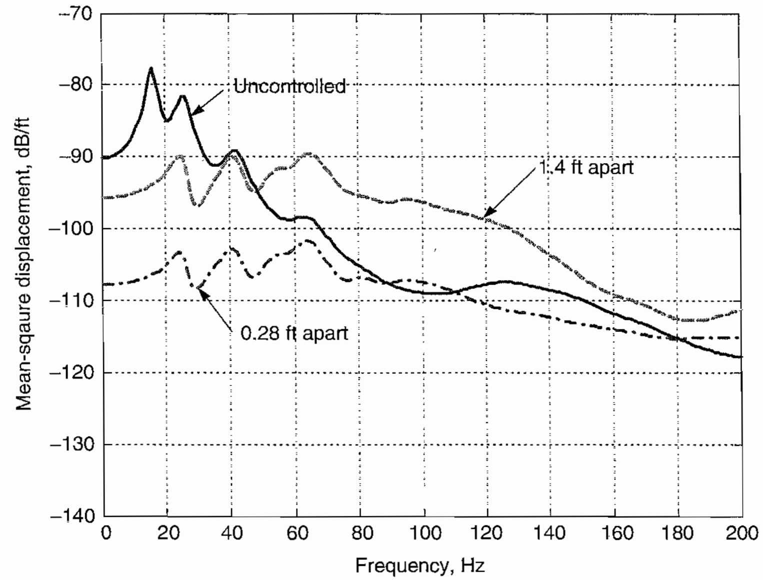

FIGURE 18.6 Controlled and uncontrolled plate response.

*Note that the actuator positions have been selected to ensure that at least one actuator is capable of exciting each of the four modes. If the actuators are placed near the node of a mode to be controlled, the actuator will be ineffective in controlling that mode.

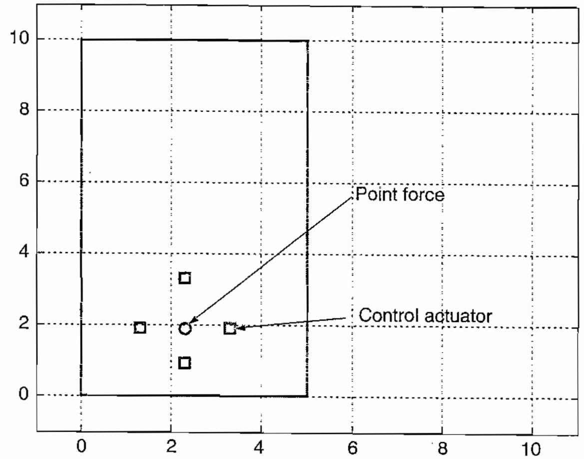

FIGURE 18.7 Location of four control actuators.

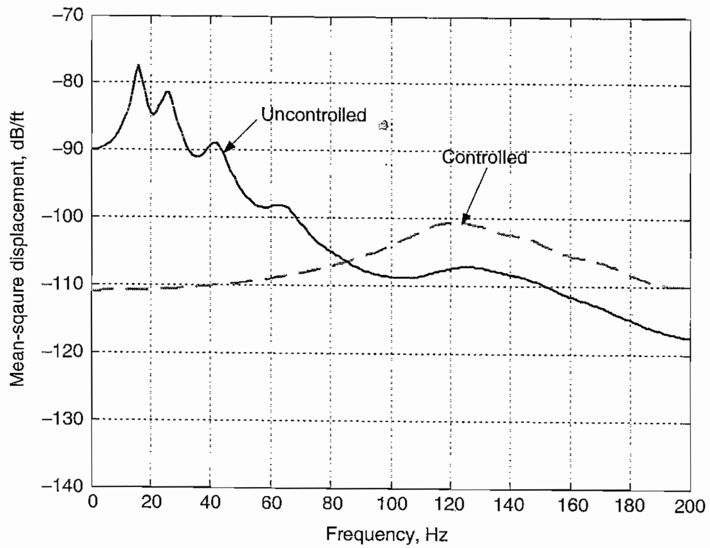

FIGURE 18.8 Change in mean-square plate vibration using four control actuators.

below 80 Hz the reduction in vibration is comparable to that achieved by bringing the control actuator very close to the disturbance point force. Good performance above 80 Hz can be achieved by continuing to increase the number of actuators and targeting more and more modes for control. Note that similar modal issues come into play in active noise control when the noise control is to be carried out in a confined space rather than in the free field in the first example.

The lesson to be learned from all of this is that, when possible, placing the control sources as close as feasible to the offending sources will provide the best noise and vibration reduction performance. When this is not possible due to the size of the source, lack of access, and so on, the loss in performance can be made up, in principle, by employing a larger number of control sources. However, increasing the number of control sources will increase the complexity of the controller needed to drive them and will certainly increase the cost of the entire system.

Control sources come in a wide variety of forms. For acoustic applications, loudspeakers are typically employed. The active elements in the speakers may be electrodynamic (voice coil), piezoelectric, or electromagnetic, to mention a few. The active element might be used to move a speaker cone, modulate airflow, or deform a structure. The most common configuration is a speaker cone driven by a voice coil. Whatever the configuration, the speaker usually needs to be enclosed for protection against physical damage, weather protection, and performance enhancement.[5] Figure 18.9 shows an enclosure arrangement developed for the active control system discussed in Section 18.7 under MIMO Feedforward Active Locomotive Exhaust Noise Control System with Passive Component. These enclosures are bandpass enclosures designed to enhance the speaker output between 40 and 250 Hz. Each contains 2–12-in. loudspeakers and 10 were employed to control the locomotive exhaust noise. Despite these efforts the

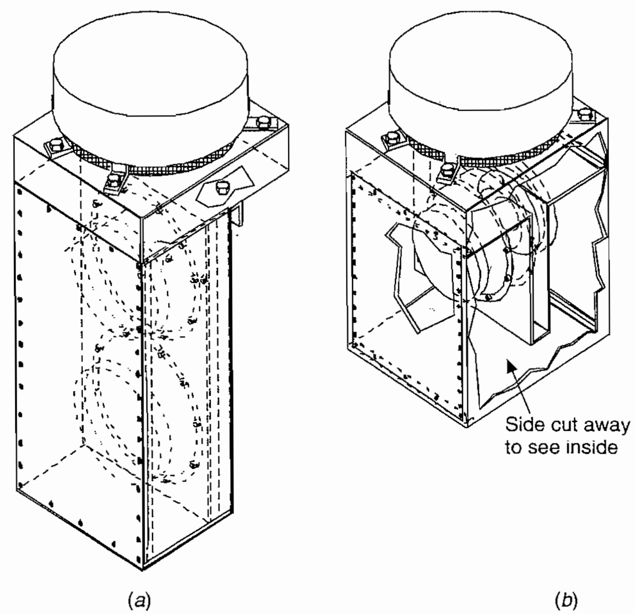

FIGURE 18.9 Typical loudspeaker enclosure arrangement.

performance of the active noise control system was limited by the output of these control sources. This is typically described as having insufficient *control authority*. Insufficient control authority is a problem often encountered in active noise control systems, and an assessment of the control source requirements is one of the first things that should be done before proceeding with any active noise and vibration control system design. If there is not sufficient space and power available to ensure adequate control authority, the active system is doomed to have inferior performance.

A wide variety of devices are available to be employed as structural control actuators. Typically these are devices that generate a force that is reacted against an inertial mass (inertial shaker) or against another part of the structure (interstructural shaker). The active element may be pneumatic,[6] hydraulic,[7] electrodynamic,[8] electromagnetic,[9] piezoelectric,[10] electrostatic,[11] or magnetostrictive,[12] to mention a few. A large-capacity electromagnetic inertially referenced shaker designed for use in an active control system is shown in Fig. 18.10.

In place of shakers piezoelectric[13] patches are sometimes applied directly to panels to control vibration or to radiate sound for noise control. Any of these devices can be very effective,* but the critical issue still remains. The device must provide sufficient control authority.

Control Sensors and Control Architectures

Sensors provide the input signals that the controller filters to drive the control sources and actuators. Sensors provide two functions, and to discuss those

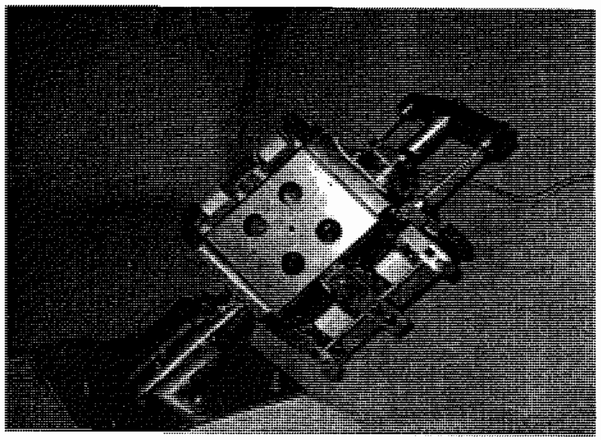

FIGURE 18.10 A 2000-lb-capacity electromagnetic inertial shaker.

*The inertial shaker usually provides better performance than the interstructural shaker, especially if the interstructural shaker creates a flanking path outside of the frequency range where the control system is functioning, but the interstructural device may be preferred when high control authority is needed with minimum weight.

functions, we need to describe the two commonly used control architectures: feedforward and feedback. The two architectures are illustrated in Fig. 18.11. In the feedforward system (Fig. 18.11*a*) one or more reference sensors measure a signal that is correlated with the disturbance to be controlled. The reference sensor output is sent to a control filter, which acts on the signal to generate an output signal that is used to drive the control actuators. The control actuators drive the system to be controlled (the plant function *P* in the figure) and the response of the plant is monitored by one or more residual sensors. The residual sensors are sometimes called the control sensors or error sensors. The purpose of the residual sensors is to monitor the performance of the control system. In later sections we will see how the reference and residual sensors are use to define and/or adapt the control filter.

In a feedback system (Fig. 18.11*b*) there are only residual sensors, or, to put it in other terms, the sensors in a feedback system provide both reference and residual functions. As in a feedforward system, the residual sensors monitor the performance of the control system. In addition, their signals are fed to the control filter, which acts on the signals to generate an output signal that is used to

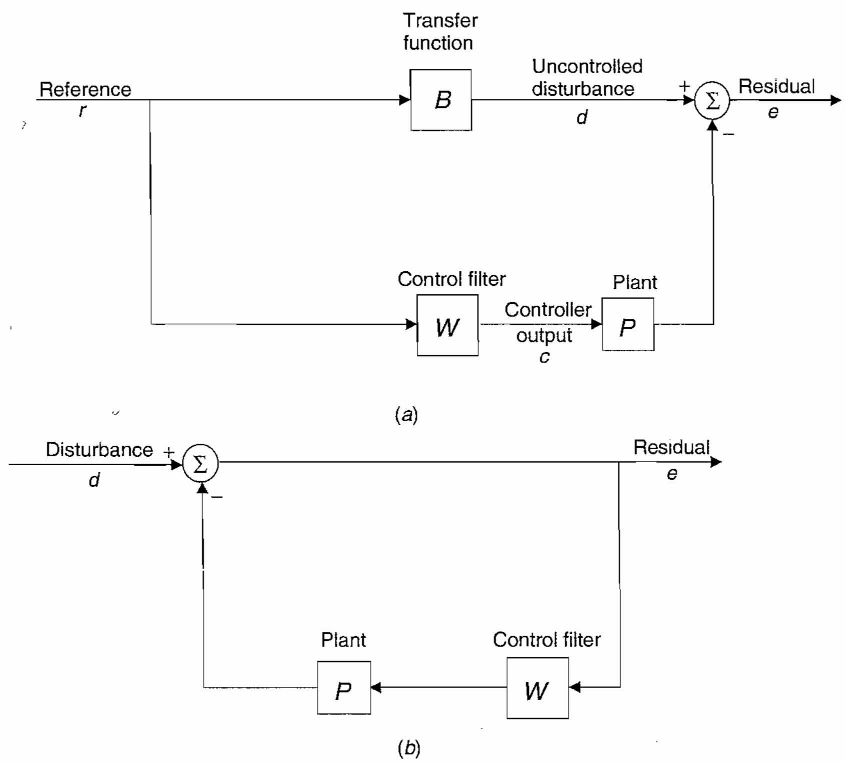

FIGURE 18.11 (*a*) Feedforward and (*b*) feedback architectures.

drive the control actuators. The control actuators drive the system and generate responses in the residual sensors through the plant transfer function, P.

The choice of whether to use feedback or feedforward architectures depends on a number of factors. In general, if reference sensors can be placed to measure a system response that is well correlated with the disturbance and residual sensors can be placed on the system such that there is sufficient delay between the reference and residual sensors (i.e., the reference sensors receive their signals before the residual sensors), then feedforward is the architecture of choice. This is especially true if the reference sensors are unaffected by the operation of the control actuators, such as would occur with a tachometer reference, for example. Feedforward is preferred (as we shall see in later sections of this chapter) because the algorithms are simple and easy to implement and the bandwidth requirements on a feedforward system are much less stringent than for feedback.

If a suitable set of reference and residual sensors satisfying the above requirements does not exist, then feedback must be used. As will be shown in later sections of this chapter, feedback control systems can present special problems. In particular, stability and out-of-band amplification requirements* can force the bandwidth of the system to be up to 100 times the control bandwidth.

As with actuators there is a wide variety of sensors used in active noise and vibration control systems. For systems designed to control only tones, a tachometer is often the reference sensor of choice, because in most cases the operation of the control system does not affect the tachometer, making the implementation of a feedforward system much easier. Other sensors that are commonly used include, accelerometers, force gauges, strain gauges and piezoelectric patches, proximity sensors, linear variable differential transformers (LVDTs), microphones, hydrophones, and pressure sensors. The requirements on the sensors are the same as for any high-quality instrumentation system: sufficient sensitivity to measure the phenomena of interest, low noise, stable operation, durability, and so on.

Performance Expectations

Active noise and vibration control systems can be powerful tools in the hands of a knowledgeable noise control engineer. In many cases, significant reductions in noise and vibration can be achieved with active systems that cannot be achieved using passive treatments with the same space and weight constraints. This is especially true at low frequencies. Despite the power of the technology, there are realistic limits on what reductions can be achieved. Figure 18.12 shows the performance achieved by the prototype active system described in Section 18.7 under Active Machinery Isolation. We present it here because it reflects the performance that is normally achievable in a properly designed active system. The figure shows the reduction in force transmitted by an active vibration isolation

*Outside of the frequency band where control is desired, the active system can amplify the disturbance unless great care is exercised in implementing the system filters to frequencies well beyond the frequency band for control.

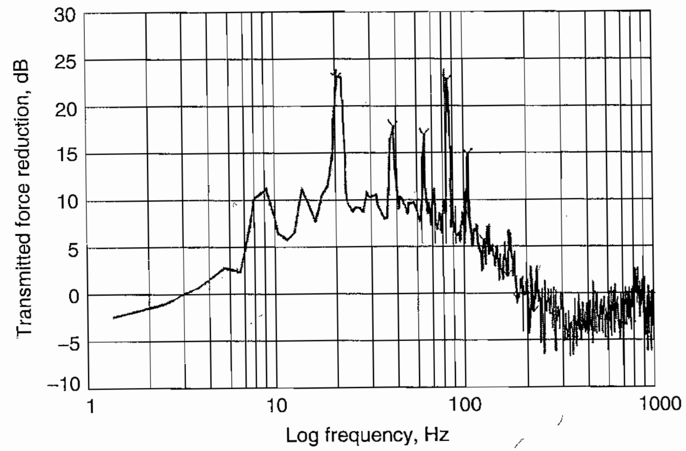

FIGURE 18.12 Typical performance of an active vibration control system.

mount. The system was a single-input, single-output (SISO) feedback control system designed for suppression of both broadband and narrow-band vibration. The narrow peaks in the figure with amplitudes of 15 to nearly 25 dB reflect the reduction in tonal components of the force transmitted by the mount. These values are what one would typically expect in tonal suppression from an active system. In addition to the peaks there is broad hill beneath them that in the frequency range of 10–100 Hz has an amplitude of from 6 to 10 dB. This too is typical of what one might expect from a system designed to provide control of broadband noise and vibration. Of course, there are many factors that go into determining the performance of an ANVC system, and there is no substitute for careful analytical/empirical modeling helping to direct the design process, but these values represent reasonable expectations for system performance when the technology is properly implemented.

Examples of Prototype ANVC Systems

There have been a vast number of ANVC prototype systems implemented over the past 50 years or so. Here we present a few examples of those systems to give the reader a sense of how the technology has been applied, where it has been most successful, and where additional technology and research is required. For a more detailed look at the early development of the technology the reader is referred to a number of review articles.[14–17]

The first patents proposing the use of a sound to cancel unwanted sound in the early 1930s proposed the type of system[18,19] illustrated in Fig. 18.13. These early proposals focused on the control of sound in a duct and involved the use of a reference microphone to sense the unwanted sound. In Fig. 18.13 the signal from that microphone was then acted on by appropriate electronics to synthesize

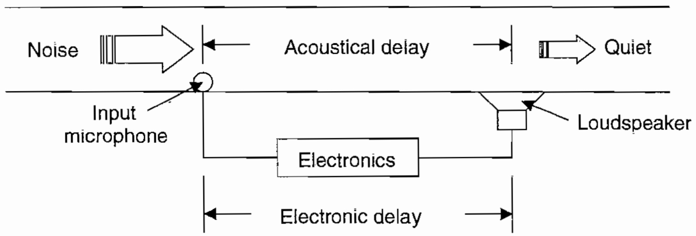

FIGURE 18.13 Schematic diagram of the active noise control concept for controlling sound in ducts.

a signal to drive a loudspeaker downstream from the microphone. The sound wave from the loudspeaker then cancels the unwanted sound. The use of active systems to control sound in ducts has received a great deal of attention over the years. Swinbanks[20] provided an extensive theoretical foundation in the early 1970s focusing on various arrangements of control sources at two different axial positions in a duct to minimize propagation of canceling sound back to the reference microphone. Other researchers[21,22] examined more complex control source configurations to deal with the control-source-to-reference coupling. Eventually laboratory experiments were carried out using analog electronics to confirm the predictions of the analysts[23] and to demonstrate both narrow-band and broadband control.[24] Eriksson's work in this area is particularly noteworthy.[25–28] His theoretical and experimental work eventually resulted in a commercially available active duct silencer utilizing digital electronics that was sold through Digisonix,* a subsidiary of Nelson Industries. The system configuration was very similar to that shown in Fig. 18.13.

Another early concept (1950s) for active noise control is illustrated in Fig. 18.14. This idea was developed by Olsen and May[29] while at the Radio

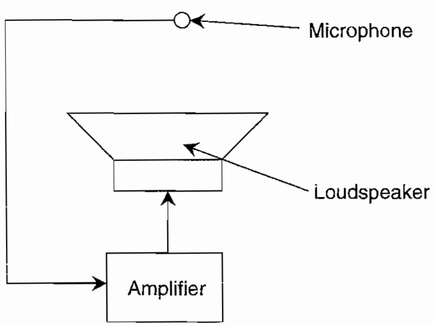

FIGURE 18.14 Olsen and May's "electronic sound absorber".

*Nelson Industries is currently owned by the Cummins Engine Company and Digisonix is no longer in business.

Corporation of America. The concept utilizes a microphone placed close to a loudspeaker in which the microphone detects the unwanted sound and the speaker generates a canceling signal that creates a zone of silence around the microphone. They assembled and successfully demonstrated their concept using only analog components. This basic concept has been extended and utilized in a number of applications, including control of automobile[30–34] and aircraft[35–38] interior noise and noise-reducing headsets.[39–41] The example in Section 18.7 under Active Control of Airborne Noise in a High-Speed Patrol Craft describes a system that uses this concept to reduce the noise in the berthing spaces of a high-speed patrol craft.

Figure 18.15 shows a schematic diagram of a notional active automotive interior noise control system. As shown, the system is designed to control noise generated by the propagation of vibration from the vehicle's suspension to the passenger compartment where it is radiated as sound to the vehicle interior (road noise) and engine noise. Feedforward active control architectures have usually been used to attack this problem. A number of reference accelerometers are placed on vehicle suspension components and in the engine compartment. Reference microphones might also be used. The reference signals are fed to a controller, which generates signals to drive the control loudspeakers in the passenger compartment. Residual microphones are located in the passenger compartment near the ears of the occupants so as to generate a zone of silence around the head of each occupant. Because of the nature of the interior noise, the control system must reduce both narrow-band and broadband noise. While the system concept is fairly simple, its successful implementation has proven difficult. First the number of residual sensors needed to sample all of the suspension sources can be quite large[42] (10–20). This can lead to significant costs due to the high channel count. In addition, the reductions achievable seem to be limited to about 6 dBA and the zone of silence around the control microphones is usefully large only at low

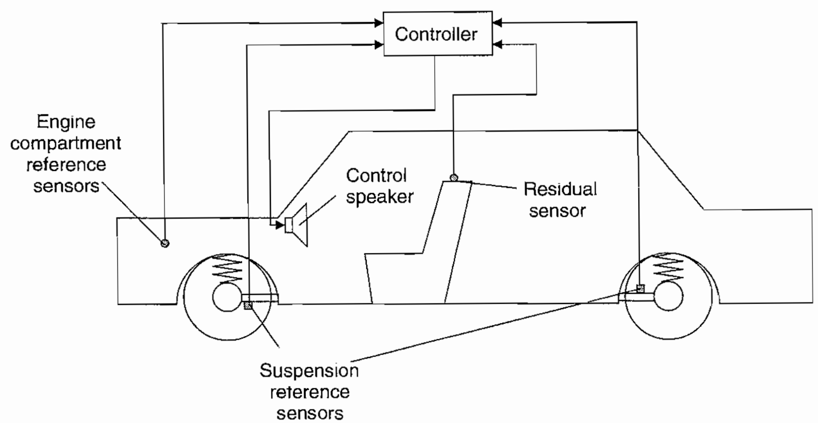

FIGURE 18.15 Schematic of an active automobile interior noise suppression system.

frequency (up to a few hundred hertz), limiting the useful frequency range of the system. Consequently, active systems providing broadband automobile interior noise control are not presently commercially available.

Systems for the control of aircraft interior noise have generally focused on tonal noise, that is, the propeller blade passage frequency and its harmonics. A schematic of a typical system is shown in Fig. 18.16. Experimental systems like that shown have generally provided about 10 dB of tonal interior noise control at the blade passage frequency and somewhat less at the higher harmonics. The system in the figure is similar to the automotive interior noise control system except that the reference is now a tachometer from the aircraft engine. The schematic shows control speakers as the actuators, but piezoelectric patches on the fuselage panels and inertial shakers on the ribs and stringers have also been tried, effectively turning the fuselage into a loudspeaker. Systems suitable for small propeller-driven business aircraft are presently commercially available from Ultra Electronics.

A number of manufacturers now provide reasonably priced active noise cancellation headsets. Figure 18.17 shows one arrangement. The figure shows the shell of one side of the headset in which there is a small speaker and colocated microphone. The signal that the wearer wishes to hear drives the speaker, the output of which is picked up by the microphone. The microphone also picks up any noise that passes through the shell. The microphone signal is then fed back, as shown in the block diagram in the figure. By increasing the gain of the filter,

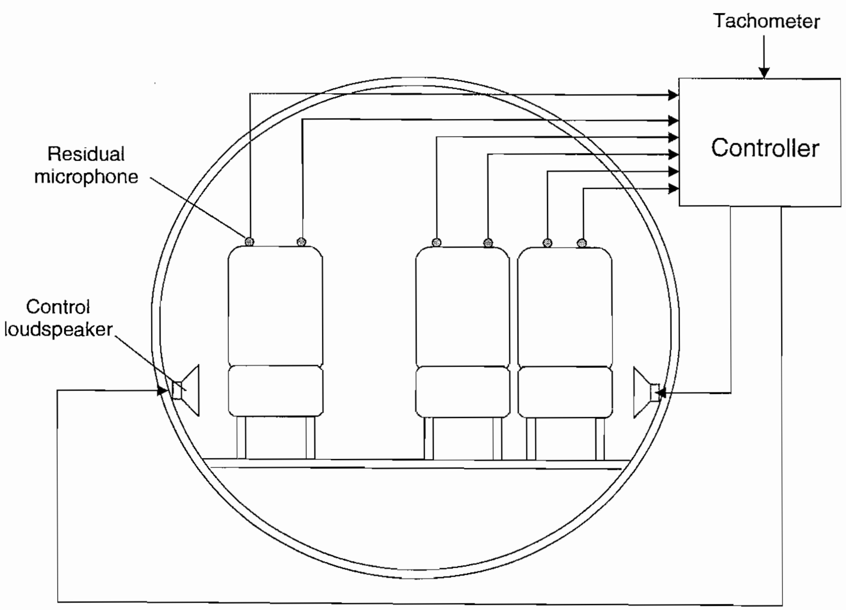

FIGURE 18.16 Schematic of an active aircraft interior noise control system.

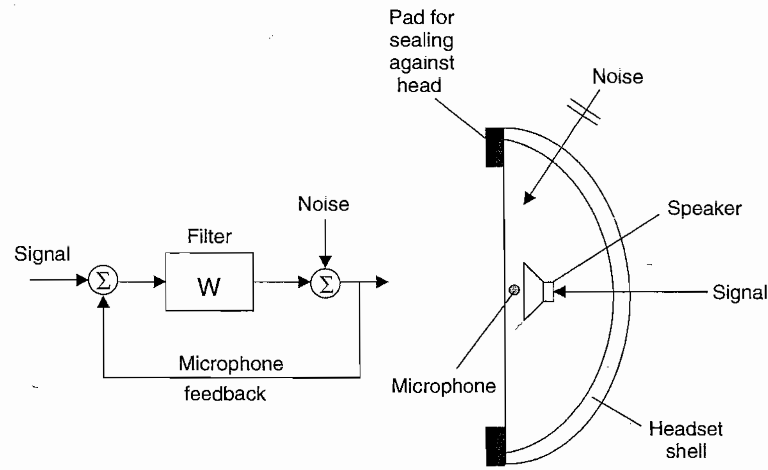

FIGURE 18.17 Typical noise cancellation headset.

W, in the block diagram* (typically an analog filter in commercial products rather than a digital one), the signal will pass through unchanged and the noise will be attenuated. Of course, this gain cannot be increased without limit, since too high a gain can result in instability and ringing. These devices produce noticeable improvement (10–15 dB) in the passive performance of hearing protection headsets above 100 Hz. The improvement gradually decreases with increasing frequency until at ~1 kHz most of the improvement has gone away. In very loud environments headsets can be limited in performance by the sound level the small speaker can generate within the shell.

Another area that has received considerable attention in recent years is the active control of tonal noise from turbofan engines.[43–50] Tonal noise from these engines is caused primarily by the interaction between the fan blade wakes and the stator vanes. The control systems for the most part have been feedforward systems utilizing a tachometer for a reference sensor. Since the fan and stator vanes are located in the bypass duct, the systems need to take into account the complex physics of the propagation of sound in ducts. The physics dictates that the fan–stator interaction noise will propagate down the duct as, so-called, spinning modes. These modes have a sinusoidal pressure variation in the circumferential directions that rotates as the mode propagates, hence the term *spinning mode*. Only a selected number of these modes are excited by the fan–stator interaction and a still smaller number propagate. Consequently, the control actuators must also generate spinning modes in order to cancel the fan–stator interaction noise without generating additional propagating modes in the duct. Figure 18.18 shows a schematic drawing of one such active noise control system. This particular

*In the block diagram *W* also contains the frequency response between the speaker input and the microphone output.

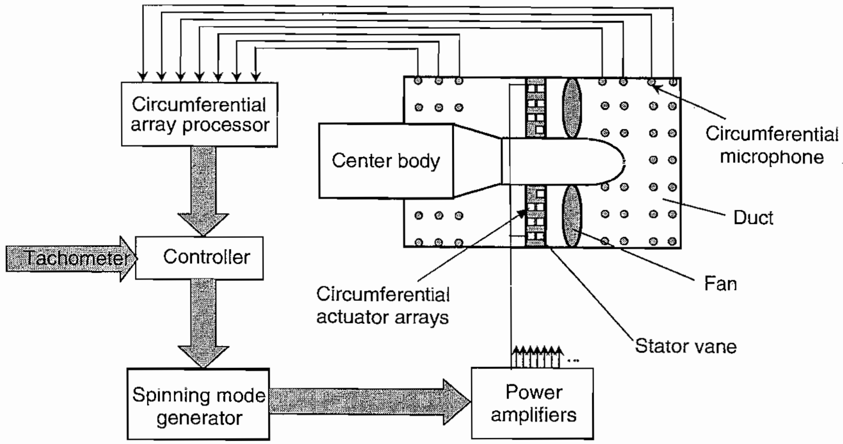

FIGURE 18.18 Schematic of the active noise control system for controlling fan-stator interaction noise.

system utilizes actuators in the stator vanes. Actuators have also been installed in the walls of the duct. The system must be designed with a sufficient number of actuators to ensure that the propagating modes to be controlled can be generated by the array without aliasing into other modes that will propagate.

Each array is driven by a single signal passed through analog or digital electronics (spinning-mode generator) that properly phase shifts the actuators in each array to produce a spinning mode of the desired circumferential order. Each actuator in the array must be the same. If there are large variations in amplitude and phase between actuators when driven by the same signal, then modes other than the desired mode will be generated, resulting in noise generation rather than suppression if the spurious modes propagate. The control sensors are typically wall-mounted microphones arranged in circumferential arrays and each array is steered (circumferential array processor) to accept a spinning mode of the circumferential mode order that is to be controlled. In a laboratory setting, systems of this type are capable of reducing the tonal noise from fan–stator interaction by 10–20 dB. In real high bypass turbofan engines, however, especially in modern-day large engines, none of the actuators tested to date have sufficient control authority to be able to overcome the disturbance. In addition, at the present time, while the controller channel count can be fairly low, typically equal to the number of modes to be controlled, the number of actuators and sensors needed to field a system can be quite large. It is very likely, however, that if active noise control is included early in the design process of an engine along with passive noise control treatments, the number of actuators and sensors needed could be substantially reduced. If more powerful actuation systems become available, commercially available active systems for the control of fan–stator interaction noise in turbofan engines may become a reality.

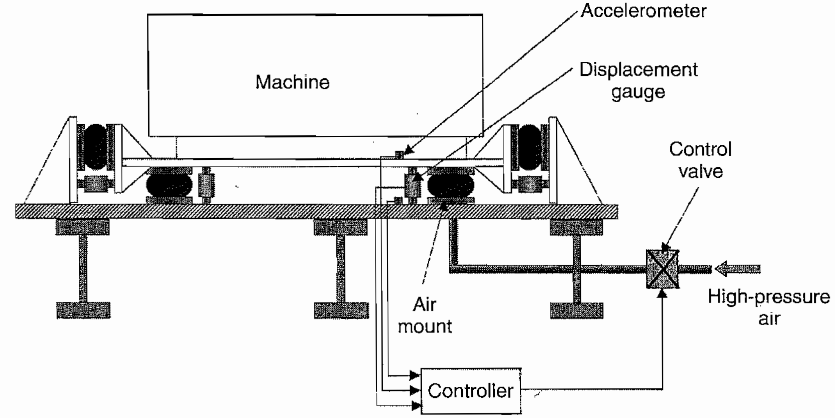

FIGURE 18.19 Notional activated vibration isolation mount.

In the 1950s Olsen[51] was the first to suggest extending active control to the control of machinery vibration. Since that time numerous studies have been carried out into the activation of vibration isolation mounts.[52–55] Figure 18.19 shows a schematic drawing of a notional active vibration isolation system. In this case, we envision a set of mounts supporting a vibrating machine on the deck of a ship. In the figure only one mount is shown activated. In actuality all (possibly 10 or 12 mounts) would be. It is desired to reduce the vibration excitation of the deck while maintaining the position of the machine, which is in a confined space, so that it does not strike any of the ship structure surrounding it during ship maneuvers. These two requirements are conflicting. Good vibration isolation performance requires a mount that is as compliant as possible while good position keeping requires a stiff mount. Two approaches can be taken to the activation of the mount. We can employ a mount that is stiff enough to ensure good position keeping and use an active system to increase the compliance of the mount at higher frequency where good vibration isolation performance is desired. We will refer to this type of system as the active isolation system. Another approach is to use a very compliant mount that provides the desired vibration isolation performance at high frequency and use the active system to provide position keeping at low frequency. We will refer to this system as the position-keeping system. For either concept to work the frequencies associated with ship maneuvers should be much lower than the frequencies where vibration isolation performance is desired. The notional system that we have shown in Fig. 18.19 incorporates air mounts. Since air mounts tend to be very compliant, they would be most appropriate for the position-keeping approach. The system would require 10–12 mounts to conveniently control all six rigid-body degrees of freedom. Each mount incorporates sensors for measuring relative displacement between the machine and the deck and for measuring the acceleration on the deck and the machine. These sensors would be used in the controller to generate a frequency-dependent linear combination of relative displacement, velocity, and acceleration at each mount. Those inputs would then be used by the controller in a feedback architecture to drive the control valves, which can inject high-pressure air into or vent it from the air mounts. Since the frequencies associated with ship maneuvers tend to be lie below 1 Hz, the machine would most likely act as a rigid body, significantly simplifying the system transfer functions and making the controller simpler as well. This approach does have some disadvantages. For example, it would require about 10–12 air mounts to conveniently implement it. In addition, all mounts must be coupled in the controller, making it a multiple-input, multiple-output (MIMO) system. On the other hand, there would only need to be six independent channels in the controller to control the six rigid-body degrees of freedom of the machine. Multi-degree-of-freedom systems of this type and of even greater complexity have been implemented in research programs, but none are commercially available. However, there remains considerable interest in active isolation systems and position-keeping systems for both military and civilian applications.

The above examples of types of ANVC systems represent only a taste of the many noise cancellation problems that have been addressed using the technology. In Section 18.7 we present three detailed examples of ANVC systems to provide the reader with a more in-depth look at the development, implementation, and performance of real prototype systems.

18.3 DIGITAL FILTERS

Advantages of Digital Filters

Active noise and vibration controllers are basically filters. The inputs are sensor signals and the outputs are the drive signals to the actuator electronics, which impart desired control forces to the physical system being controlled. For some ANVC applications, implementing these filters using analog electronics is an efficient and cost-effective approach. In particular, analog controllers should be considered for applications where the required magnitude and phase responses of the filters are a relatively simple function of frequency and when these filters are not required to change over time. An example of an application where analog controllers have been used effectively is active headsets. However, when the required magnitude and phase responses vary significantly as a function of frequency and the characteristics of these filters are required to change over time to maintain a desired level of performance, digital controllers are often the best choice. The filters implemented within these digital controllers are referred to as digital filters.

Digital controllers offer many advantages over analog controllers. As discussed by Nelson and Elliott,[56] these advantages include the following:

Flexibility. Digital controllers implement digital filters by running programs written to operate on digital signal processor (DSP) chips. The codes to implement these filters can be written to allow for these filters to change their characteristics over time (i.e., adapt). Further, these codes can be written to accommodate increases in the number of input and output channels. Additionally, the complexity of the digital filters can be increased or decreased by modifying the codes running on the DSPs.

Accuracy. Many DSPs support floating-point computations running in either single- or double-precision arithmetic. Although greater accuracy in the calculations can be achieved using double precision, this increased precision is seldom required and comes at the cost of increased memory requirements. The accuracy of single-precision controllers has been demonstrated for a wide variety of ANVC applications, including those with large numbers of input and output signals and digital filters requiring very complex magnitude and phase responses as a function of frequency.

Adaptability. Applications of ANVC often require the controller to alter filtering characteristics over time to maintain a desired level of performance. Controllers that satisfy this requirement are said to be "adaptive." An example of an adaptive controller is ANVC applied to systems whose dynamics (as a function of frequency) change over time. Digital controllers implemented using DSPs can be designed to adapt to these changes.

Cost. The cost of DSPs has continued to drop over the past 15 years. At the same time, the computational and memory capabilities of these chips have continued to increase. Currently available DSPs deliver up to 1×10^9 floating-point operations per second (1 gigaflop, abbreviated Gflop) and are equipped with up to 256 Mbytes of local, fast-access memory. In addition, the architecture of these chips has expanded to allow communications between DSPs to support efficient implementation of digital controllers employing multiple DSPs for large-scale applications. Both fixed- and floating-point DSPs are available. Fixed-point processors are cheaper than floating-point processors but are generally more difficult to program, resulting in increased software development costs.

In the following section the concepts of digital sampling and filtering are discussed. Subsequent sections use these concepts to summarize optimal digital and adaptive digital filter designs.

Description of Digital Filters

There are many good texts covering the concepts of digital sequences, sampling, and filtering.[56–59] For purposes here, we summarize these concepts following the developments of Nelson and Elliott[56] and Oppenheim and Schafer.[57] The interested reader should look to these references for more detailed discussions.

The input to a digital controller is typically an analog signal from a sensor that passes through an analog-to-digital (A/D) converter. The purpose of the A/D converter is to sample the input signal at regular time intervals (Δt) to produce a sequence of numbers corresponding to the amplitude of the input signal at each sample time. A schematic of the operation of an A/D converter is shown in

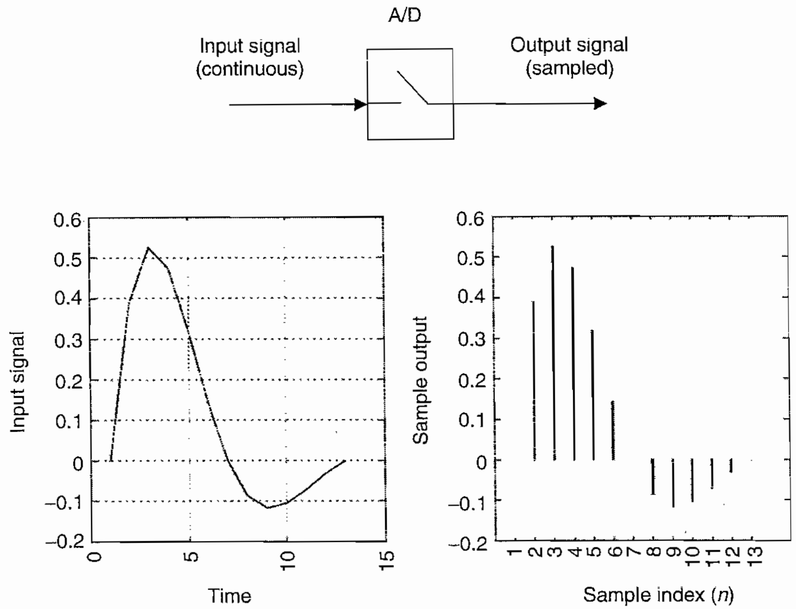

FIGURE 18.20 Digital sampling of an analog signal.

Fig. 18.20. The output of the A/D converter can be related to the continuous-time input signal through the following relationship:

$$f(n) = \sum_{i=-\infty}^{\infty} f(i)\delta(n-i) \tag{18.1}$$

where $\delta(n-i)$ is called the Kronecker delta function, or unit-sample sequence, and is defined as

$$\delta(n-i) = \begin{cases} 1 & n = i \\ 0 & n \neq i \end{cases} \tag{18.2}$$

The sampled signal in Eq. (18.1) is only defined for integer values of n. That is, $f(n)$ is only defined for $n = 0, \pm 1, \pm 2, \ldots$ An example of a continuous-time signal and the corresponding sampled signal $f(n)$ is shown in the lower portion of Fig. 18.20. The sample index n can be related to a discrete time by $t_n = n\ \Delta t$, where Δt is the fixed time interval between samples.

A digital system (e.g., digital filter) operates on a sequence of numbers to produce an output sequence. This is shown schematically in Fig. 18.21. The *impulse response* $w(n)$ of the digital system W is defined as the output corresponding to a unit-sample input [i.e., $\delta(n-i)$, $i = 0$]:

$$w(n) = W\{\delta(n)\} \tag{18.3}$$

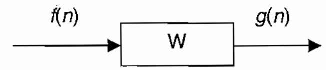

FIGURE 18.21 Digital filter operating on input $f(n)$ to produce an output $g(n)$.

where $w(i) = 0$ for $i < 0$ ensures that the output of the filter does not occur before the input sequence is applied. Filters that obey this constraint are referred to as *causal* filters.

The filter operation implied by the block diagram of Fig. 18.21 can be expressed mathematically as

$$g(n) = \sum_{i=0}^{I-1} w(i) f(n-i) \tag{18.4}$$

where the impulse response of the digital filter $w(i)$ in Eq. (18.4) is assumed to be a sequence of numbers of length I. It is common to refer to these numbers as the coefficients, taps, or weights of the digital filter. For example, $w(i)$ is called the ith coefficient of the digital filter w. Using this nomenclature, Eq. (18.4) states that the output of the digital filter w at time step n is equal to the summation over i of the ith coefficient of w times the input at time step $n - i$. In vector notation, this operation is equivalent to the inner product of a row vector and a column vector such that

$$g(n) = \mathbf{f}^{\mathrm{T}}(n)\mathbf{w} \tag{18.5}$$

where $(\cdot)^{\mathrm{T}}$ represents the vector transpose operator and $\mathbf{w}$ and $\mathbf{f}(n)$ are defined as

$$\begin{aligned} \mathbf{w}^{\mathrm{T}} &= [w(0), w(1), w(2), \ldots, w(I-1)] \\ \mathbf{f}^{\mathrm{T}}(n) &= [f(n), f(n-1), \ldots, f(n-I+1)] \end{aligned} \tag{18.6}$$

An example of this filtering process is shown schematically in Figs. 18.22 and 18.23. Figure 18.22 shows the input time sequence $f(n)$ and the impulse response of the digital filter $w(i)$. Figure 18.23 depicts the filtering of Eq. (18.4) at three increments in time during the filtering operation. The upper three charts plot the input sequence $f(n-i)$ for $n = 0, 4, 9$. The middle three charts plot the impulse response of the digital filter w. The lower three charts plot the output $g(n)$ at time step $n = 0, 4, 9$. As shown in these figures, the output of the filter is obtained by computing the summation of the time-reversed input signal as it slides past the impulse response of the filter.

The digital filter of Eq. (18.4) depends only on current and past values of the input sequence and is limited in length to I coefficients. These types of digital filters are referred to as finite impulse response (FIR) filters because their impulse response is zero after a finite number of taps or coefficients. These filters are also known as "tapped delay line," "moving-average" (MA), "nonrecursive," "all zero," or "transversal" filters.

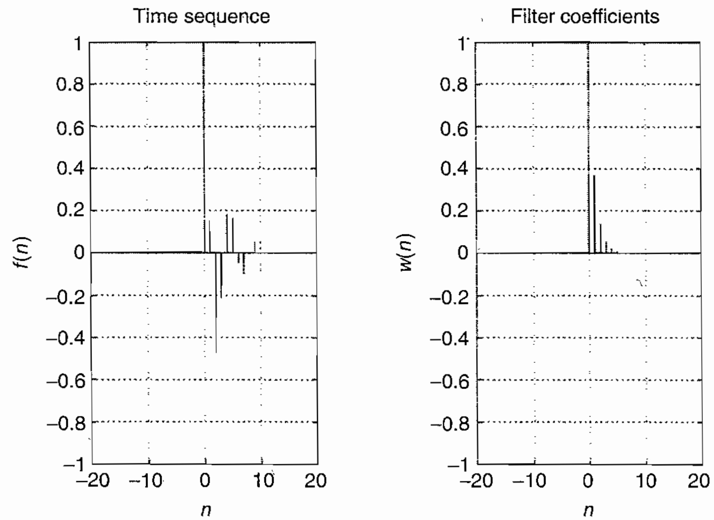

FIGURE 18.22 Example input sequence and impulse response.

A more general class of filters is defined as

$$g(n) = \sum_{i=0}^{I-1} a_i f(n-i) + \sum_{k=1}^{K} b_k g(n-k) \tag{18.7}$$

In addition to depending on current and past values of the inputs, the current output of the digital filter represented by Eq. (18.7) depends on past values of the output. Digital filters of this type are referred to as infinite impulse response (IIR) filters because, in general, the impulse response of these filters never decays to zero. These filters are also known as "recursive," "pole-zero," or "autoregressive moving average" (ARMA) filters. The general form of Eq. (18.7) reduces to a FIR filter when $b_k = 0$ for all k.

Implementations of FIR and IIR filters can be represented schematically if we define a delay operator z^{-k} such that

$$f(n-k) = z^{-k}\{f(n)\} \tag{18.8}$$

Using the property of the delay operator in Eq. (18.8) and the general filter representation in Eq. (18.7), a FIR filter can be implemented as shown in Fig. 18.24. A corresponding implementation for an IIR filter is shown in Fig. 18.25. A desired filter response can be approximated digitally using either the FIR or IIR filter structures discussed above. The choice between these two involves certain trade-offs, including the following:

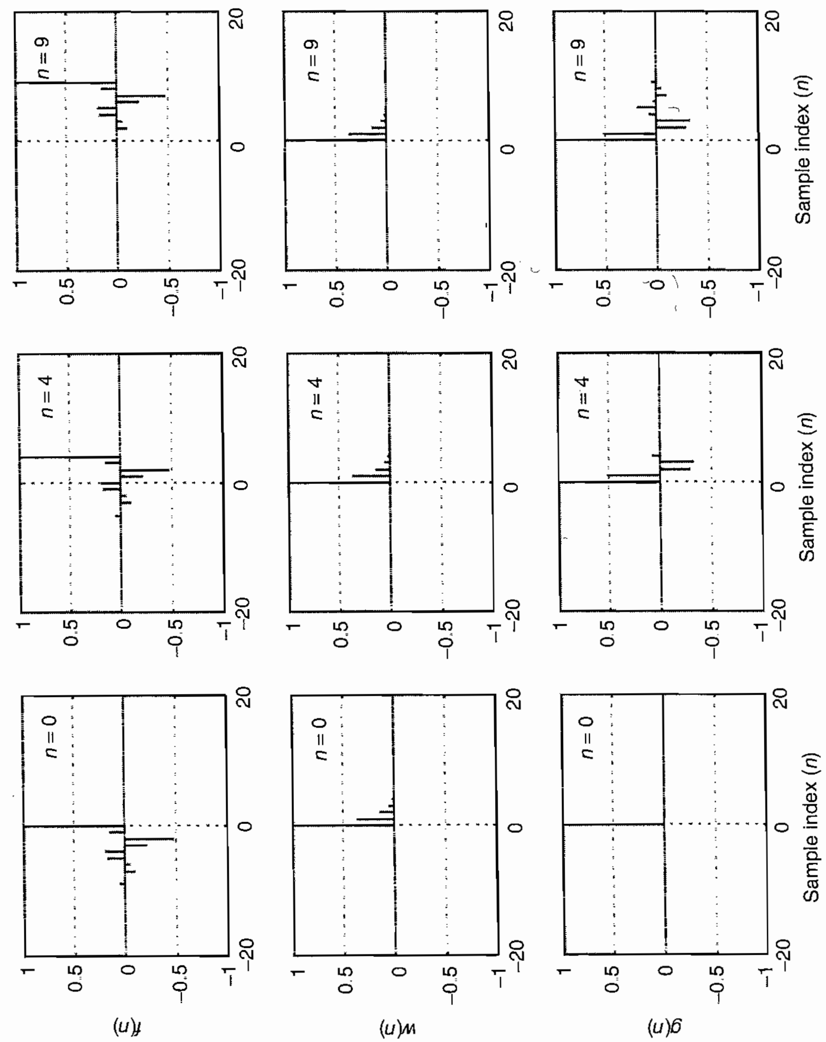

FIGURE 18.23 Representation of digital filtering as a discrete convolution.

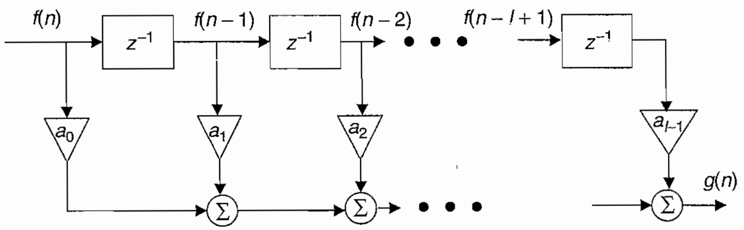

FIGURE 18.24 Implementation of a FIR filter using current and delayed values of the input.

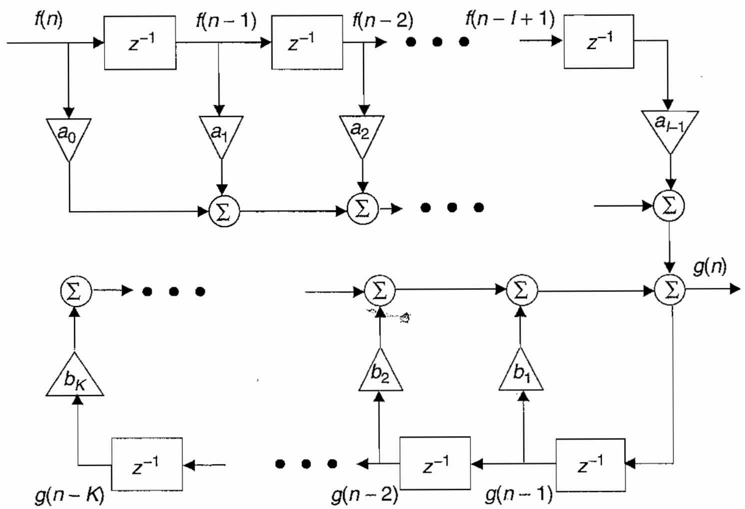

FIGURE 18.25 Implementation of an IIR filter using current input and delayed values of the inputs and outputs.

- FIR filters are guaranteed to be stable provided the coefficients are finite: Bounded inputs produce bounded outputs.
- IIR filters can be unstable even when all coefficients are finite: Bounded inputs can produce unbounded outputs.
- IIR filters may require fewer coefficients than FIR filters to approximate the frequency response necessary to provide active noise and vibration control: Typical transfer functions associated with structural acoustics include both poles and zeros, as do IIR filters, whereas FIR filters have only zeros.
- Design procedures to solve for FIR filter coefficients are generally numerically better behaved than those to solve for IIR filter coefficients.

Although there are advantages and disadvantages to both approaches, the vast majority of ANVC applications rely on the numerically stable design procedures and guaranteed stability associated with FIR filters and consequently implement the digital filters within ANVC controllers as FIR filters or composites of FIR filters.

Optimal Digital Filter Design

Having described the concept of digital filtering in the previous section, we focus in this section on design procedures to solve for the optimal coefficients of a digital filter for a particular class of problems. The class of problems considered is illustrated in Fig. 18.26. This problem is referred to as the electrical noise cancellation problem and is discussed in detail in references[56,58, and 59]. This is an important class of problems because it introduces the concept of minimizing a mean-square error metric and because it has strong parallels to problems encountered in ANVC applications; the main difference is that ANVC applications will have a nonunity transfer function relating the output of the control filter to the error signal response.

As shown in Fig. 18.26, the input signal $f(n)$, which is also referred to as the reference signal, is filtered by the FIR filter **w** to produce an output sequence $y(n)$. The desired signal, $\hat{d}(n)$, is contaminated by noise correlated with the input signal but presumably uncorrelated with the desired signal. The resulting signal plus noise is shown in the figure as $d(n)$. The correlation of the noise and the input signal is indicated by the unknown physical impulse response function h_i. The objective for this problem is to solve for the coefficients of the FIR filter that will take the input sequence $f(n)$ and generate the output sequence $y(n)$ that will remove the unwanted noise from the signal $d(n)$. In other words, we seek to design the optimal FIR filter to remove the part of $d(n)$ that is correlated with the input signal $f(n)$. If successful, the error signal $e(n)$ will be uncorrelated with the input signal when the filter is in place.

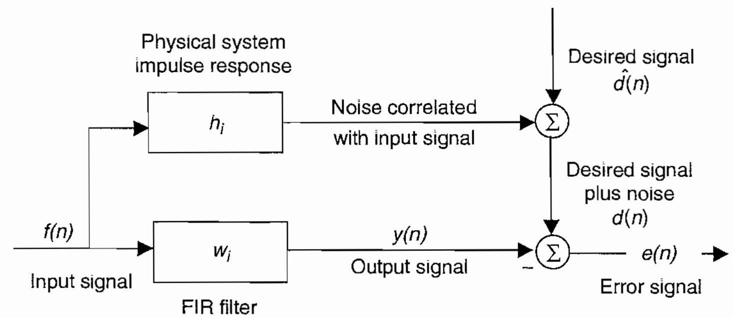

FIGURE 18.26 Electrical noise cancellation problem.

Following the developments in references 56 and 58 the error signal can be expressed in terms of the desired signal plus noise, the input signal, and the FIR filter coefficients:

$$\begin{aligned} e(n) &= d(n) - \sum_{i=0}^{I} w(i) f(n-i) \\ &= d(n) - \mathbf{w}^{\mathrm{T}}\mathbf{f}(n) = d(n) - \mathbf{f}^{\mathrm{T}}(n)\mathbf{w} \end{aligned} \tag{18.9}$$

where the lower equation has been used to express this relationship using vector inner products and $f(n)$ is defined in Eq. (18.6).

An expression for the mean-square error can be obtained by expanding terms in Eq. (18.9) and taking the expected value:

$$E\{e^2(n)\} = E\{d^2(n)\} - 2\mathbf{w}^{\mathrm{T}} E\{\mathbf{f}(n)d(n)\} + \mathbf{w}^{\mathrm{T}} E\{\mathbf{f}(n)\mathbf{f}^{\mathrm{T}}(n)\}\mathbf{w} \tag{18.10}$$

Equation (18.10) is a key result because it reveals that the mean-square error is a quadratic function of the weights of the FIR filter. The quadratic function will have a *global minimum* provided that the matrix $E\{\mathbf{f}(n)\mathbf{f}^{\mathrm{T}}(n)\}$ in the third term is *positive definite*,[56,58–60] which means that all of its eigenvalues are greater than zero. Assuming this requirement is met, if one were to plot the mean-square error as a function of any two of the coefficients of the FIR filters, the "error surface" would be a bowl, as shown in Fig. 18.27. As a consequence, the FIR filter coefficients that correspond to the minimum mean-square error can be determined by differentiating Eq. (18.10) with respect to each coefficient of the FIR filter and setting the resulting set of equations equal to zero.

This process of differentiating and equating the results to zero will produce a set of linear equations in terms of the unknown coefficients of the FIR filter. This matrix equation can be expressed as

$$[\mathbf{A}]\mathbf{w} = \mathbf{b} \tag{18.11}$$

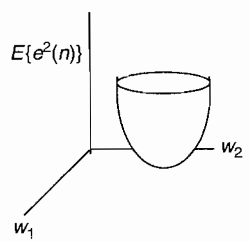

FIGURE 18.27 Error surface for a quadratic function in terms of coefficients w_1 and w_2.

where [**A**] is the *input correlation matrix* defined as

$$[\mathbf{A}] = \begin{bmatrix} R_{ff}(0) & R_{ff}(1) & \cdots & R_{ff}(I-1) \\ R_{ff}(1) & R_{ff}(0) & & \\ \vdots & & \ddots & \vdots \\ R_{ff}(I-1) & & & R_{ff}(0) \end{bmatrix} \tag{18.12}$$

where

$$R_{ff}(m) = E\{f(n)f(n-m)\} = E\{f(n)f(n+m)\} \tag{18.13}$$

The vector **b** in Eq. (18.11) corresponds to the lag values of the cross correlation between the reference sequence and the desired sequence given by

$$\mathbf{b} = [\, R_{fd}(0) \quad R_{fd}(1) \quad \cdots \quad R_{fd}(I-1)\,]^{\mathrm{T}} \tag{18.14}$$

where

$$R_{fd}(m) = E\{f(n)d(n+m)\} = E\{f(n-m)d(n)\} \tag{18.15}$$

With the above definitions for [**A**] and **b**, the coefficients of the optimal FIR filter can be expressed in terms of auto- and cross-correlation functions of the input and the desired signals. Provided that the input correlation matrix [**A**] is invertible, the optimal coefficients are given by

$$\mathbf{w}_{\mathrm{opt}} = [\mathbf{A}]^{-1}\mathbf{b} \tag{18.16}$$

where $[\mathbf{A}]^{-1}$ is the inverse of the matrix [**A**]. As discussed by Widrow and Stearns[59] and Elliott,[58] the solution of Eq. (18.16) is called the *Wiener filter*. It can be shown that using this filter will cause the cross correlation between the error signal and input signal to be zero over the length of the filter $(I-1)$. For the problem posed in Fig. 18.26, this implies that the Wiener filter will remove any portion of the signal, $d(n)$, that is correlated with the input signal $f(n)$.

The residual mean-square error can be determined by substituting Eq. (18.16) into Eq. (18.10):

$$E\{e^2(n)\}_{\min} = E\{d^2(n)\} - \mathbf{b}^{\mathrm{T}}[\mathbf{A}]^{-1}\mathbf{b} \tag{18.17}$$

Solving for $\mathbf{w}_{\mathrm{opt}}$ in Eq. (18.16), however, requires computing the inverse of the input correlation matrix [**A**], which can be computationally expensive and may be numerically ill-conditioned (i.e., singular). As a consequence, procedures have been developed to search for the minimum of Eq. (18.10) using iterative techniques. One of the most computationally efficient iterative techniques, the least mean-square (LMS) algorithm, is introduced in the next section.

Adaptive Digital Filter Design

Gradient Descent Algorithms. As discussed in the previous section, the mean-square error is a quadratic function in terms of the optimal weights of the FIR filter. As such, gradient descent algorithms are guaranteed to converge to the global minimum, provided [**A**] is positive definite and the algorithm is itself stable.

The basic concept of a gradient descent algorithm is to estimate the gradient (i.e., derivative) of the mean-square error with respect to the FIR filter coefficients and update the filter coefficients by moving in the direction of the negative of the local gradient. There are many different algorithms that can be used to adaptively determine the filter coefficients corresponding to the global minimum. These algorithms include Newton-based algorithms, steepest-descent algorithms, and the LMS algorithm, which was introduced by Widrow and Stearns.[59] These algorithms typically trade off convergence speed versus numerical stability (for IIR filters) and computational complexity. Details of these algorithms can be found in texts written by Widrow and Stearns[59] and Elliott.[58] While sometimes having performance advantages over FIR filters, IIR filters can encounter numerical stability problems during design and can converge to nonglobal minima, resulting in less than optimal performance. On the other hand, the LMS algorithm discussed in the next section (for FIR filter design) approximates the gradient term, thus significantly reducing the required number of computations while ensuring convergence to the optimal coefficient vector.

LMS Algorithm. Widrow and Stearns[59] developed an elegant algorithm that greatly simplifies the computational complexity yet still converges to the optimal coefficient vector (i.e., Wiener filter). This algorithm estimates the gradient term using the instantaneous value of the error, as opposed to performing a matrix inversion or estimating expected values as required by Newton's algorithm and steepest-descent algorithm, respectively. As a consequence, the gradient term is approximated as [see Eq. (18.10)]

$$\frac{\partial E\{e^2(n)\}}{\partial \mathbf{w}} \approx 2e(n)\frac{\partial e(n)}{\partial \mathbf{w}} \approx -2\mathbf{f}(n)e(n) \tag{18.18}$$

Using this expression for the gradient, the update equation of the filter coefficients using the LMS algorithm is given by

$$\mathbf{w}(n+1) = \mathbf{w}(n) + 2\mu\mathbf{f}(n)e(n) \tag{18.19}$$

where μ is a constant known as the adaptation coefficient, which characterizes the speed of convergence of the algorithm. This equation states that the vector of filter coefficients at time step $n+1$ can be determined from the vector of coefficients at time step n plus a correction term in the direction of the negative of the gradient of the error surface as estimated by Eq. (18.18).

Widrow and others have shown that this algorithm will converge to the optimal solution and is guaranteed to be stable provided that the value of the convergence parameter satisfies the relationship

$$0 < \mu < \frac{2}{m\overline{f^2}} \tag{18.20}$$

The denominator of the right-hand term is an approximation to the trace of the input correlation matrix, where m is the number of FIR filter coefficients and $\overline{f^2}$ is equal to the mean-square value of $f(n)$.

Another important parameter associated with the LMS algorithm is termed the *misadjustment*, which is the ratio of the excess mean-square error to the minimum mean-square error. Essentially, this is a measure of how close the algorithm will converge toward the bottom of the quadratic performance surface (see, e.g., Fig. 18.27) for a particular value of μ. It can be shown that the *misadjustment* is equal to the convergence parameter times the trace of the input correlation matrix for the LMS algorithm.[59] If we invoke the same approximation to this trace as in Eq. (18.20), we obtain an expression for the convergence parameter in terms of the misadjustment and mean-square value of the input sequence:

$$\mu_{\max} = \frac{\rho}{m\overline{f^2}} \tag{18.21}$$

where ρ is the misadjustment factor. This final expression provides a useful procedure for selecting the convergence parameter. In fact, it is often useful to specify the desired misadjustment (e.g., $\rho = 0.01$) and let the adaptation coefficient be calculated from Eq. (18.21). In this way, the resulting adaptation coefficient will be normalized by the power of the reference signal. When the adaptation coefficient is adjusted to be inversely proportional to the power of the input signal, the algorithm is referred to as the *normalized* LMS algorithm. In practice, the value of the convergence coefficient obtained in this way serves as a starting point and manual adjustment is often necessary to obtain the desired performance.

To preserve clarity, we have presented the LMS algorithm assuming a SISO error signal. However, the algorithm is easily extendable to the MIMO case. Details for the MIMO implementation can be found in Widrow and Stearns,[59] Nelson and Elliott,[16] and Elliott.[58]

Because of its computational simplicity and good convergence properties, the LMS algorithm has been used extensively in a variety of applications (e.g., in-wire cancellation, system identification) and is the basis for the filtered-x LMS algorithm that is most often used in ANVC applications. In fact, the LMS algorithm is typically used to estimate the impulse response between the filter output and the error signal (i.e., plant), which is needed for the implementation of the filtered-x LMS algorithm. Details and examples of the filtered-x LMS algorithm are covered in the next section.

18.4 FEEDFORWARD CONTROL SYSTEMS

Basic Architecture

The basic architecture of a feedforward active control system is shown in Fig. 18.28. The figure shows a disturbance d exciting a system which is to be controlled. A transfer function T relates the disturbance to the system output o.

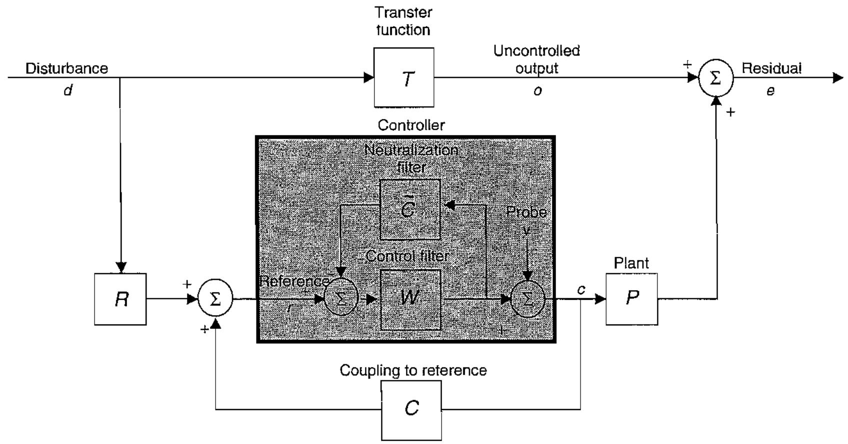

FIGURE 18.28 Basic feedforward architecture without adaptation.

A reference signal r correlated with the disturbance is used by the controller to generate a signal that drives a control actuator to excite the system and reduce the system response to the disturbance. The transfer function R is shown simply to indicate that the disturbance and the reference are correlated. The transfer function P, referred to as the plant, relates the controller output to the system output. The block diagram shows that the actuator, when driven by the controller output, is coupled not only to the system output but also to the reference through the transfer function C. The feedback to the reference signal is not desirable and the controller contains a filter $\tilde{C}$ the transfer function of which is a copy of the coupling transfer function between the control actuator and the reference sensor. The purpose of this neutralization filter is to cancel or neutralize the coupling between actuator and reference signal. In addition to $\tilde{C}$, the controller contains a second filter, W, the purpose of which is to take the reference signal and generate a signal to drive the actuator to reduce the system output o. If the neutralization filter performs properly, the coupling to the reference is removed and the block diagram simplifies to that shown in Fig. 18.29. Note that an alternate approach has been pioneered by Eriksson and his colleagues in which the designs of W and $\tilde{C}$ are combined in a slightly different architecture from that shown here. The interested reader is referred to references 25 and 61–63.

To see what the block diagram in Fig. 18.28 means physically, consider the duct problem described in Section 18.2. Figure 18.30 show a schematic of the duct with a reference microphone, controller, and control speaker. The disturbance, a sound wave of amplitude d, can be seen to the left propagating down the duct toward the control speaker. The transfer function T relates the disturbance pressure to the uncontrolled pressure, o, downstream of the speaker location in the duct. The reference microphone senses the disturbance pressure and sends a reference signal r to the controller. The control filter W operates

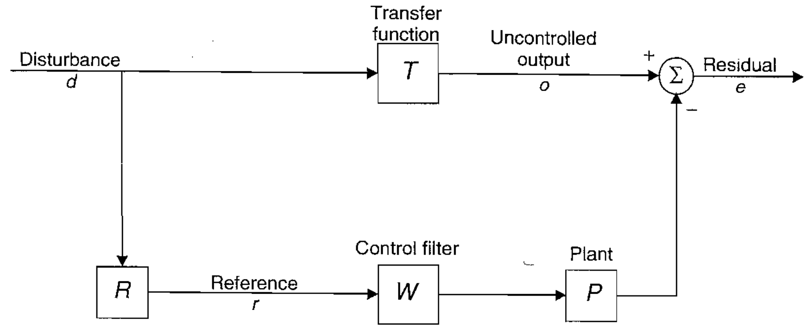

FIGURE 18.29 Simplified feedforward architecture with coupling to reference removed.

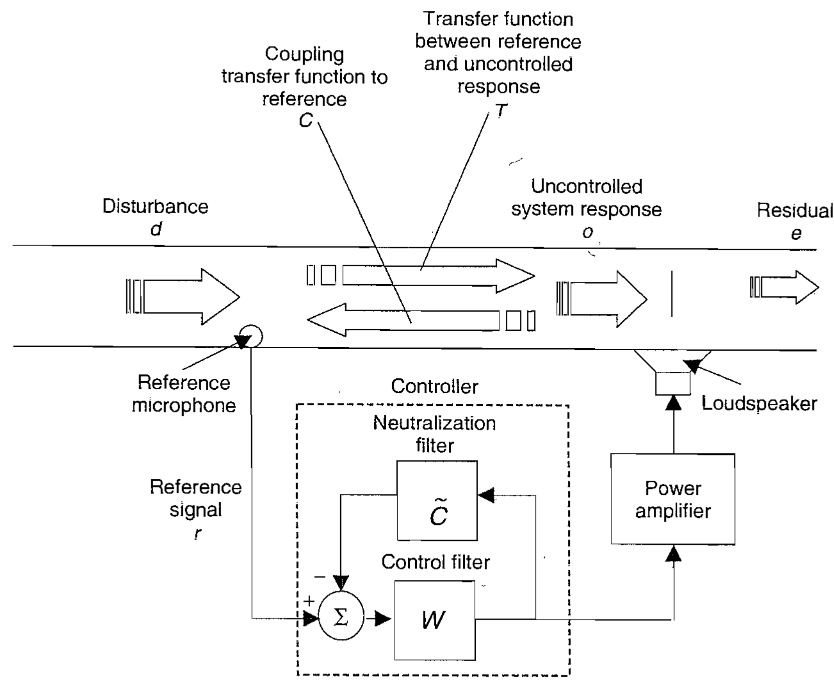

FIGURE 18.30 Feedforward architecture applied to the control of noise in a duct.

on the reference and sends the resulting signal to the power amplifier, which in turn drives the speaker. The transfer function relating the controller output signal to the pressure in the duct at the speaker is the plant transfer function P. The pressure generated by the speaker interacts with the disturbance propagating down the duct, reducing the amplitude and producing the residual sound wave of amplitude e. In an adaptive system there would be a microphone in the duct downstream of the control speaker to sense this residual. As we shall see later, this residual, or error, signal and the reference signal can then be used in the controller electronics to update, or adapt, the coefficients of the control filter. In addition to generating a sound wave that interferes with the sound propagating down the duct, the speaker also generates a sound wave which travels upstream to the reference microphone, contaminating the reference signal. The filter $\tilde{C}$ is a copy of the transfer function relating the controller output to the pressure at the reference microphone. It electronically removes the contamination from the control speaker in the reference microphone before it reaches the control filter W.

The architecture in Figs. 18.28 and 18.29 has been discussed as if there were only one reference signal and one residual. In fact, the controller need not be restricted to the SISO case. There commonly are cases with multiple references and multiple residuals. In fact, for feedforward systems the procedures for estimating the optimum control filter W for the MIMO case as well as the SISO case are well in hand. In addition the block diagrams in Figs. 18.28 and 18.29 are completely general and apply equally to SISO or MIMO systems. The only difference is that the blocks, which for SISO systems are transfer functions, for MIMO systems become transfer function matrices.

Optimal Control Filter Estimation

Tonal Disturbances. We will first consider the case of narrow-band, or tonal, disturbances. To do so, we will first modify the block diagram of Fig. 18.29 by showing a functional connection between the reference and the disturbance indicated by the transfer function B, as shown in Fig. 18.31. Mathematically this is equivalent to setting $T = 1$ and $B = R^{-1}$. A simple equation can be written for the residual e in terms of the controller transfer function in Fig. 18.31:

$$e(\omega) = d(\omega) - P(\omega)W(\omega)r(\omega) \tag{18.22}$$

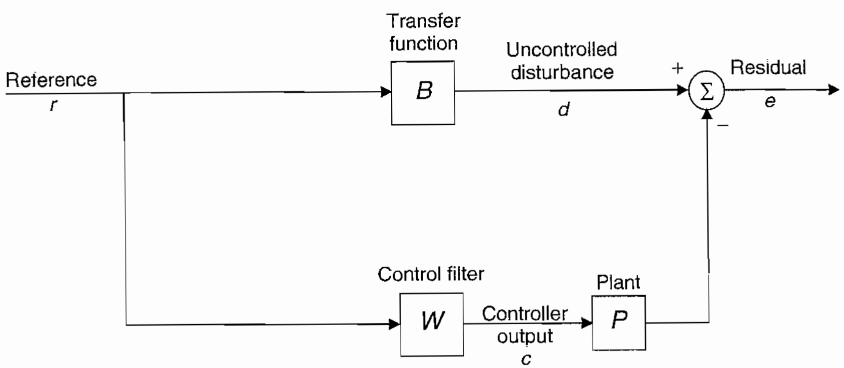

FIGURE 18.31 Simplified feedforward block diagram.

where ω is the frequency of the disturbance, the other variables are defined in Fig. 18.31, and all of the variables are scalars. We can use this equation to express the autospectrum of the residual as $S_{ee}(\omega) = E\{e(\omega)e^*(\omega)\}$, where $E\{\cdot\}$ means the expected value. Substituting Eq. (18.22) into this equation, we obtain

$$\begin{aligned} S_{ee}(\omega) &= S_{dd}(\omega) - P(\omega)W(\omega)S_{rd}(\omega) \\ &\quad - P^*(\omega)W(\omega)^*S_{dr}(\omega) + |P^2(\omega)|S_{rr}(\omega)|W(\omega)^2| \end{aligned} \tag{18.23}$$

where $(\cdot)^*$ means complex conjugate, S_{dd} is the autospectrum of the disturbance, S_{rr} is the autospectrum of the reference, $S_{dr} = E\{dr^*\}$ is the cross-spectra of the disturbance and the reference, and $S_{rd} = E\{rd^*\}$ is the complex conjugate of that cross-spectrum. If we take the derivative of Eq. (18.23) with respect to W and equate it to zero and solve for $W(\omega)$, we obtain

$$W(\omega) = \{|P^2(\omega)|S_{rr}(\omega)\}^{-1}P^*(\omega)S_{rd}(\omega) = P^{-1}(\omega)\left\{\frac{S_{rd}(\omega)}{S_{rr}(\omega)}\right\} = P^{-1}(\omega)B(\omega) \tag{18.24}$$

where we have taken advantage of the fact that $\{S_{rd}(\omega)/S_{rr}(\omega)\}$ is an estimate of the transfer function between the disturbance and the reference. In Eq. (18.24) W is the optimum control filter. It consists of the inverse of the plant times an estimate of the transfer function between the reference and the disturbance. Such a form for the control filter makes a lot of sense, because W is attempting to take the reference signal r and turn it into the disturbance d. To do so, the filter must first remove the influence of the plant transfer function, which is the purpose of the plant inverse. It then must include an estimate of the transfer function between the reference and the disturbance, which is the purpose of the term in brackets.

If we substitute Eq. (18.24) into Eq. (18.23), we can obtain an estimate of the spectrum of the residual when this control filter is used:

$$S_{ee}(\omega) = S_{dd}(\omega) - \frac{|S_{rd}(\omega)|^2}{S_{rr}(\omega)} \tag{18.25}$$

This equation shows that for perfect correlation between the reference and disturbance ($d = \gamma r$), where γ is constant, the spectrum of the residual goes to zero.

Note that this approach does not guarantee that the control filter will be causal. As discussed in Section 18.3, a causal filter is one whose impulse response is zero for $t < 0$. Causal filters can be formulated as FIR or stable IIR digital filters. Noncausal filters cannot. Consequently, a digital representation of a noncausal filter cannot be found for use in a control system. The filter is simply not realizable.

In some cases using the above control filter can result in excessive demands on the actuators, in which case it is useful to be able to limit the output of the control filter. Control effort weighting is one means of reducing the actuator effort. It can be included in the design equations for the filter by adding a term to Eq. (18.23), the equation for the residual. The term that is added is the weighted output of the controller given by

$$\alpha^2(\omega)|W(\omega)^2|S_{rr}(\omega) \tag{18.26}$$

where α^2 is a real positive scalar that might be a function of frequency. By selecting increasing values of α^2, the minimization of the residual can be adjusted. If α^2 is very small, the control filter will be designed as if there were no control effort weighting. If α^2 is large, the control effort will be reduced, and the performance of the control system will also be reduced. Including Eq. (18.26) in Eq. (18.23) results in a control filter given by

$$W(\omega) = \{[|P^2(\omega)| + \alpha^2(\omega)]S_{rr}(\omega)\}^{-1}P^*(\omega)S_{rd}(\omega) \tag{18.27}$$

and the residual is given by

$$S_{ee}(\omega) = S_{dd}(\omega) - \left\{\frac{|P^2(\omega)|}{|P^2(\omega)| + \alpha^2(\omega)}\right\}\left\{2 - \frac{|P^2(\omega)|}{|P^2(\omega)| + \alpha^2(\omega)}\right\}\frac{|S_{rd}(\omega)|^2}{S_{rr}(\omega)} \tag{18.28}$$

It is clear from this equation that as α^2 approaches zero the residual becomes the same as Eq. (18.25) with no control effort weighting. However, as α^2 becomes large, $S_{ee} \to S_{dd}$ and the control performance is reduced. Similarly the spectrum of the controller output c (see Fig. 18.31) is given by

$$S_{cc}(\omega) = |W^2(\omega)|S_{rr}(\omega) = \frac{|P^2(\omega)|}{\{|P^2(\omega)| + \alpha^2(\omega)\}^2}\frac{|S_{rd}(\omega)|^2}{S_{rr}(\omega)}$$

This equation shows that as α^2 increases the spectrum of the controller output will decrease, reducing the drive to the actuators. As a result increasing the control effort weighting will decrease the actuator drive at the cost of increasing the residual.

Broadband Disturbances. For a pure-tone disturbance, Eqs. (18.24) and (18.27) provide the proper control filter representation (amplitude and phase) at the frequency of the disturbance. For a broadband disturbance, if the broadband filter defined by these equations is noncausal, as it often is, then, a different approach that includes a constraint on causality needs to be employed to determine the optimum causal filter. We can ensure that the control filter is causal by inserting the form of a causal filter into Eq. (18.23) and carrying out the same optimization procedure. Because it results in a set of linear equations, we will use the form of an FIR digital filter given by

$$W(\omega) = \sum_{n=0}^{N-1} W_n e^{-j\omega n\Delta t} \tag{18.29}$$

where N is the number of taps in the filter, W_n is the real amplitude associated with each tap, and Δt is the sampling period (1/sampling rate). Before substituting Eq. (18.29) into (18.23) we need to modify Eq. (18.23) slightly. Since we are now concerned with a broadband disturbance, we need to integrate the residual spectrum over the frequency range where control is desired. Following the same procedure as for Eq. (18.23), we obtain for the optimum control filter the matrix equation

$$\begin{Bmatrix} W_0 \\ W_1 \\ \vdots \\ W_{N-1} \end{Bmatrix} = \begin{bmatrix} C_0 & C_{-1} & \cdots & C_{1-N} \\ C_1 & C_0 & \cdots & C_{2-N} \\ \vdots & & & \vdots \\ C_{N-1} & C_{N-2} & \cdots & C_0 \end{bmatrix}^{-1} \begin{Bmatrix} A_0 \\ A_1 \\ \vdots \\ A_{N-1} \end{Bmatrix} \tag{18.30}$$

where

$$A_p = \mathrm{Re}\left\{\sum_{k=0}^{K-1} P(k)S_{rd}(k)e^{-jpk(2\pi/K)}\right\}$$

$$C_{(p-m)} = \mathrm{Re}\left\{\sum_{k=0}^{K-1}\{|P^2(k)| + \alpha^2(k)\}\,S_{rr}(k)e^{-j(p-m)k(2\pi/K)}\right\} \tag{18.31}$$

and $p = 0, 1, \ldots, N-1$ and $m = 0, 1, \ldots, N-1$. In writing this equation, we have substituted a discrete sum for the integrals. The knowledgeable reader will recognize that Eq. (18.31) is in the form of the discrete Fourier transform (DFT), allowing for the efficient use of the fast Fourier transform algorithm in the evaluation of the vector and matrix elements in Eq. (18.30). In the equations K is the number of elements in the DFT.

Example. To illustrate these ideas, we will compute the noncausal and causal control filters for a simple example. We will use the following parameters:

$$S_{dd} = 1 \qquad S_{rr} = 1$$

$$S_{rd} = e^{-j\omega T}\left\{\frac{\omega_{\mathrm{BW}}^4}{\omega^4 + \omega_{\mathrm{BW}}^4}\right\} \tag{18.32}$$

$$P = \frac{\omega_0^2}{-\omega^2 + j\eta\omega_0\omega + \omega_0^2} \tag{18.33}$$

$$T = 0.02\ \mathrm{s} \qquad f_0 = \frac{\omega_0}{2\pi} = 25\ \mathrm{Hz}$$

$$\eta = 0.1 \qquad f_{\mathrm{BW}} = \frac{\omega_{\mathrm{BW}}}{2\pi} = 40\ \mathrm{Hz}$$

Sampling rate = 200 Hz Filter length = 100 taps

In this case the autocorrelations of the disturbance and reference are taken as unity. The cross-spectral density S_{rd} shows a delay of $T = 0.02$ s and includes a transfer function (in brackets) that decreases with increasing frequency. The plant P is a simple second-order system with a natural frequency of 25 Hz and a loss factor of 0.1. For the causal control filter estimation procedure we will use the indicated sampling rate and filter length.

Figure 18.32 compares the frequency responses of the control filters estimated using the noncausal and causal estimation procedures. The two estimation procedures give different filters but not markedly so. The difference is slightly more evident in Figs. 18.33a and 18.33b, where the impulse response of the control filter estimated using the noncausal approach and the filter tap coefficients of the filter from the causal procedure are compared. Bear in mind that if we plot the filter tap coefficients separated by the sampling period (0.005 s at 200 Hz sampling rate), we will obtain a graph corresponding to the impulse response of the filter. The two figures are similar except that in the noncausal impulse response there is a small increase near the end of the time interval. Because of the periodicity of the impulse response of the filter obtained using the DFT, the increase at the end of the time interval actually indicates that the filter is responding before $t = 0$ and consequently that the filter is noncausal. The effect in this

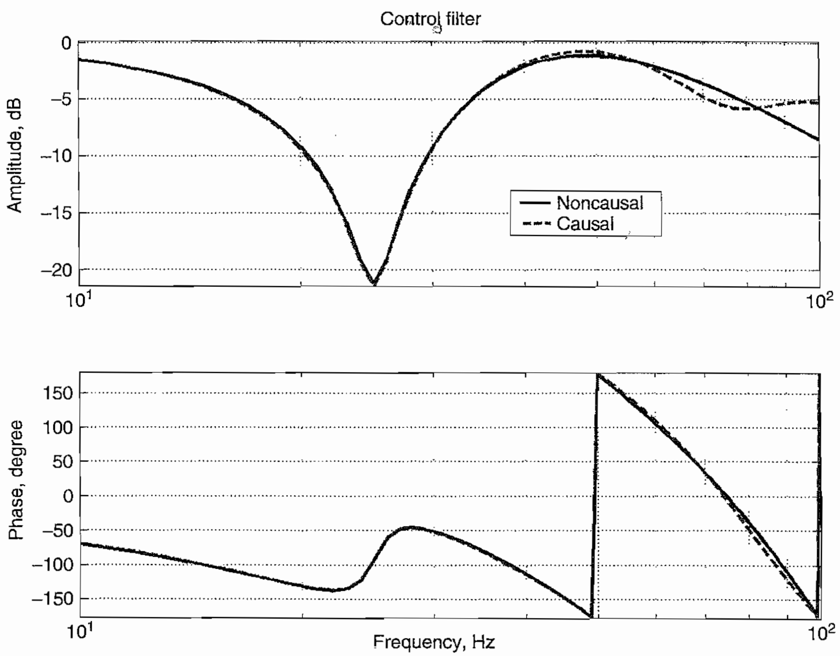

FIGURE 18.32 Control filter frequency response using the noncausal and causal estimation procedures.

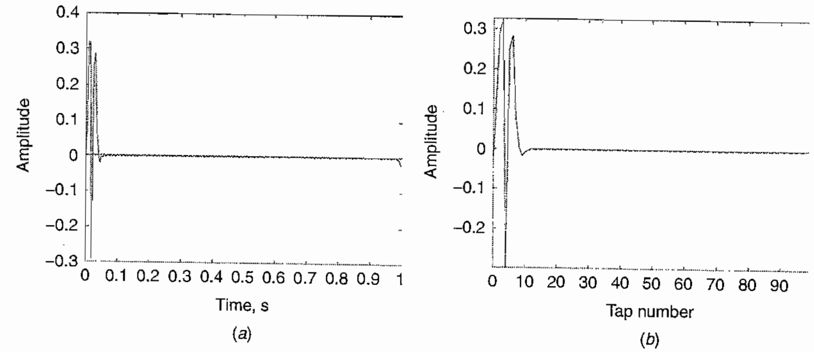

FIGURE 18.33 Comparison of the impulse response of (a) the noncausal control filter and (b) the tap coefficients of the causal filter.

instance is small; however, in later examples where we bring more realism into the calculation by including anti-aliasing filters and other practical considerations we will see much larger noncausal effects. Note that the tap coefficients of the filter estimated using the causal procedure show no such increase and the higher tap coefficients decrease to zero.

The performance of this system using the causal control filter is shown in Fig. 18.34. The figure shows the ratio of the spectrum of the controlled residual to the spectrum of the uncontrolled residual $\{S_{ee}(\omega)/S_{dd}(\omega)\}$ as a function of

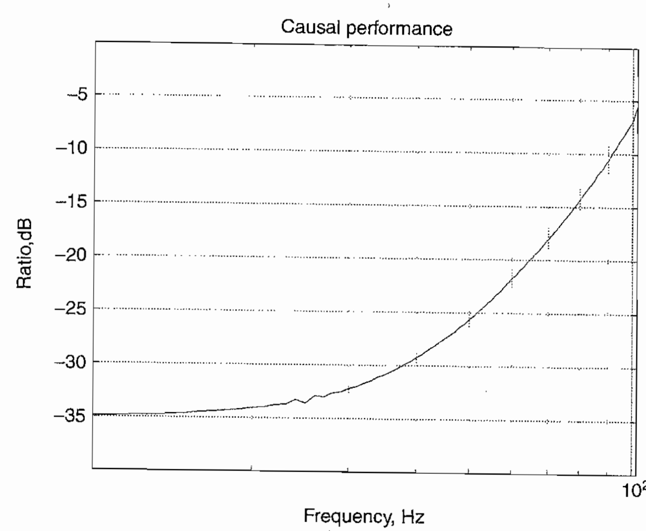

FIGURE 18.34 Ratio of the residual to the disturbance using the control filter in Fig. 18.32.

frequency out to the Nyquist frequency. Note that the performance of the non-causal filter (not shown in the graph) would be predicted to be perfect, that is, the residual would be zero for all frequencies.

The performance shown in the Fig. 18.34 is unrealistically large for a broadband active control system. This is a consequence of the fact that, at this stage, we have neglected to include other elements in the analysis that would add more realism to the estimate, such as system delays, anti-aliasing filters, sensor noise, and so on. In addition the figure only shows system performance up to the Nyquist frequency (one-half the sampling frequency). As we shall see in a later section, the digital control filter is periodic in frequency with a period equal to the sampling frequency. Consequently, the performance above the Nyquist frequency may also need to be controlled, especially if there is significant energy in the disturbance at those frequencies. We will see how this is done in a later section.

Adaptive Control

In the previous section we discussed the design of a control filter to reduce optimally a chosen residual in a least-squares sense. In that derivation the system to be controlled was assumed to be fixed. In reality the transfer functions defining dynamic systems often change with time. This means that those transfer functions must be measured periodically and the new results used to update the control filter coefficients. We will discuss this process of system identification in the next section. Here we examine an adaptive control algorithm based on the LMS algorithm that continuously updates the control filter coefficients in order to minimize the chosen residual sensor signals. The filtered-x algorithm, as it has come to be called, updates the control filter coefficients at each time step.

The filtered-x LMS algorithm, a modification of the LMS algorithm[59] commonly used for cancellation of electronic noise, was first proposed by Morgan.[64] If used unmodified in an active cancellation system, the LMS algorithm can lead to instabilities because the signal from the controller must pass through the plant dynamics where it will experience amplitude changes and phase shifts. The solution to this problem proposed by Morgan was also proposed independently by Widrow et al.[65] and Burgess.[66] Morgan's solution, which has come to be called the filtered-x LMS algorithm, is used extensively today and has been generalized to MIMO systems by Elliott and Nelson.[67]

Figure 18.35a shows a block diagram of a simplified feedforward control system. If we change the order of the plant and control filter in the block diagram, the response will be unchanged as long as the system is linear. The resulting block diagram is shown Fig. 18.35b. The result is a new reference signal u that is the original reference signal filtered by the plant transfer function P. The residual of this new system can be written as

$$e(n) = d(n) - \sum_{n=0}^{N_w-1} w(k)u(n-k) = d(n) - \mathbf{w}^{\mathrm{T}}\mathbf{u} \tag{18.34}$$

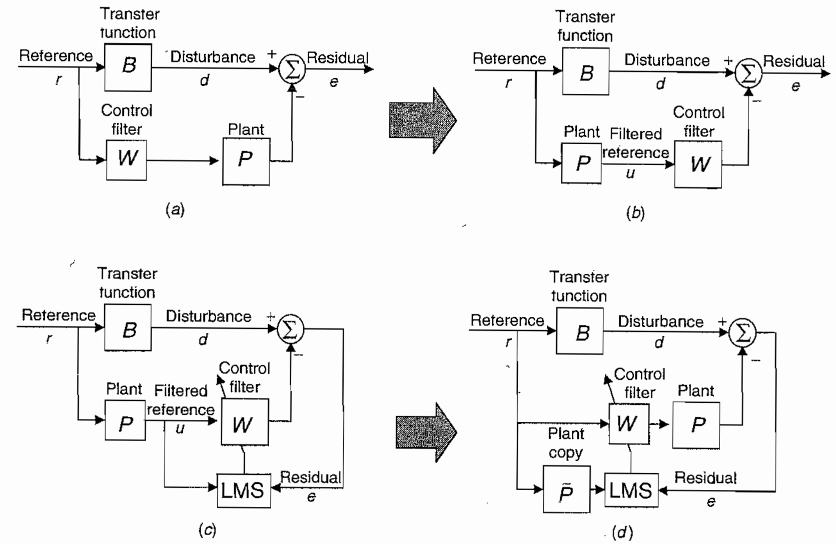

FIGURE 18.35 Feedforward block diagram with and without adaptation showing the progression to the LMS filtered-x algorithm: (a) original diagram; (b) changing the order of plant and control filter; (c) LMS algorithm; (d) filtered-x algorithm.

where $e(n)$ is the nth element of a time sequence $e, d(n)$ is similarly defined, $\mathbf{w}^{\mathrm{T}}$ is the transpose of a vector, the N_w elements of which are the control filter tap coefficients, and $\mathbf{u}$ is a column vector of the last N_w samples in the filtered reference, which is given by

$$u(n) = \sum_{m=0}^{N_w-1} p(m)r(n-m) \tag{18.35}$$

where p is the impulse response of the system estimate of the plant filter P and r is the reference signal time sequence. The block diagram showing the adaptation process is shown in Fig. 18.35c, and a slight rearrangement of the blocks in the block diagram in Fig. 18.35d results in the specialized LMS algorithm called the filtered-x LMS algorithm.

Unlike the direct-estimation approach in the previous section in which the filter coefficients are estimated in a single calculation, the filtered-x algorithm uses an iterative approach which updates the estimate at each time step. The update equation for the control filter is derived similarly to that for the LMS algorithm (see Adaptive Digital Filter Design in Section 18.3). The resulting equation to estimate the coefficients of w is typically written as

$$\mathbf{w}(n+1) = \mathbf{w}(n) + 2\mu e(n)\mathbf{u}(n) \tag{18.36}$$

where

$$\mathbf{w}(n) = \begin{Bmatrix} w(0) \\ w(1) \\ \vdots \\ w(N_w - 1) \end{Bmatrix}$$

is a column vector of the nth estimate of the N_w control filter coefficients, $w(0)$ is the first filter coefficient, $w(1)$ is the second, and so on,

$$\mathbf{u}(n) = \begin{Bmatrix} u(n) \\ u(n-1) \\ \vdots \\ u(n - N_w + 1) \end{Bmatrix}$$

is a column vector of the last N_w samples in the filtered reference, and μ is a scalar convergence coefficient set by the user to ensure stable convergence to the optimum filter coefficients. This equation is very similar to that derived for the LMS algorithm, the only difference being that the filtered reference $\mathbf{u}(n)$ is used in the update equation rather than the reference itself.

In Eq. (18.36) the larger is μ, the faster the algorithm will converge to the optimum filter coefficients. However, if μ is too large, the algorithm will go unstable and will not converge. The convergence coefficient can be selected using the following rule of thumb[58]:

$$0 < \mu \leq \frac{1}{N_w E\{u^2\}} \tag{18.37}$$

where N_w is the number of control filter coefficients and $E\{u^2\}$ is the mean-square value of the filtered reference. This is very similar to the rule of thumb for the LMS algorithm presented in Section 18.3 except that the mean-square value of the filtered reference, $E\{u^2\}$, is substituted for mean-square value of the reference itself, $E\{r^2\}$.

Equation (18.36) along with Eq. (18.35) states the SISO filtered-x algorithm. This algorithm has enjoyed a great deal of popularity because it is very easy to implement and functions well in the presence of errors in the plant estimate used to filter the reference. If the convergence rate is kept slow enough, the algorithm will still find the optimum filter coefficients even in the presence of plant phase errors of up to 90°.[64] In addition, the algorithm can be very effective in maintaining control even if the reference is nonstationary. Finally, it is possible to introduce something comparable to control effort weighting as discussed in the previous section. In the filtered-x algorithm this is referred to as *leakage*. By reducing the control filter coefficients by a small percentage at each time step,[59] the effect is similar to broadband control effort weighting.

Example. To illustrate the application of this algorithm, we will utilize it to design an optimum filter for the system of the previous section. To do so, we will require the impulse response function (IRF) associated with the cross-spectrum between disturbance and reference, S_{rd}, and the IRF of the plant, P. We obtain these by simply inverse Fourier transforming the FRF functions in Eqs. (18.32) and (18.33), respectively, and retaining a sufficient number of terms to ensure that we capture all of the impulse response. Figure 18.36 illustrates the two IRFs. The plant IRF is a decaying sinusoid with a frequency of 25 Hz, the natural frequency of the plant. The cross-spectrum IRF shows the delay of 0.02 s introduced into the model. We will retain the full 1 s duration (200 taps at a sampling rate of 200 Hz) of the IRFs in the figure, although it would probably be sufficient to retain substantially less. The filter coefficients obtained using the direct [Eq. (18.30)] and filtered-x [Eqs. (18.35) and (18.36)] estimation procedures are compared in Fig. 18.37, and the frequency response functions are compared in Fig. 18.38. There are clear differences between the two control filters that may be a consequence of the fact that the filtered-x procedure is still converging. That the procedure is still converging can be seen in Fig. 18.39, which shows a time history of the residual, or controlled disturbance. Even after over 80 s the residual still shows a tendency to decrease. Figure 18.40 shows the ratio of the spectrum of the controlled disturbance to the spectrum of the uncontrolled disturbance as a function of frequency at the end of the time interval in Fig. 18.39. Also shown in the figure is the same ratio for the direct-estimation procedure. In this case the two procedures give comparable results despite the differences in the control filters.

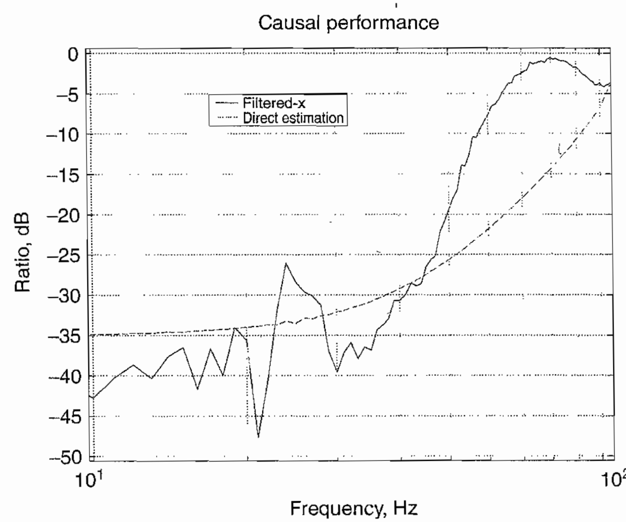

FIGURE 18.40 Ratio of controlled to uncontrolled disturbance.

Control of Aliasing Effects

In the previous sections we have focused on control of the disturbance below the Nyquist frequency. In fact, because digital filters are periodic in the frequency domain with a period equal to the sampling frequency, we must also concern ourselves with the performance above the Nyquist frequency, especially if the disturbance has significant amplitude there. Figure 18.41 shows the ratio

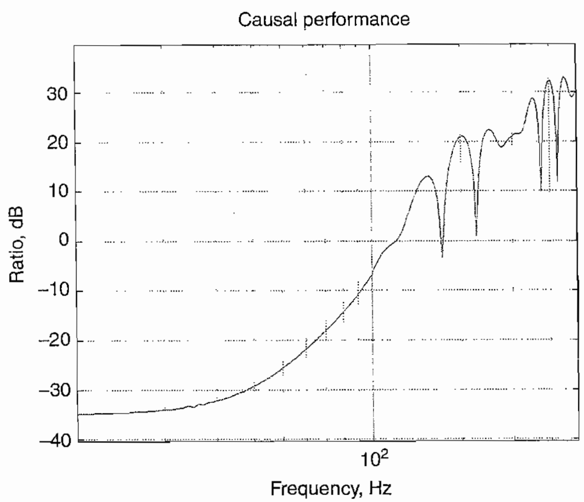

FIGURE 18.41 Change in the ratio of controlled to uncontrolled disturbance beyond the Nyquist frequency.

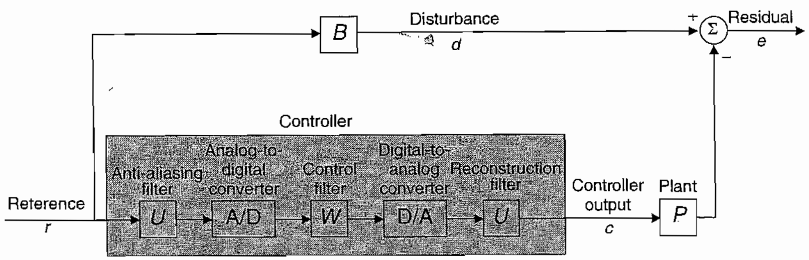

FIGURE 18.42 Feedforward block diagram further simplified (adaptation blocks not shown).

of the controlled-to-uncontrolled disturbance beyond the Nyquist frequency for the direct-estimation case in the previous section on optimal control filter estimation. Above ~125 Hz the figure shows that the control system will amplify the disturbance. To control this out-of-band amplification, one usually employs anti-aliasing filters, low-pass filters that minimize energy above the Nyquist frequency entering the controller. In addition, there are other low-pass filters and delays that should be included in a more realistic model of the active control system. To that end Fig. 18.42 shows the controller expanded into five blocks. First the analog reference signal needs to be digitized before the controller can utilize it. That is the function of the A/D converter shown as the second block in the controller. The first block is a low-pass filter called the anti-aliasing filter. Its cutoff frequency is usually set slightly below the Nyquist frequency in order

to reduce aliasing in the digital controller, as described above. The third block is the digital control filter, the output of which is fed to a D/A converter to convert the digital signals to analog signals. The D/A converter is usually a sample-and-hold device that produces a signal with discrete steps or jumps at the sampling rate. Consequently, there is usually a low-pass filter at the output of the D/A converter, typically called a reconstruction filter, to smooth or reconstruct the signal. This filter is typically the same as the anti-aliasing filter, although there is no requirement that the two filters be the same. The output of the reconstruction filter is an analog signal, c, that is applied to power electronics that will in turn drive a speaker or other actuator. The plant, P, accounts for all of the dynamics relating the controller output to the control signal, which cancels the disturbance d. In designing the control filter there may be significant delays associated with the anti-aliasing filter, the reconstruction filter, and the D/A converter, which need to be included in designing and evaluating the control filter. The delays associated with the A/D converter are usually small and can, in most cases, be neglected. The delays associated with the D/A converter, on the other hand, are on the order of half a sample period and usually need to be included in the design and evaluation process. To carry out the analysis, the anti-aliasing filter, reconstruction filter, and sample-and-hold delay (D/A converter) are usually lumped in with the plant transfer function. The D/A converter is typically modeled by a simple delay of one-half of the sample period. The total plant then becomes

$$U^2(\omega)P(\omega)e^{-j\omega\Delta T/2} \tag{18.38}$$

where ΔT is the sample period and $U^2(\omega)$ is the product of the frequency response functions of the anti-aliasing and reconstruction filters. To illustrate the impact on the design process and on the resulting performance, we will select an anti-aliasing filter and go through the design process once again using the same plant and disturbance-to-residual transfer function as used in Section 18.4 and given by Eqs. (18.32) and (18.33). As will be discussed in Section 18.6 under Hardware Selection, there is a wide variety of low-pass filter types that are commonly used for anti-aliasing and reconstruction, such as Butterworth, Bessel, and elliptical (Cauer), to name just a few. In this example we will use the third-order elliptical filter whose frequency response function is shown in Fig. 18.43. The filter has a cutoff frequency of 70 Hz, slightly below the Nyquist frequency, and the ratio of passband to stop-band amplitude is nominally 50 dB.

Using the direct-estimation procedure outlined in Section 18.4 under Optimal Control Filter Estimation, we obtain the causal control filter whose frequency response is shown in Fig. 18.44. Also shown in the figure is the noncausal control filter given by $B(\omega)\{U^2(\omega)P(\omega)\}^{-1}e^{j\omega\Delta T/2}$. The frequency response functions of the two filters are clearly quite different, but the difference is more clearly seen in Figs. 18.45a and b, where the impulse response function of the noncausal control filter and the filter coefficients of the causal control filter, respectively, are compared. The noncausal filter IRF shows a strong increase at the end of the time interval, which, as explained earlier, indicates that the filter responds before

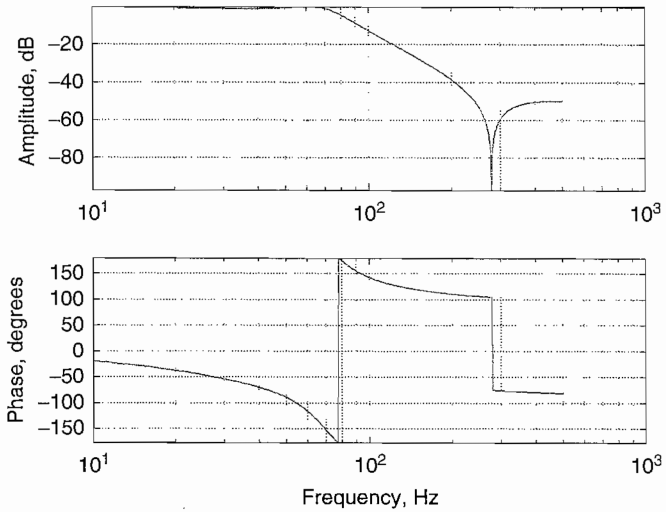

FIGURE 18.43 Frequency response function for a third-order elliptical filter with a cutoff frequency of 70 Hz and a passband–stop band ratio of 50 dB.

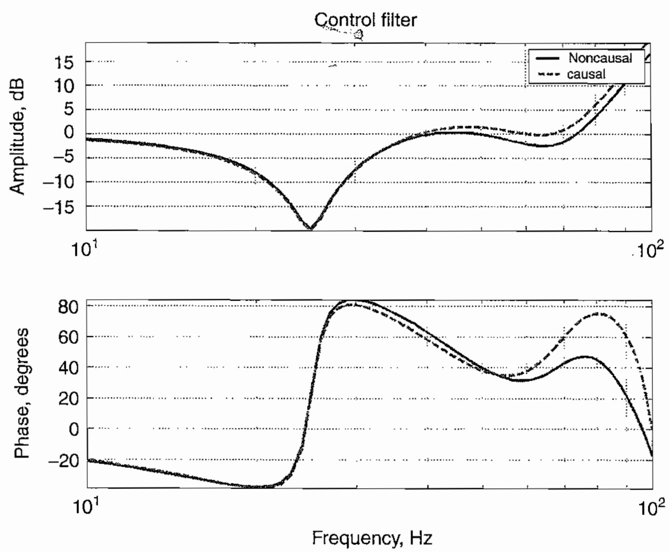

FIGURE 18.44 Comparison of the causal and noncausal control filter frequency response functions.

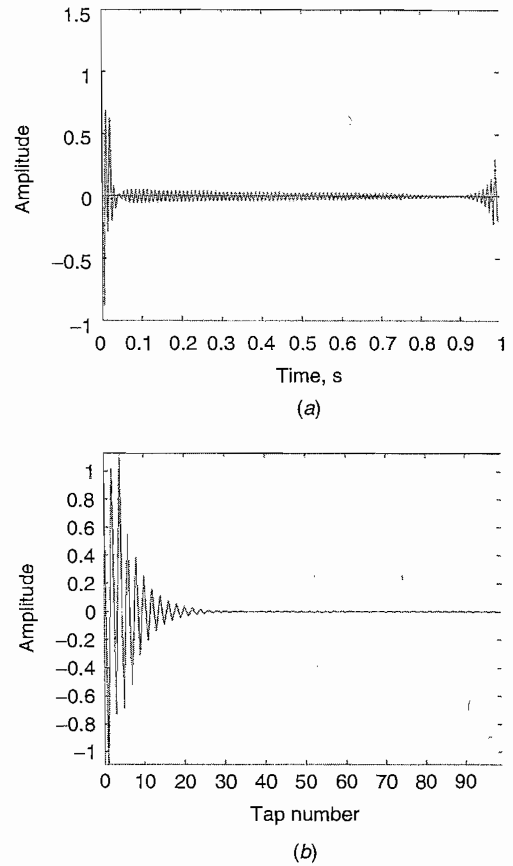

FIGURE 18.45 Comparison of (*a*) the noncausal control filter impulse response function and (*b*) the filter coefficients of the causal control filter.

it receives an input signal and is clearly noncausal. The filter coefficients of the causal filter, on the other hand, decay away to zero. The performance of the active control system is shown in Fig. 18.46. The figure shows the ratio of the controlled disturbance spectrum to the uncontrolled spectrum. The performance has clearly been degraded, especially in the vicinity of the Nyquist frequency. Nevertheless, the out-of-band amplification clearly visible in Fig. 18.41 has been completely removed through the use of the anti-aliasing and reconstruction filters.

System Identification

The control algorithms discussed in the previous sections require internal models of the transfer functions between the outputs of the controller (i.e., the signals sent

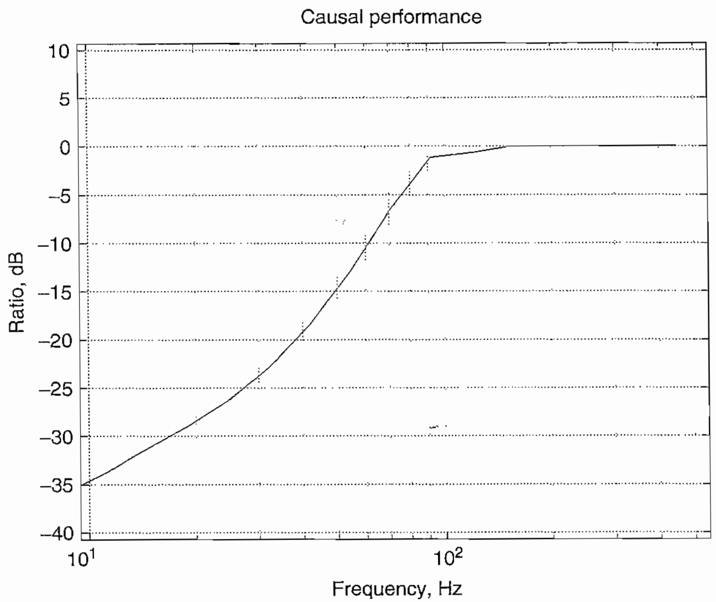

FIGURE 18.46 Ratio of controlled to uncontrolled disturbance with anti-aliasing filters, reconstruction filters, and D/A converter delays.

to the D/A converters) and the inputs to the controller from the residual sensors (i.e., outputs from the A/D converters). These transfer functions are commonly referred to as *plant* transfer functions. The procedure used to measure these transfer functions (or equivalently impulse response functions) is referred to as *system identification*. In this section, we discussed system identification approaches that apply to feedforward controllers.

Since most control algorithms require plant models for the control algorithms to converge to (or solve directly for) the optimal control filters,[58] system identification must be performed prior to any adjustments to the control filters. As such, when system identification is performed with control filters set to zero (i.e., all coefficients are equal to zero), it is referred to as "*open-loop*" system identification. It derives this name because the system identification algorithms are run when the control loop is open (i.e., no signals are allowed to pass through the control filters). The plant estimates obtained during open-loop system identification are used to initialize the plant models within the controller to support the control algorithms that subsequently adjust the control filter coefficients.

For systems where the plant transfer functions are expected to be time invariant (i.e., they do not change characteristics as a function of time), the plant estimates obtained during open-loop system identification can be held constant as the control filter coefficients are adjusted. It is more common, however, to expect that these transfer functions will change over time. These changes may

occur because of changes in environmental conditions (e.g., temperature, pressure), changes in the operating conditions of the system to be controlled (e.g., speed, load), or the presence of external factors (e.g., number and movement of passengers in an automobile).

There are two basic approaches to account for time-varying transfer functions that may be encountered in ANVC systems: the use of robust control algorithms and periodic system identification. Control algorithms are often formulated to allow for certain levels of uncertainty associated with the internal plant models. For example, the magnitude and phase response of the plant at a given frequency may only be known to within, say, ± 2 dB in magnitude and $\pm 10°$ in phase. In effect, these algorithms recognize that the internal plant model is "close" to the actual plant transfer function but not exact. Control algorithms that are stable and provide performance in the presence of this plant uncertainty are called "robust." For example, the filtered-x LMS algorithm is robust to errors in the plant model of up to 90°.[68] The second approach to account for time-varying transfer functions is to perform system identification at the same time that control filter coefficients are being adjusted. This approach provides *periodically updated* plant models to the control algorithms that track changes in the plant over time. System identification performed in this manner is referred to as *closed-loop* or *concurrent* since it occurs while the control loop is closed.

In practice, a combination of both approaches is often required to account for time-varying plants while at the same time maximizing achievable system performance. Control algorithms that rely on exact models of the plants to be controlled can offer maximum performance but are also very sensitive to slight changes in the plant transfer function. As such, small changes in the plant can lead to instability, and for this reason such systems are rarely used in practice. On the other hand, algorithms that make do with very inaccurate plant models will often provide very little performance. As such, there is a trade-off between control system robustness and performance. These trade-offs ultimately influence the approach chosen for system identification.

We now discuss procedures for open- and closed-loop system identification that are applicable to feedforward control systems. Consider first the feedforward system of Fig. 18.47. For this system, the plant, P, is the transfer function between the output of the control filter, y, and the response of the residual sensor, e. Though not shown explicitly, the plant transfer function P is assumed to include the following: D/A sample and hold, smoothing filters, transfer function through the structure to be controlled, anti-alias filters, and A/D converters. An open-loop estimate of P can be performed by setting the coefficients of the control filter, W, to zero and injecting a band-limited probe signal v into the output of the control filter. The probe signal is therefore a digital signal that adds to the output of the control filter y to produce a net signal c at the output of the controller.

The bandwidth of the probe signal is chosen to span the frequency range over which control performance is desired. For a tonal control problem, where the tone is nominally fixed in frequency, the probe signal may span only a few hertz.

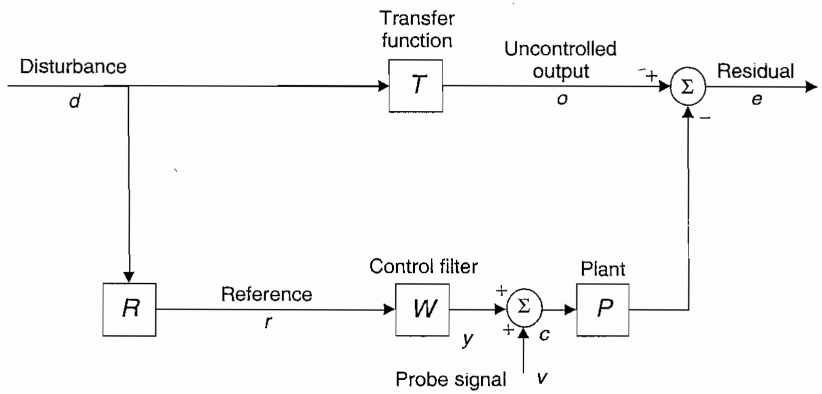

FIGURE 18.47 Probe signal injection for system identification in a feedforward system with no coupling between actuators and reference.

For broadband control, the probe signal bandwidth is often chosen to extend marginally beyond the control bandwidth to ensure an accurate plant estimate throughout the bandwidth for control.

The transfer function between the probe, v, and the residual, e, can be estimated in the frequency domain using the expression

$$\hat{P} = -S_{ve}S_{vv}^{-1} \tag{18.39}$$

where $\hat{P}$ = estimate of plant transfer function P
S_{ve} = cross-spectrum between probe and residual
S_{vv} = autospectrum of probe

This expression will provide an unbiased estimate of the plant transfer function for $W = 0$ (i.e., open-loop system identification) as well as for $W \neq 0$ (i.e., closed-loop system identification) provided the probe signal is uncorrelated with the disturbance and sufficient averaging time is allowed to obtain good estimates of S_{ve}.

An estimate of the plant transfer function in Fig. 18.47 can be made in the frequency domain using Fourier transforms of the probe and residual signals as outlined above. Alternatively, an estimate of the plant *impulse response* can be obtained using the optimal or adaptive FIR filter design procedures discussed in Section 18.3.

An example of system identification using the LMS algorithm integrated into a filtered-x control algorithm is depicted in Fig. 18.48. The filtered-x algorithm adapts the coefficients of the control filter W using the filtered reference signal and a modified residual signal (see later) as inputs. A separate LMS algorithm is used to identify the plant impulse response as shown in the lower portion of the figure. A probe signal v is injected into the control loop and sums with

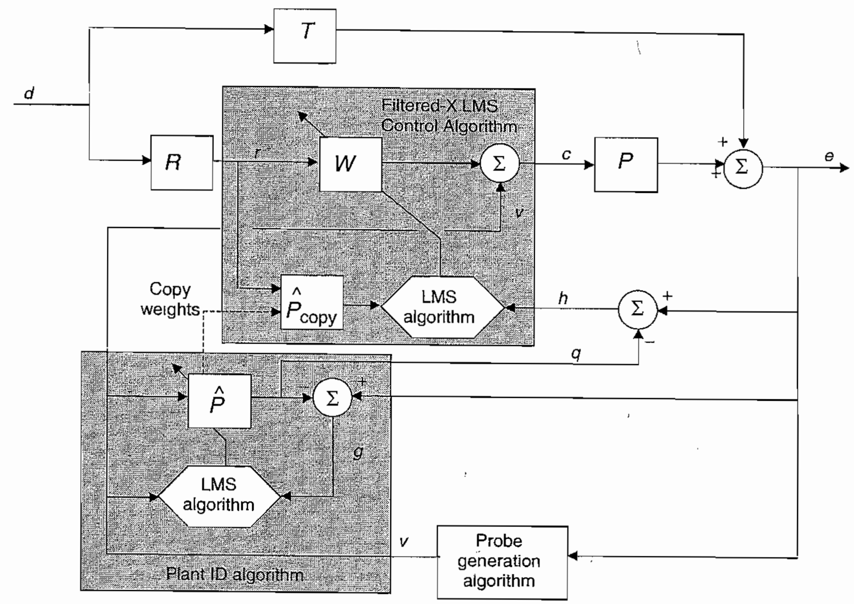

FIGURE 18.48 System identification using the LMS algorithm, embedded within filtered-x LMS controller.

the output of the control filter. The probe signal is also filtered by the adaptive FIR filter that is labeled $\hat{P}$. Finally, the probe signal is an input signal to the LMS algorithm that adapts the coefficients of $\hat{P}$. The output of $\hat{P}$ is summed with the residual signal e to form the error signal g, which is the second input to the LMS algorithm adapting the coefficients of $\hat{P}$. The coefficients of $\hat{P}$ are adapted to minimize the contribution in g that is correlated with the probe, v, in a least-squares sense. An optimal estimate of $\hat{P}$ is achieved when the LMS error signal g becomes uncorrelated with the probe, v. The coefficients of $\hat{P}$ are copied periodically into the filter, $\hat{P}_{copy}$, which filters the reference signal r, as required by the filtered-x LMS control algorithm.

Following the development of Section 18.3 under Adaptive Digital Filter Design, the update equation for the plant estimate is

$$\hat{\mathbf{p}}(n+1) = \hat{\mathbf{p}}(n) + 2\mu\mathbf{v}(n)g(n) \tag{18.40}$$

where

$$\hat{\mathbf{p}}^{\mathrm{T}} = [\hat{p}(0), \hat{p}(1), \hat{p}(2), \ldots, \hat{p}(I-1)] \tag{18.41}$$
$$\mathbf{v}^{\mathrm{T}}(n) = [v(n), v(n-1), \ldots, v(n-I+1)]$$

We note here that the convergence behavior of the LMS algorithm of Eq. (18.40) is improved if the portion of the residual signal correlated with the reference is removed before being used as input for the plant estimate. This can be achieved by including a third LMS algorithm with the reference and residual signals as inputs, and the modified residual signal as output. The update equation is similar to that in Eq. (18.40). Though not shown explicitly in Fig. 18.84 to preserve clarity, this approach was used for the adaptive feedforward control example presented near the end of this chapter (MIMO Feedforward Active Locomotive Exhaust Noise Control System with Passive Component) and is illustrated there in Fig. 18.93.

A consequence of being able to periodically update the model of the plant using the system identification procedure outlined in Fig. 18.48 is that the injected probe signal will increase the residual signal e. For purposes of system identification, it is desirable to used high-level probe signals because the probe signal will dominate the response at the residual sensor, and consequently accurate plant estimates can be obtained in a shorter length of time. During open-loop identification of ANVC systems, it is often acceptable to use high levels of probe signals. During closed-loop operation, however, the use of high-level probe signals is not acceptable since performance gains achieved as a result of the control filter will be overwhelmed by the presence of the probe signals reaching the residual. As a consequence, low-level (i.e., *covert*) probe signals are required during closed-loop operation.* The drawback to using low-level probes is that the plant estimate will adapt slowly and will not be able to track changes in the plant that occur over relatively short time frames. When this is the case, the control algorithms must be adjusted to deal with larger levels of uncertainty in the plant models or alternative strategies involving gain scheduling[69] must be considered.

For systems where the time constants of plant changes are *large* relative to the adaptation time of the LMS algorithm when using low-level probes, the system identification approach of Fig. 18.48 has been used effectively. For these cases, the probe signals can be generated using low-level band-limited "white" noise. However, fixed-level, white-noise probe signals are not necessarily the best choice. In particular, drawbacks of using white-noise probes include the following:

- The magnitude of the probe signal is held constant. Therefore, as the magnitude of the disturbance increases, the effective convergence rate for the plant filter will decrease. Alternatively, as the disturbance decreases relative to the probe, the convergence rate will increase at the expense of increasing the level of the closed-loop residual signals.
- The spectral shape of the probe signal is independent of the spectral shape of the residual signal and plant transfer function. Consequently, the quality (e.g., estimation errors) of the plant estimate will vary as a function of frequency. This can lead to temporary losses in system performance for control of slewing tonals and nonuniform control of broadband noise.

*Typically the probe signal is sized such that the resulting signal at the residual sensors is nominally 6 dB below the closed-loop signal (absent the probe) in those sensors.

For ANVC applications where white-noise probes may not be appropriate, probe-shaping algorithms can be employed to generate probe signals that provide plant estimates with nominally uniform estimation errors as a function of frequency. Further, these algorithms can account for changes in the disturbance spectrum and plant transfer functions over time.[70–72] Probe generation approaches are depicted collectively by the *probe generation* block in Fig. 18.48.

The final aspect to discuss concerning Fig. 18.48 is possible interaction between the filtered-x LMS algorithm adapting the control filter and the LMS algorithm adapting the plant estimate. In particular, we consider the effects of probe signal injection on convergence of the control filters. Note that the injected probe signal used for system identification contributes to the net residual signal e, which is typically used to adapt the control filter coefficients using the filtered-x LMS algorithm. The contribution from the probe signal is, by design, uncorrelated with the reference signal r. However, its presence in the residual signal will impact the instantaneous residual signal used in the gradient estimate and reduce the convergence speed of the filtered-x algorithm. As a consequence, it is beneficial to remove an estimate of the probe's contribution to the residual signal by subtracting the output of the filter, $\hat{P}$ (labeled q in Fig. 18.48), from the residual, e. This modified residual signal (labeled h in Fig. 18.48) is then used to adapt the control filter coefficients using the filtered-x LMS algorithm.

Up to this point, we have assumed that any coupling from the actuators back to the reference sensors is negligible (i.e., sufficiently small that it can be ignored with respect to system performance and stability). This is not always the case. In general, there exists physical coupling which must be accounted for by both the control algorithm and the system identification algorithms. Control algorithms that account for this path include *feedback neutralization* and Eriksson's *filtered-U* algorithm, both of which were discussed in the previous section. A fully adaptive filtered-U algorithm that includes concurrent system identification is discussed by Eriksson and Allie.[61] In those instances where the physical coupling to the references becomes so strong that electronic cancellation of the coupling may be ineffective, other approaches must be employed to minimize the physical coupling, such as the use of directional reference sensors and selection of alternate sensors.

Figure 18.49 shows the injection of a probe signal in a feedforward system that contains coupling C from the controller output to the reference input and neutralization filter $\tilde{C}$ in the controller to minimize the effects of this feedback path. The procedures for open-loop identification of the coupling transfer function C follows from the discussion above for identifying P, provided the reference signals are used in place of the residual signals. As such, unbiased estimates of the coupling transfer function can be obtained during open-loop operation, provided that the probe signal is uncorrelated with the disturbance. During closed-loop operation, however, transfer functions from the probe signal to the residual and

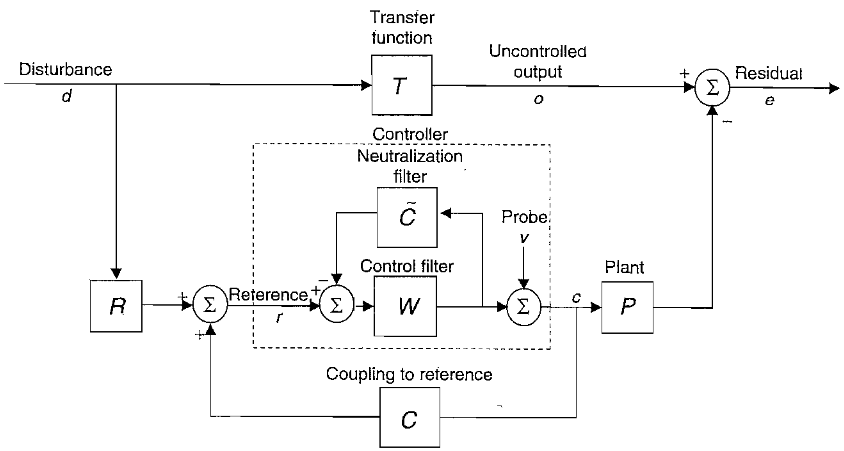

FIGURE 18.49 Probe signal injection in feedforward system with coupling to reference sensor and feedback neutralization filter.

reference sensors no longer provide unbiased estimates of P and C. Instead, these transfer functions include the loop gain associated with the feedback loop comprised of the coupling transfer function, neutralization filter, and control filter.

Following the nomenclature of Fig. 18.49, these transfer functions are given by

$$G_e = \frac{S_{ve}}{S_{vv}} = \frac{-P}{1-(C-\tilde{C})W} \qquad G_r = \frac{S_{vr}}{S_{vv}} = \frac{C}{1-(C-\tilde{C})W} \tag{18.42}$$

These expressions for G_e and G_c contain the desired transfer functions for P and C in the numerator, but both contain the impact of the feedback loop in the denominator. The denominator term can be isolated by estimating the transfer function from the probe signal to the controller output signal c. This transfer function is given by

$$G_c = \frac{S_{vc}}{S_{vv}} = \frac{1}{1-(C-\tilde{C})W} \tag{18.43}$$

Asymptotically unbiased estimates for the plant and coupling transfer functions can then be obtained by combining Eqs. (18.42) and (18.43) such that

$$\hat{P} = \frac{-G_e}{G_c} = P \qquad \tilde{C} = \frac{G_r}{G_c} = C \tag{18.44}$$

This approach for closed-loop identification is known as the joint input–output method.[73] Estimates of P and C can be made in the frequency domain by estimating the cross-spectra in Eqs. (18.42) and (18.43) and taking the ratios as indicated in Eq. (18.44). Alternatively, multiple-embedded LMS algorithms could be employed to adapt estimates of P and C on a sample-by-sample basis.

Although we have discussed the joint input–output method applied to a feedforward system with feedback to the reference sensors, it is a general approach that is applicable to traditional feedback systems. As such, this method of concurrent system identification can be used to implement fully adaptive feedforward and feedback control systems. Further, the method is valid for use during open- and closed-loop operation. An example of a fully adaptive feedback control system using this approach to system identification when applied to an active machinery mount can be found in Berkman et al.,[74] Curtis et al.,[75] and Berkman and Bender[76] and is included here as an example in Section 18.7 under Active Machinery Isolation.

Extension to MIMO Systems

The equations and examples so far have considered only SISO controllers. In many instances there will be the need to design controllers that can handle multiple inputs and/or multiple outputs. While a complete consideration of the issues involved in the design of MIMO systems is beyond the scope of this chapter, we provide here a brief look at the algorithms for the design of optimum MIMO control filters.

Let us begin by defining a notional MIMO system like that shown in Fig. 18.50, where K reference signals, **r**, are applied to a control filter which in turn generates M output signals, **u**, to drive actuators on the system to be controlled. The system has L control sensors to monitor the system performance. Since there are multiple inputs and multiple outputs to each of the blocks in Fig. 18.50, the variables in the blocks $B(\omega)$, $W(\omega)$, and $P(\omega)$ no longer represent scalar transfer functions but must be transfer function matrices. For example, if there are M actuators driving the plant and L control sensors monitoring the system response, the plant transfer function $P(\omega)$ between the sensors and the

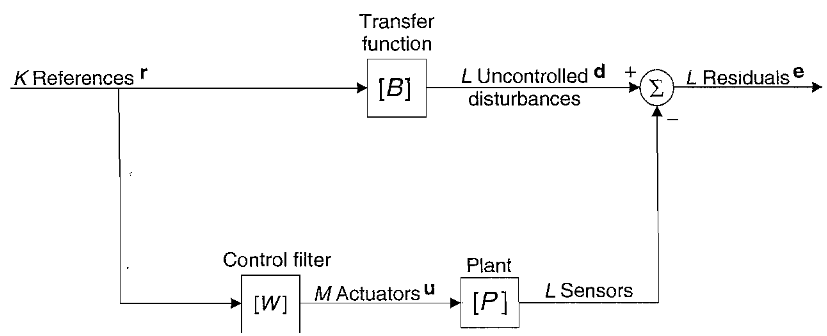

FIGURE 18.50 Notional MIMO control system.

actuators becomes the matrix of transfer functions $[P(\omega)]$:

$$[P(\omega)] = \begin{bmatrix} P_{11}(\omega) & P_{12}(\omega) & \cdots & P_{1M}(\omega) \\ P_{21}(\omega) & & & \vdots \\ \vdots & \ddots & \ddots & \\ P_{L1}(\omega) & \cdots & \cdots & P_{LM}(\omega) \end{bmatrix} \tag{18.45}$$

where the $P_{nm}(\omega)$ are each frequency response functions relating sensor output n to actuator input m.

In Eq. (18.24) we defined an optimum SISO control filter for tonal disturbances given by $W(\omega) = P(\omega)^{-1}B(\omega)$. It turns out that the optimal MIMO control filter is given by a very similar expression if the plant is a square transfer function matrix, that is, $L = M$:

$$[W(\omega)] = [P(\omega)]^{-1}[B(\omega)] \tag{18.46}$$

In the equation the square brackets indicate that the variables are transfer function matrices and not scalar transfer functions. For the more general case of a nonsquare plant matrix of K rows and L columns the same expression applies except that the pseudoinverse of the plant matrix is substituted for the normal inverse:

$$[W(\omega)] = [P(\omega)]^{\#}[B(\omega)] \tag{18.47}$$

where the pseudoinverse of the plant, $[P(\omega)]^{\#}$, is given by

$$[P]^{\#} = \begin{cases} \{[P]^H[P]\}^{-1}[P]^H & \text{for } K \le L \\ [P]^H\{[P][P]^H\}^{-1} & \text{for } K > L \end{cases}$$

where $[\cdot]^H$ means the complex conjugate of the transpose of the matrix. Since for broadband disturbances Eq. (18.47) can result in noncausal control filters, there is a need to apply causality constraints to the MIMO filter design process similar to those applied to the SISO case in Section 18.4 under Optimal Control Filter Estimation. Unfortunately the derivation of the direct-estimation equations for the optimal MIMO control filter is very involved and beyond the scope of this chapter. The interested reader is referred to reference 77.

Fortunately the MIMO filtered-x algorithm is much simpler than the MIMO direct-estimation algorithm, and the equations have been developed by Nelson and Elliott.[16,67] The residual that we are seeking to minimize is given by

$$e_l(n) = d_l(n) - \sum_{m=1}^{M}\sum_{j=0}^{J-1} P_{lmj}u_m(n-j) \tag{18.48}$$

where P_{lmj} is the jth filter coefficient of the plant transfer function relating the lth sensor output to the mth actuator input, M is the number of actuators, J is the length of the digital representation of the plant transfer functions, and u_m is the mth output of the control filter driven by the K references as indicated in the equation

$$u_m(n) = \sum_{k=1}^{K}\sum_{i=0}^{I-1} w_{mki}r_k(n-i) \tag{18.49}$$

In this equation w_{mki} is the ith coefficient of the control filter relating the mth actuator drive signal to the kth reference, I is the length of each control filter, and r_k is the kth reference signal input to the control filters. The MIMO filtered-x update equation for each control filter coefficient is given by

$$w_{mki}(n+1) = w_{mki}(n) + 2\mu\sum_{l=1}^{L} e_l(n)q_{lmk}(n-i) \tag{18.50}$$

where $w_{mki}(n)$ is the existing estimate of the ith filter coefficient for the control filter connecting reference k to actuator m, $w_{mki}(n+1)$ is the new estimate, and

$$q_{lmk}(n) = \sum_{j=0}^{J-1} P_{lmj}r_k(n-j) \tag{18.51}$$

Equation (18.50) is the MIMO filtered-x control filter update equation for multiple references, multiple sensors, and multiple actuators. It is similar in form (except for the sum over control sensors) to the SISO case, since the coefficients are updated by the product of the residual and the reference filtered by the plant transfer function. Its simple form allows for easy, computationally efficient implementation and, as a consequence, has become a very popular MIMO algorithm for feedforward applications. Furthermore, as we shall see in the next section, it can also be applied to feedback systems.

18.5 FEEDBACK CONTROL SYSTEMS

Basic Architecture

The block diagram of Fig. 18.51 shows the basic architecture of a SISO feedback control system. Such a block diagram might arise from the notional physical system shown in Fig. 18.52. The physical system consists of a second-order oscillator with a control sensor, an accelerometer for example, to monitor the motion of the mass. In addition there is a control actuator which can apply forces to the mass to control its motion. In the block diagram the residual, e, is the output signal from the residual sensor. That output is fed to a control filter,

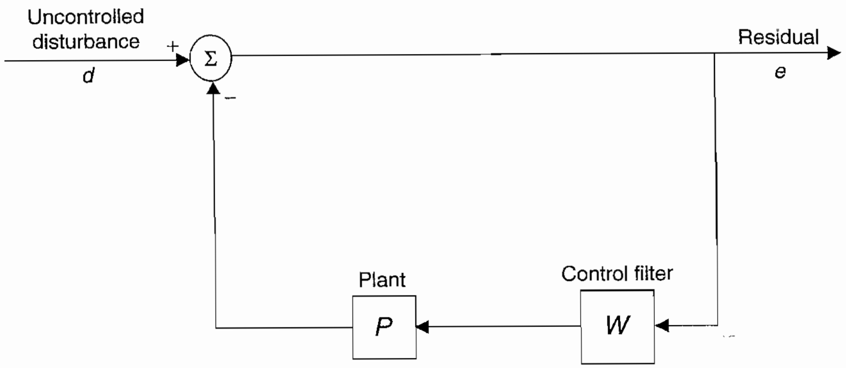

FIGURE 18.51 Basic feedback architecture.

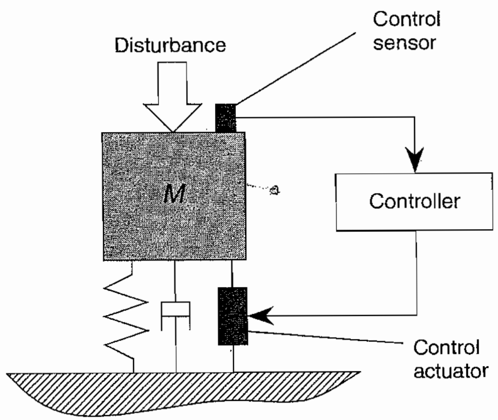

FIGURE 18.52 Notional system with a feedback controller.

which is shown as W in the block diagram. The control filter output drives an actuator that is used to control the motion of the mass.

The plant transfer function P in the block diagram relates the control filter output signal, which drives the actuator to the residual sensor output. In Fig. 18.51 the control filter drives the actuator in such a way as to reduce the input to the control filter. This is in contrast to feedforward systems in which the input to the control filter is a reference signal correlated with the disturbance. In one sense, feedback control systems can be thought of as feedforward systems in which the reference and control (residual) sensors are the same.

The solution for the closed-loop response is given by

$$e(\omega) = \{1 + P(\omega)W(\omega)\}^{-1} d(\omega) \tag{18.52}$$

Clearly the residual will be small if $PW \gg 1$, and in the limit the residual amplitude will become

$$e(\omega) = \{P(\omega)W(\omega)\}^{-1} d(\omega) \tag{18.53}$$

The quantity PW is referred to as the loop gain and the residual amplitude will be inversely proportional to the loop gain. Consequently, good performance from a feedback controller will be achieved if the loop gain is made sufficiently large. In addition, when the loop gain is large, the phase of PW is immaterial to the performance such that if the control filter deviates somewhat from its design goals the performance will suffer only minimally.

The above discussion makes the design of a feedback control filter seem easy. Unfortunately, stability considerations limit our ability to increase the loop gain without limit. Stability issues will be discussed more fully below under Alternate Suboptimum Control Filter Estimation, where the compensator-regulator approach to feedback control filter design is discussed.

Optimal Control Filter Estimation

The literature dealing with the design of optimal feedback controllers is vast and beyond the scope of what can be reasonably included in this chapter. Instead we will focus on two approaches—one optimal and one suboptimal—that each provide tools for the design of SISO or MIMO controllers. The collection of methods often referred to as *modern optimal control theory* will not be dealt with here. Those methods, while providing powerful tools for control filter design when an analytical model of the plant dynamics is available, are not especially well suited to the types of problems where only measured data on the plant dynamics are available. While curve-fitting techniques can be utilized to obtain an analytical model that approximates the measured data, many of those techniques begin to founder if the order of the system model (number of states) becomes too large. For a sampling of the technology in this field the interested reader is referred to references[78–81].

In this section, we focus on what has come to be called the Youla transform or inner model formulation. Through selection of a particular feedback architecture, the Youla transform allows the feedback problem to be transformed into a feedforward problem, making it possible for the feedforward control filter design techniques in Section 18.4 to be used for feedback. In addition, because the system is effectively transformed to a feedforward system, the resulting system is guaranteed to be stable, provided an accurate digital model of the plant has been utilized.

Figure 18.53 shows a simplified block diagram of the Youla transform. In the figure a second feedback loop has been inserted around the control filter. In that second loop a digital filter approximating the plant transfer function has been inserted. The term *inner model* is often used when referring to this approach, precisely because a digital model of the plant is inserted into the control filter.

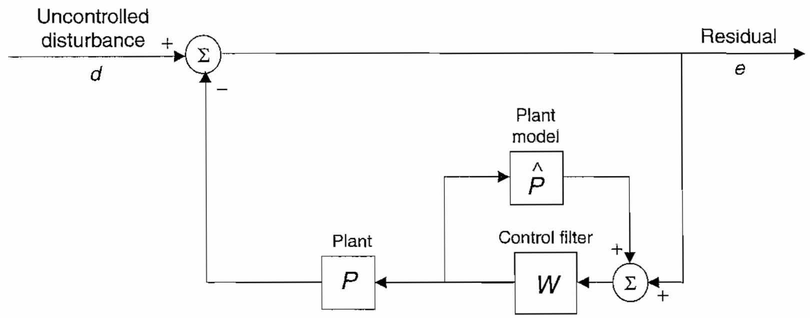

FIGURE 18.53 Youla transform architecture.

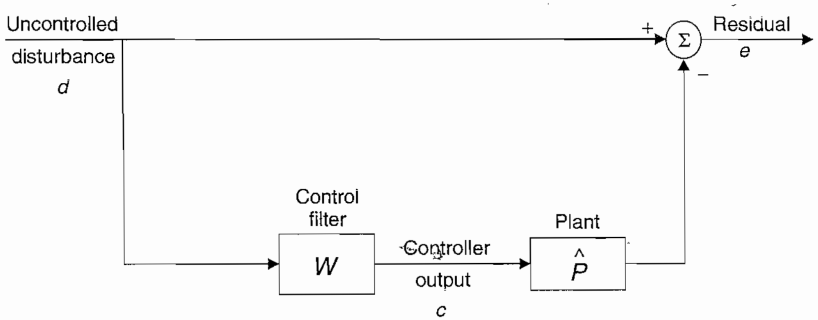

FIGURE 18.54 Feedforward system resulting from the Youla transform.

By making this change in the architecture of the feedback system, we have modified the transfer function from that shown in Eq. (18.52) to the following:

$$e(\omega) = \{1 - \hat{P}(\omega)W(\omega)\}\{1 + (P(\omega) - \hat{P}(\omega))W(\omega)\}^{-1}d(\omega) \tag{18.54}$$

Note that if $\hat{P}$ is a good match to P, then Eq. (18.54) simplifies to

$$e(\omega) = \{1 - \hat{P}(\omega)W(\omega)\}d(\omega) \tag{18.55}$$

Equation (18.55) is the equation for the residual of a feedforward system, the block diagram for which is shown in Fig. 18.54. The resulting block diagram is identical to the feedforward block diagram in Fig. 18.31 if the transfer function $B(\omega)$ is set to unity. Consequently, virtually all of the control filter design equations in Section 18.4 can be applied to a feedback system to which the Youla transform has been applied provided $B(\omega) = 1$. From Eq. (18.24) the noncausal control filter becomes

$$W(\omega) = \hat{P}^{-1}(\omega) \tag{18.56}$$

For the filtered-x algorithm Eqs. (18.35) and (18.36) can be applied to the Youla transform feedback system by simply changing the reference time sequence $r(n)$ in the equations to the disturbance time sequence $d(n)$ in Fig. 18.54:

$$\mathbf{w}(n+1) = \mathbf{w}(n) + \mu e(n)\mathbf{u}(n) \tag{18.57}$$

where $\mathbf{w}(n+1)$ is the new vector of filter coefficients, $\mathbf{w}(n)$ is the old vector,

$$\mathbf{u}(n) = \begin{Bmatrix} u(n) \\ u(n-1) \\ \vdots \\ u(n-N_w+1) \end{Bmatrix} \qquad u(n) = \sum_{m=0}^{N_w-1} \hat{p}(m)d(n-m)$$

and $\hat{p}(m)$ is the mth filter coefficient of the FIR filter representation of the plant frequency response function $\hat{P}(\omega)$.

The equations for determining the optimum feedforward control filter with causality constraints using the direct-estimation approach can be similarly employed by simply interchanging the disturbance d for the reference r. In this case what are affected are the autospectra and cross-spectra in the equations. Modifying Eqs. (18.30) and (18.31), we obtain for a control filter with N taps

$$\begin{Bmatrix} W_0 \\ W_1 \\ \vdots \\ W_{N-1} \end{Bmatrix} = \begin{bmatrix} C_0 & C_{-1} & \cdots & C_{1-N} \\ C_1 & C_0 & \cdots & C_{2-N} \\ \vdots & \vdots & \ddots & \vdots \\ C_{N-1} & C_{N-2} & \cdots & C_0 \end{bmatrix}^{-1} \begin{Bmatrix} A_0 \\ A_1 \\ \vdots \\ A_{N-1} \end{Bmatrix} \tag{18.58}$$

where the coefficients in the matrix equation become

$$A_p = \mathrm{Re}\left\{\int_{\omega_1}^{\omega_2} P S_{dd} e^{-jp\omega\Delta t} d\omega\right\}$$
$$C_{(p-m)} = \mathrm{Re}\left\{\int_{\omega_1}^{\omega_2} \{|P^2| + \alpha^2\} S_{dd} e^{-j(p-m)\omega\Delta t} d\omega\right\} \tag{18.59}$$

where $p, m = 0, 1, \ldots N-1$, S_{dd} is the autospectrum of the disturbance, and α^2 is the control effort weighting factor.

For MIMO systems the equations of Section 18.4 under Extension to MIMO Systems can be similarly adjusted for the design of a MIMO controller in the Youla feedback architecture.

The transformation of Eq. (18.54), a feedback system, into Eq. (18.55), a feedforward system, only occurs if $\hat{P} = P$. Consequently, one would expect that the digital representation of the plant transfer function would have to be fairly accurate. If it is not, the term

$$\{1 + (P(\omega) - \hat{P}(\omega))W(\omega)\}^{-1} \tag{18.60}$$

may indeed lead to instability if the error in the plant model is large enough. If we substitute $E(\omega)$ for the difference between the true plant and the digital representation, Eq. (18.60) becomes

$$\{1 + E(\omega)W(\omega)\}^{-1} \tag{18.61}$$

A simple criterion to ensure that the feedback system remains stable is to require for all frequencies where the controller is functioning that

$$|E(\omega)W(\omega)| < 1 \tag{18.62}$$

where $|\cdot|$ means the absolute value. Furthermore, it can be easily shown that $|E(\omega)W(\omega)| = |E(\omega)||W(\omega)|$. Consequently, we can write a simple criterion for the maximum allowable error in the plant model:

$$|E(\omega)| = |\hat{P}(\omega) - P(\omega)| \le \frac{\beta}{|W(\omega)|} \qquad 0 < \beta < 1 \tag{18.63}$$

where the criterion applies to all frequencies where the control system is functioning and β provides some stability margin. For example, if $\beta = 0.1$, Eq. (18.63) will provide, at least, 20 dB of stability margin. This is a very simple criterion requiring that we know only the amplitude of the control filter as a function of frequency. No phase information is required. However, it is also very conservative, and systems that violate it may not necessarily be unstable. A more precise method for determining stability is to employ the Nyquist criterion, which we will discuss in the next section. Note that a similar criterion can be fashioned for MIMO systems based on the maximum singular values of the matrices $[E(\omega)]$ and $[\hat{P}(\omega)]$. The interested reader is referred to references 80 and 81.

Alternate Suboptimum Control Filter Estimation

Compensator-Regulator Architecture. The compensator-regulator approach to feedback controller design results in a suboptimal system but provides useful insights into functions performed by the controller by breaking the control filter up into a cascade of two filters, as illustrated in Fig. 18.55. The compensation filter is designed to approximate the plant inverse and *compensate* for its amplitude and phase over a range of frequency, which we will refer to as the compensation band. Consequently, if the compensation filter is given by

$$G(\omega) \approx P(\omega)^{-1} \tag{18.64}$$

then we conclude from Eq. (18.52) that the closed-loop residual response $e(\omega)$ is related to the disturbance $d(\omega)$ by

$$\frac{e(\omega)}{d(\omega)} = \frac{1}{1 + H(\omega)} \tag{18.65}$$

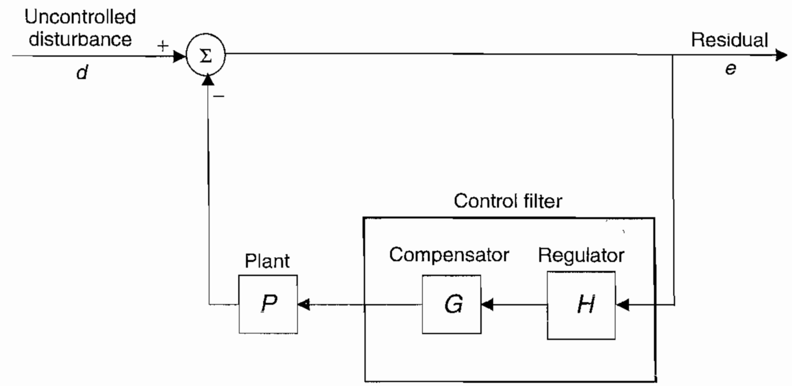

FIGURE 18.55 Compensator-regulator controller architecture.

where $H(\omega)$ is the regulation filter. As this equation shows, to provide reduction in the residual, $|H(\omega)| \gg 1$. When $|H(\omega)| \gg 1$,

$$\frac{e}{d} = \frac{1}{H(\omega)} \ll 1$$

and when $|H(\omega)| \ll 1$,

$$\frac{e}{d} = 1$$

As a result, the design of the regulation filter involves making its magnitude or loop gain large at those frequencies where control is desired (the regulation band) and small where control is not desired. As we shall see in the next section, the trick is to reduce the magnitude and phase of $H(\omega)$ in such a way as to maintain stability and avoid excessive noise amplification outside of the regulation band.

Regulation Filter Design. The range of frequency over which $|H(\omega)| \gg 1$ is referred to as the regulation band. To ensure stability as the magnitude of $H(\omega)$ is reduced outside of the regulation band, the phase of $H(\omega)$ should not exceed 180° until the magnitude is less than 1. This requirement is a consequence of the Nyquist stability criterion.

To employ the Nyquist criterion, one must plot in the phase plane the loop gain, or the change in amplitude and phase as a signal propagates around the feedback loop. In Eq. (18.65) $H(\omega)$ is the loop gain. In the phase plane, the real part of the loop gain is plotted on the horizontal axis and the imaginary part is plotted on the vertical axis such that as the frequency changes, a curve is traced out in two dimensions, as illustrated in Fig. 18.56. In the phase plane, the radius from the origin to a point on the curve represents the magnitude of the loop gain at a particular frequency, and the angle the radius makes with the positive horizontal axis is the phase angle. This is shown in Fig. 18.56 for

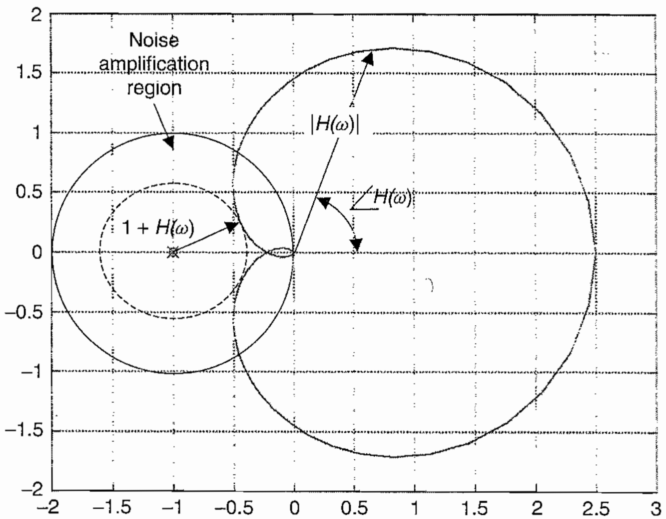

FIGURE 18.56 Stability and noise amplification requirement in the phase plane.

the case where the loop gain is $H(\omega)$. We will not present any proof here of the Nyquist criterion but will simply illustrate its application. For the interested reader, detailed discussions of the Nyquist criterion can be found in a number of texts on control theory.[56,82]

To apply the Nyquist criterion, one simply plots $H(\omega)$ on the phase plane as the frequency ω varies from $-\infty$ *to* ∞ and counts the number of times that -1 is encircled. That number is equal for most cases of interest to the number of unstable poles of $\{1 + H(\omega)\}^{-1}$. Figure 18.56 shows a Nyquist plot of a notional $H(\omega)$ in the phase plane. The amplitude and phase of $H(\omega)$ at a particular frequency are shown in the figure when the phase is less than 180° but the amplitude is greater than 1. As the frequency increases and the phase of $H(\omega)$ approaches 180° in the figure, the amplitude decreases to less than 1, satisfying the criterion. As the figure shows, this ensures that that the curve of $H(\omega)$ will not encircle -1 and that the system is stable.

In the figure, when the phase of $H(\omega)$ is 180°, the amplitude is ~0.2, which gives a modest gain margin of ~14 dB. This means that the amplitude of $H(\omega)$ would have to be 14 dB higher before the feedback control system would go unstable. Similarly, when the amplitude of $H(\omega)$ is unity, the phase is approximately 120°, giving a phase margin of 60°, meaning that the phase would have to increase by approximately 60° before the system would go unstable.

To ensure that there will be no noise amplification as the magnitude of $H(\omega)$ is reduced outside of the regulation band, the curve traced out by $H(\omega)$ in the phase plane should not enter a circle of unit radius centered on -1. This last requirement is also illustrated in Fig. 18.56. There, the trajectory of $H(\omega)$ is seen

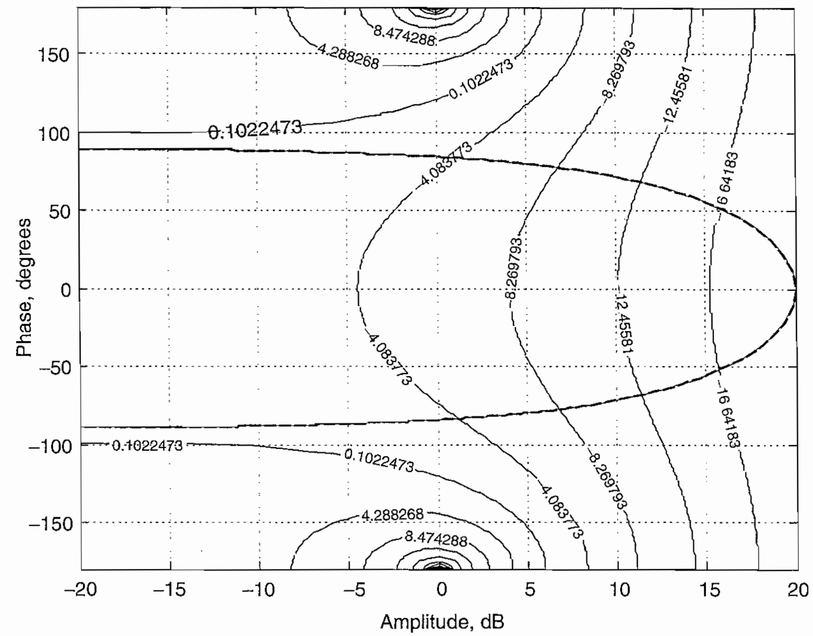

FIGURE 18.57 Nichols plot showing noise amplification in a feedback system as a function of the amplitude and phase of the loop gain.

entering the unit circle, indicating that some degree of noise amplification will occur.

While the loop gain plot in the phase plane can be used to estimate the noise amplification, the so-called Nichols plot provides that information more directly. Figure 18.57 shows a Nichols plot. In the figure, the phase of the loop gain is plotted on the vertical axis and the amplitude is plotted on the horizontal axis. The dashed curve in the figure is the loop gain of a second-order filter.* The contour lines in the plot show the noise amplification. Whenever the dashed curve crosses one of the contour lines, the feedback system with that loop gain will have the noise amplification in decibels indicated by the number on the contour line. For example, Fig. 18.57 shows that the second-order filter with the loop gain given by the dashed curve will never have a noise amplification greater than 0 dB. In fact, a simple examination of the Nyquist and Nichols plots will show that *any*

*The form of the filter is given by

$$H(\omega) = K\left\{\frac{j(\omega/\omega_0)}{(1-(\omega/\omega_0)^2 + j\eta\omega/\omega_0)}\right\}$$

where ω is the frequency and the other terms are constants.

filter whose phase is bounded by ±90°, as the second-order filter is, will always be stable with 0 dB noise amplification when placed in a feedback loop.

All of the above discussion assumes that $P(\omega)$ has been measured accurately and that a good causal representation of $P(\omega)^{-1}$ exists. If, however, the causal representation of $P(\omega)^{-1}$ is imperfect, then the loop gain in the controller will not be just $H(\omega)$ but will be $P(\omega)G(\omega)H(\omega)$. The same criteria for stability and noise amplification apply to this modified loop gain. The consequence is that $H(\omega)$ may need to be designed with larger gain and/or phase margins to maintain stability, and this may result in decreased performance. In addition, the imperfectly compensated system may also have increased noise amplification.

Another consideration is the frequency band over which the compensation filter, $G(\omega)$, must be a good representation of $P(\omega)^{-1}$. In general, the compensation bandwidth must be much greater than the regulation bandwidth to ensure stability and to control noise amplification. To determine the required compensation bandwidth, we first consider noise amplification. The basic approach is to compensate the plant until $H(\omega)$ is small enough so that uncompensated variations in the plant, $P(\omega)$, times the aliased compensation filter, $G(\omega)$, will not lead to noise amplification greater than that specified. If there are measurements of $P(\omega)$ up to frequencies well beyond even the compensation bandwidth, then it is possible to construct the Nyquist plot similar to that shown in Fig. 18.56 for $P(\omega)G(\omega)H(\omega)$ and determine the noise amplification for candidate compensation bandwidths in the same way as illustrated in the figure. Unfortunately, information on the plant is rarely available over such a broad bandwidth, and one must design in robustness by utilizing margins of safety. For example, let us assume that 2 dB of noise amplification is all that is allowed. For this to be true for any phase angle, the amplitude of the regulation filter must satisfy $|H(\omega)| < 0.206$ (−14 dB). If we have a margin of safety of, say, 6 dB to allow for uncompensated plant variations, we must compensate the plant until the regulation filter has declined to −20 dB. If we design the regulation filter to provide 10 dB of performance reduction in the residual, then $H(\omega)$ must have an amplitude of at least 10 dB in the regulation band. Consequently, we will need to compensate the plant out to frequencies beyond the regulation frequency until the amplitude of $H(\omega)$ has decreased by 30 dB from its maximum. Since we must not allow $H(\omega)$ to decrease too rapidly with increasing frequency or instability will result, the resulting compensation bandwidth can easily exceed the regulation bandwidth by a factor of 10–100.

To illustrate these concepts, we will carry out an example for narrow-band control and broadband control, in both cases assuming perfect compensation. For the narrow-band case we choose

$$H(\omega) = K\frac{j\omega/\omega_0}{1-(\omega/\omega_0)^2 + j\eta(\omega/\omega_0)} \tag{18.66}$$

where K and η are constant, $\omega = 2\pi f$, and f is the frequency in hertz. Equation (18.66) is a narrow-band regulation filter with high gain near $\omega = \omega_0$. The frequency response is shown in Fig. 18.58 for $\eta = 0.1$ and $K = 1$. This filter will provide approximately 20 dB of loop gain at the center frequency and consequently we would expect about 20 dB reduction in the residual. In addition, as mentioned above, the phase of the filter is bounded by ±90° and consequently, when placed in the feedback loop, will be stable with 0 dB noise amplification.

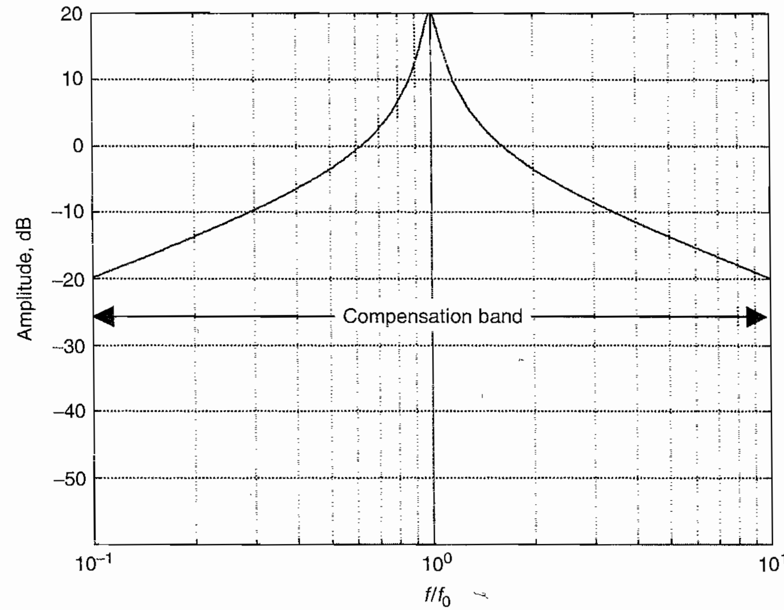

FIGURE 18.58 Narrow-band regulation filter.

Figure 18.59 shows the reduction in the residual with this regulation filter in the feedback loop. The system frequency response looks like a notch filter with approximately 20 dB of noise reduction over a bandwidth of about 5% of the center frequency f_0. It shows no out-of-band noise amplification, as expected.

These estimates have assumed that the compensation for the plant is perfect and that $G(\omega) = P(\omega)^{-1}$ for all frequencies. In reality we need to define a realistic range over which the plant will be measured and the compensation filter will be designed to work. The compensation band should be extended out far enough in frequency such that the regulation filter gain is small enough to ensure that no matter what uncompensated plant phase is introduced, the noise amplification will not exceed a design value (e.g., 2 dB). Earlier we determined that that criterion would be satisfied if $|H(\omega)| < 0.206$ (−14 dB). To allow for possible increases in loop gain as the compensation is gradually turned off, we introduce some margin by reducing this value by an additional factor of 2 (6 dB). Consequently, the plant will be compensated until the regulation filter reduces its amplitude to −20 dB. From Fig. 18.58 we can see that the compensation bandwidth must extend from $\sim 0.1f_0$ to $\sim 10f_0$, or 2 decades. This is substantially broader than the control bandwidth.

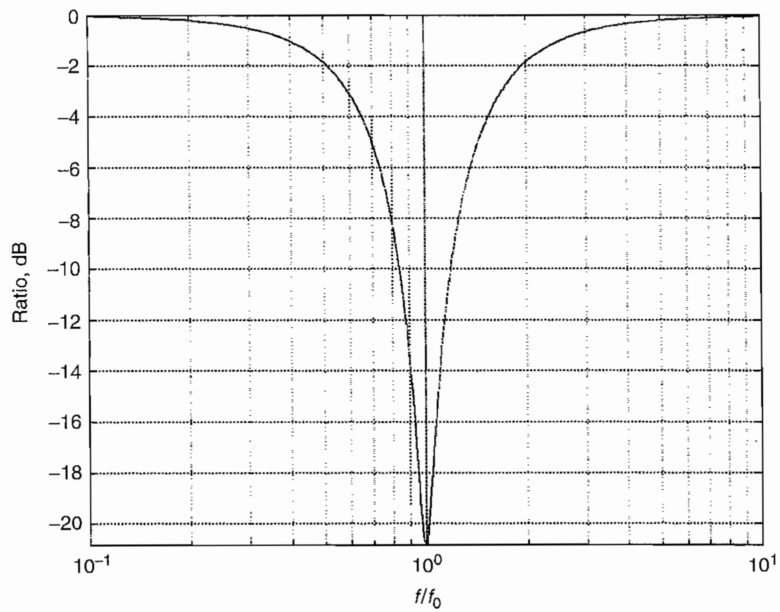

FIGURE 18.59 Ratio of controlled to uncontrolled residual for the narrow-band regulation filter.

Note that the bandwidth and noise reduction in Fig. 18.59 can be adjusted by varying the parameters of the regulation filter. For example, increasing η will increase the bandwidth but decrease the noise reduction performance of the feedback system, essentially broadening the notch and decreasing its depth in Fig. 18.59. Increasing K will increase the noise reduction performance, essentially deepening the notch in the figure but requiring that we compensate the plant out to still higher frequency to control noise amplification.

For broadband control we will use a second-order bandpass filter for the regulation filter given by

$$H(\omega) = Kb\left\{\frac{j(\omega/\omega_0)}{(j\omega/\omega_0 + a)(j\omega/\omega_0 + b)}\right\} \tag{18.67}$$

where ω_0 is the center frequency of the filter.

The frequency response of the filter with $K = 3$, $a = 0.1$, and $b = 10$ is shown in Fig. 18.60. The phase of this filter (not shown) is also bounded by $\pm 90°$ and hence the system would be expected to be stable with no noise amplification, provided the plant is properly compensated. The noise reduction performance of the feedback system employing this regulation filter is shown in Fig. 18.61. The figure shows about 10 dB or more of noise reduction for $0.12 f_0 < f < 8 f_0$. It

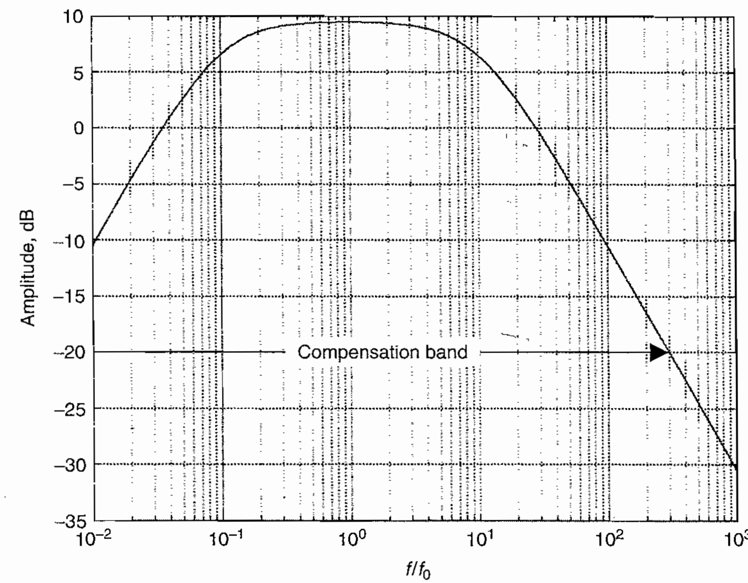

FIGURE 18.60 Frequency response of the broadband second-order regulation filter.

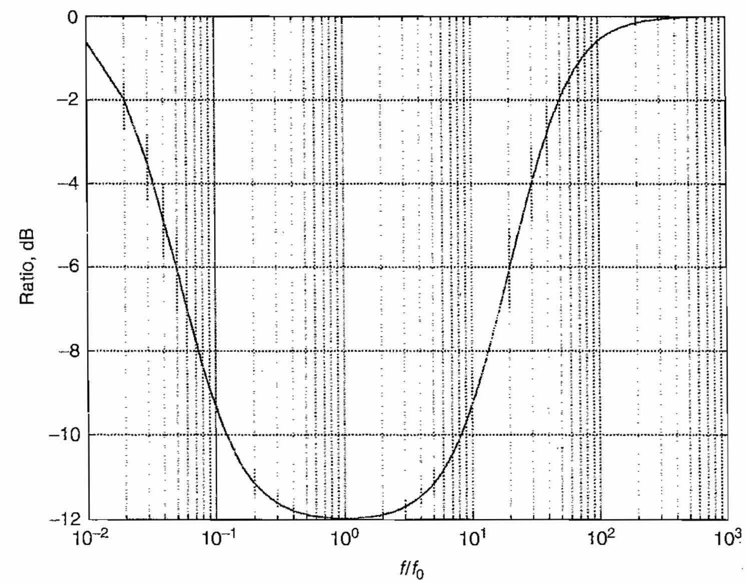

FIGURE 18.61 Ratio of controlled to uncontrolled residual for the broadband regulation filter.

also shows that there is no out-of-band noise amplification above and below the regulation frequency band, as expected.

The above calculations assume that the plant has been perfectly compensated. As for the narrow-band case, the compensation band should be extended out at least far enough in frequency such that the regulation filter gain is small enough to ensure that no matter what the phase, the noise amplification will not exceed 2 dB. Earlier we determined that that criterion would be satisfied if $|H(\omega)| < 0.206$ (-14 dB). Again, to allow for possible increases in loop gain as the compensation is gradually turned off, we introduce some margin by reducing this value by a factor of 2 (6 dB). Consequently, the plant will be compensated until the regulation filter reduces its amplitude to -20 dB. From Fig. 18.60 we can determine that the compensation band must extend out to $300 f_0$, or almost 40 times the highest frequency in the regulation frequency band. Since this is a fairly broad band over which to provide good compensation, it would be interesting to examine what would happen if we used a higher order filter. Since the loop gain associated with a higher order regulation filter would decrease more rapidly with frequency, the compensation band should be narrower. For example, if we simply square the frequency response function of the second-order filter in Eq. (18.67), we would have a fourth-order filter given by

$$H(\omega) = Kb \left\{ \frac{j(\omega/\omega_0)}{(j\omega/\omega_0 + a)(j\omega/\omega_0 + b)} \right\}^2 \tag{18.68}$$

The frequency response function of this filter is shown in Fig. 18.62, which indicates that this filter rolls off much more quickly than the second-order filter. The compensation band now extends out to $\sim 50 f_0$ rather than $300 f_0$. There is, however, a penalty for this higher rolloff. That penalty is illustrated in the Nyquist and Nichols plots of Fig. 18.63 and the noise reduction performance plot of Fig. 18.64. The Nyquist plot shows that the system is stable but that the curve formed by $H(\omega)$ enters the noise amplification region. The Nichols plot shows that the expected noise amplification should be about 2.5 dB, which is confirmed in Fig. 18.64. Finally the regulation frequency band over which the noise reduction is 10 dB or more has been reduced slightly due to the more rapid rolloff of this higher order filter. The noise reduction performance and regulation bandwidth issues can be dealt with by changing the parameter values in the filter frequency response function (with concomitant increases in the compensation bandwidth and noise amplification). However, *the noise amplification generated by this higher order filter occurs even with perfect compensation and is the real reason the low-order filter is preferred.*

Compensation Filter. There are a number of approaches that can be applied to designing the compensation filter. Here we will examine the use of feedforward control filter design techniques, as discussed in Section 18.4, to design a control filter that will converge to the inverse of the plant. The notion for this approach is illustrated in the feedforward control architecture of Fig. 18.65. There the plant,

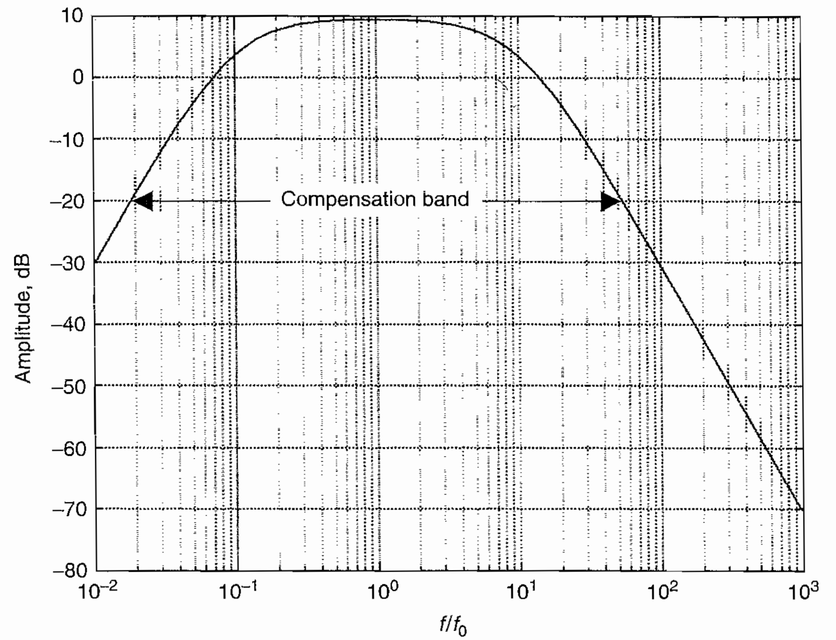

FIGURE 18.62 Frequency response of the broadband fourth-order regulation filter.

$P(\omega)$, and the compensation filter, $G(\omega)$, are connected in series and the disturbance and the residual are the same function, that is, the transfer function $B(\omega)$ in the simplified feedforward architecture of Fig. 18.31 is unity. With this arrangement, the control filter design algorithms will attempt to make $G(\omega)P(\omega) = 1$ or $G(\omega) \approx P(\omega)^{-1}$. Both the direct-estimation and filtered-x design tools can be applied to this problem and the inverses of both MIMO and SISO plants can be determined.

Example. To illustrate this approach, we define the notional position-keeping system for the suspended mass shown in Fig. 18.66. The mass might be machinery that is vibration isolated from the deck of a ship. For frequencies well above ω_0 the suspension system under the mass will reduce the excitation of the deck due to machine vibration from imbalance, for example. Our position-keeping system prevents the machinery from striking the deck when the ship encounters rough seas. In this system the relative displacement between the machine and the deck is measured and used as the input to a controller. The controller in turn generates a control force to minimize that relative deflection so that the machine and the deck do not come into contact. The control force could be generated by an inertial shaker or an interstructural shaker between the deck and the machine.

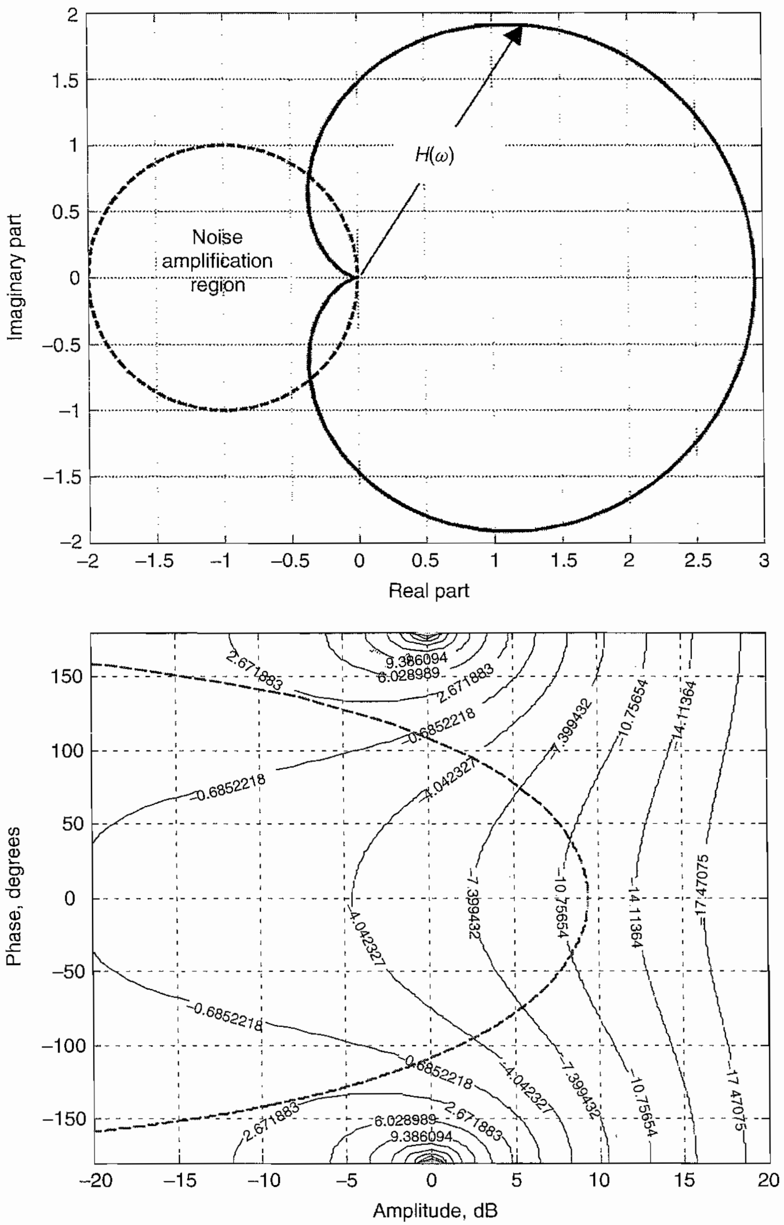

FIGURE 18.63 Nyquist and Nichols plot for the broadband fourth-order regulation filter.

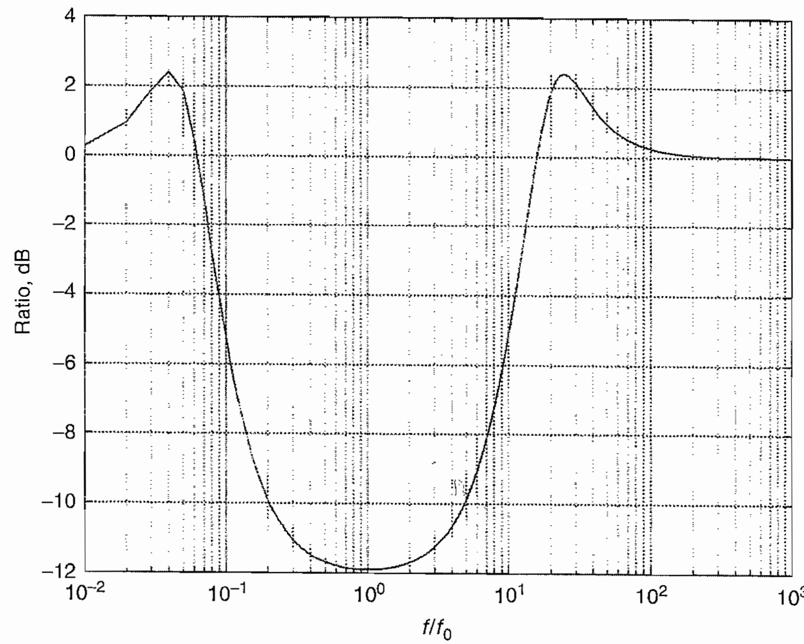

FIGURE 18.64 Ratio of controlled to uncontrolled residual for the broadband fourth-order regulation filter.

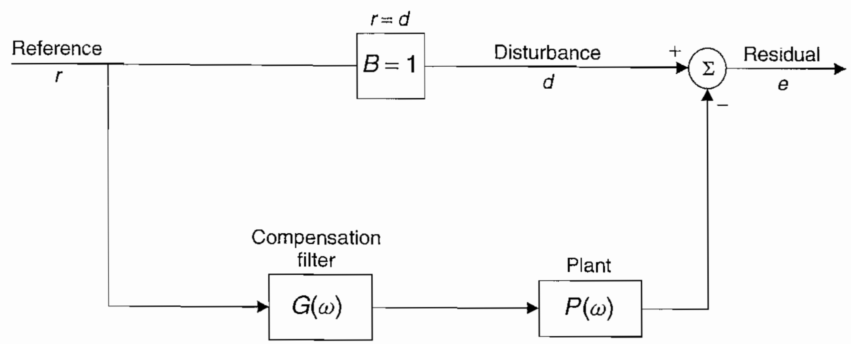

FIGURE 18.65 Feedforward architecture for estimating the plant inverse.

The plant for this system, which is the ratio of the relative deflection between deck and machine to actuator force is given by

$$P(\omega) = \frac{1}{M\omega_0^2\{1 - (\omega/\omega_0)^2 + j(\omega/\omega_0)\eta\}} \tag{18.69}$$

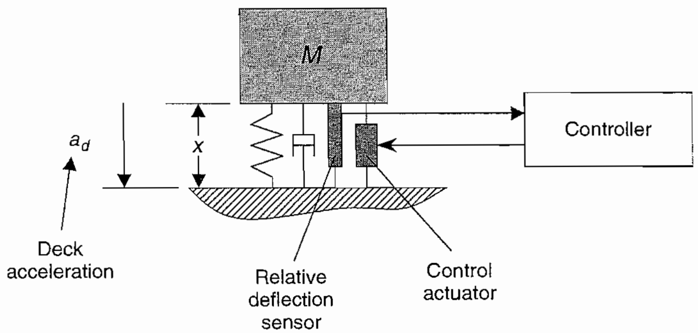

FIGURE 18.66 Notional feedback position-keeping system.

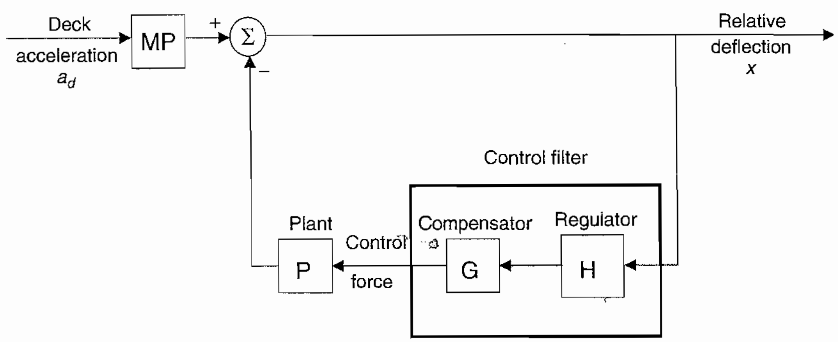

FIGURE 18.67 Block diagram of the notional feedback position-keeping system.

where ω_0 is the natural frequency of the mass on its suspension and η is the loss factor for the system. The feedback control system block diagram for our notional position-keeping system is shown in Fig. 18.67.

The parameter values that we will use are

$$f_o = \frac{\omega_0}{2\pi} = 25 \text{ Hz} \qquad \eta = 0.1$$

For this calculation we will not use any anti-aliasing or reconstruction filters but will rely on the plant itself to provide low-pass filtering. If we were to use any additional low-pass filtering, the frequency response of those filters would simply be included with the plant, since the compensation filter will have to compensate for the amplitude and phase variations of those components as well. In a real system with more complex high-frequency response than our simple notional system we would probably not be able to eliminate anti-aliasing and reconstruction filters, but eliminating them here simplifies the example. Finally, we must account

for the half-sample delay introduced by the sample-and-hold D/A converters. We simply include that delay in the plant frequency response function.

For a regulation filter we will use the second-order broadband filter of Eq. (18.67) with the following parameters:

$$K = 3 \qquad a = 0 \qquad b = 10$$
$$f_o = \frac{\omega_0}{2\pi} = 1$$

These parameters make the regulation filter have the low-pass characteristics illustrated in Fig. 18.68. The filter has a nominal loop gain of ~10 dB out to ~10 Hz.

Based on the results in Fig. 18.60, we know that the compensation band will need to extend out to about 40 times the highest frequency in the regulation band or out to 400 Hz. Since we cannot expect to design a compensation filter that will be effective right out to the Nyquist frequency (one-half the sampling rate), we will put in a margin of safety and use a sampling rate of 1000 Hz, which gives a Nyquist frequency of 500 Hz. Using the direct-estimation filter design technique

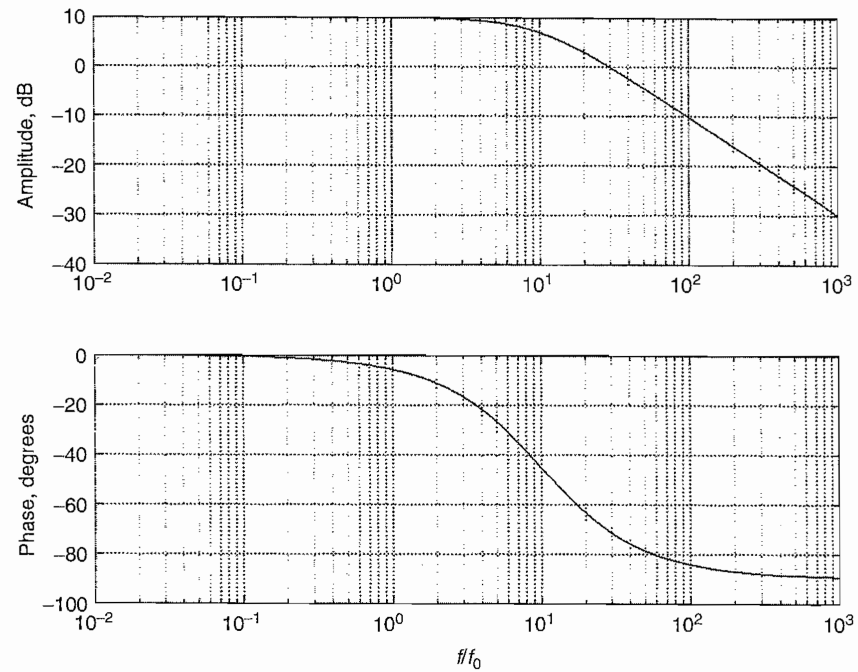

FIGURE 18.68 Amplitude and phase of the regulation filter.

of Section 18.4 for the system in Fig. 18.65, we obtain a 50-tap compensation filter $G(\omega)$ that when multiplied by the plant transfer function gives the result shown in Fig. 18.69. If the filter were a perfect compensator, the amplitude of $G(\omega)P(\omega)$ would be unity and the phase would be zero.

The figure shows that the amplitude is very close to unity almost all the way to the Nyquist frequency.* The phase, however, reaches almost 180° at 300 Hz, which indicates that we should expect some noise amplification due to imperfect compensation. That expectation is confirmed in the Nichols plot of Fig. 18.70 and the noise reduction performance plot of Fig. 18.71, which each slow a little over 2 dB of noise amplification. The Nyquist plot also in Fig. 18.70 shows that the system is stable. The noise reduction performance in Fig. 18.71 shows that 10 dB of noise reduction has been achieved up to more than 10 Hz.

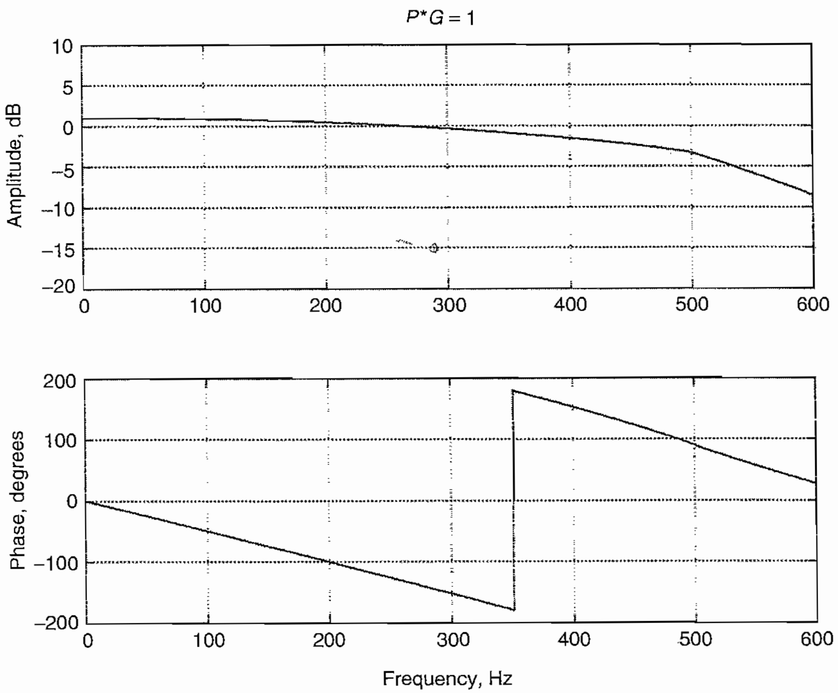

FIGURE 18.69 Amplitude and phase of the product of the compensation filter and the plant transfer function $\{G(\omega)P(\omega)\}$ as a function of frequency.

*Note that in computing the compensation filter using the direct-estimation approach it is sometimes necessary to introduce a small delay in the block diagram of Fig. 18.65 to deal with uncompensatable delays in the plant. Instead of setting $B(\omega) = 1$, we set it to $B(\omega) = e^{-j\omega\lambda T}$, where T is the sample period and λ a constant representing the length of the delay in sample periods. While introducing some phase error in the compensator, this approach often results in a better plant compensator than if no delay were introduced. For the case examined here best results were obtained with $\lambda \sim 1.5$.

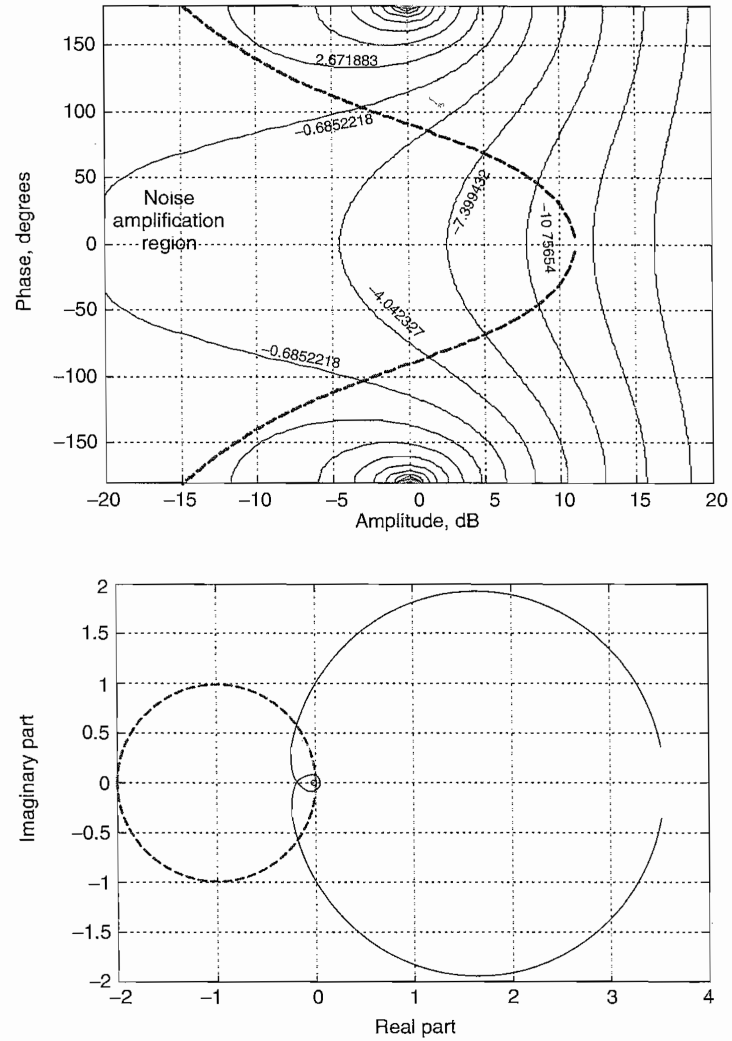

FIGURE 18.70 Nichols and Nyquist plots for the feedback control system of Fig. 18.67.

This example points out how feedback control systems can make severe demands on hardware, typically much more severe than feedforward systems. To achieve 10 dB of noise reduction out to 10 Hz required in this case a sampling rate of 1 kHz, 100 times higher than the regulation bandwidth. *Such a huge factor between regulation bandwidth and compensation bandwidth is not uncommon and is one of the reasons why feedforward systems are often favored over feedback.*

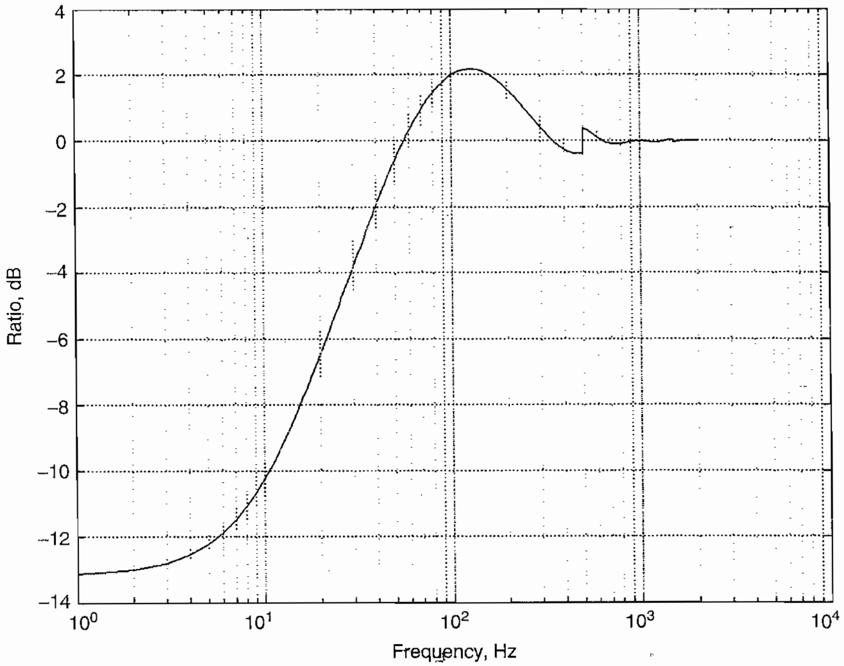

FIGURE 18.71 Ratio of controlled to uncontrolled residual for the feedback control system of Fig. 18.67.

18.6 CONTROL SYSTEM DESIGN CONSIDERATIONS

In this section, we discuss the process and steps involved in designing and implementing a successful ANVC system. This process is illustrated in the flow chart of Fig. 18.72 As shown, the first step is to establish design goals and requirements, which include performance goals and objectives. These goals, together with experimental data or structural–acoustic models, are used to conduct simulations to predict achievable system performance. These performance simulations typically involve trade-off studies of system performance as a function of actuator output levels, sensor dynamic ranges and noise floors, control algorithms, architecture, and controller parameters (e.g., sample rate, analog filter characteristics, digital filter sizes, computational load, and memory requirements). These simulations ultimately guide decisions concerning hardware selection, such as analog filtering, A/D and D/A converters, and digital-controller hardware. The output of this simulation step is a set of design specifications for the sensor and actuator subsystems as well as for the controller (i.e., control algorithm and architecture). Preliminary and detailed designs are then performed to produce sets of component specifications for each subsystem as well as interface control documentation between each subsystem and with the system to be controlled. At this

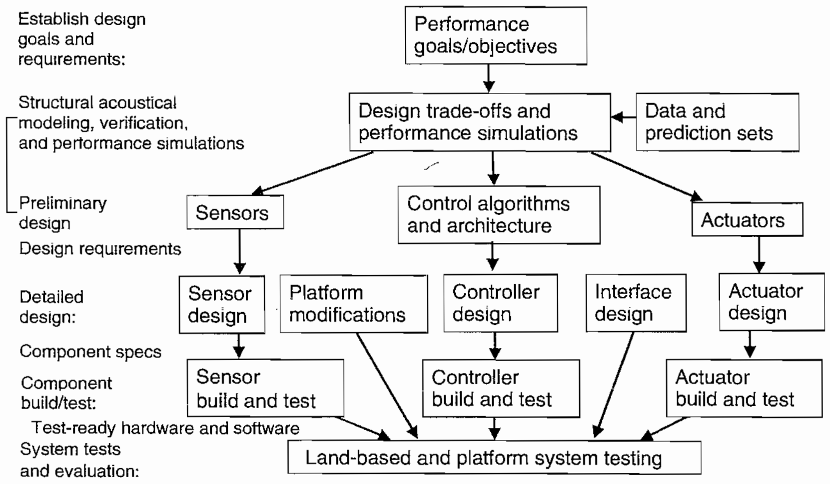

FIGURE 18.72 Flow chart for ANVC system development and implementation.

point, the subsystems are acquired if they are commercially available and fabricated if not. Each is then tested to ensure that both hardware and software meet specifications. The components are then integrated with the system to be controlled. Typically, a series of tests is conducted to validate system performance. If successful, more extensive in-service testing is usually performed to determine long-term performance and reliability before the prototype system is transformed into a commercial product or deployable system. That transformation, which can be an extensive and costly process, is not discussed here.

In the sections that follow, we discuss the major steps in this development process, including identification of performance goals, specification of actuator and sensor requirements, and selection of control architecture. Also discussed in what follows are the benefits of conducting both non causal and causal performance simulations; practical considerations concerning hardware selection of analog filters, D/A and A/D converters, and digital signal processors; and an overview of issues related to control system user interface, operating modes of the system, and system testing guidelines.

Identifying Performance Goals

Identifying performance goals is an important, yet often overlooked, first step in developing an ANVC system. Performance goals state what effect the control system should have on a particular physical quantity as a function of frequency. A schematic that is useful for discussing performance goals is shown in Fig. 18.73. This figure shows two conceptual curves as a function of frequency. The solid curve is representative of the uncontrolled response (e.g., mean-square vibration level on a particular component). The dashed curve is the desired mean-square

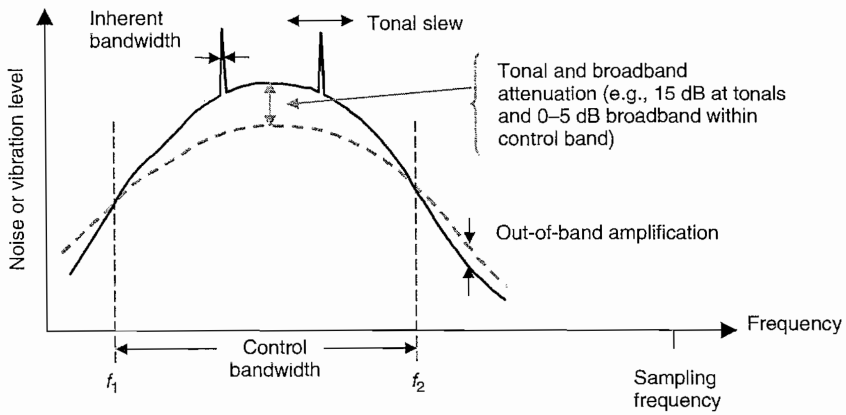

FIGURE 18.73 Schematic of performance goal specification, uncontrolled response (solid line), controlled response (dashed line).

response as a result of implementing an ANVC system. This desired response may be required to meet product specifications or may be related to meeting certain radiated noise specifications. In either case, the difference between these two curves identifies the reductions, as a function of frequency, that are required. As an example, the performance goals for the case illustrated in Fig. 18.73 might include the following:

- Reduce tonal components in mean-square vibration response by at least 15 dB.
- Maintain tonal performance in the presence of slewing tonals (e.g., where the tonal frequency changes over time at a rate of less than 3 Hz/s).
- Reduce broadband mean-square response in the control band (i.e., between frequencies f_1 and f_2) by 0–5 dB.
- Maintain performance in the presence of changes in the dynamics of the system (i.e., plant) that will occur over time.
- Limit out-of-band noise amplification to less than 2 dB at any frequencies outside the control band.

Identifying performance goals is important for several reasons. First, the expectations for the ANVC system are clearly stated and can be evaluated versus practically achievable ANVC performance. For example, typical ANVC systems can provide 15–20 dB of tonal reductions, depending on the slew rate of the tonals. Further, broadband performance in excess of 10 dB is typically associated with some level of out-of-band amplification. Second, these specifications will directly impact implementation aspects of the ANVC system. With regard to the above example, we can make the following initial observations. The broadband performance requirement will require a feedback implementation

or a feedforward implementation with reference sensors that are well correlated with the mean-square response to be controlled. The need to provide additional reductions at slewing tonal frequencies will require control filters that adapt relatively quickly in response to changing tonal frequency. In addition, since the plant transfer functions are expected to change over time, the control system will need to support concurrent system identification and adaptation to track relatively slower changes in the system dynamics. Finally, the constraint on noise amplification will impact the bandwidth of a feedback implementation (as discussed in Section 18.5) and probe signal design (as discussed in Section 18.4 under System Identification).

In general, the performance goals will have a direct impact on *all* aspects of the ANVC system design (e.g., sensors, actuators, and controller). In the next sections, we discuss how the performance goals impact each of these subsystems. In particular, we discuss procedures to answer the following questions:

- What number of actuator channels is required?
- Where should the actuators typically be located?
- What are the output drive requirements (force, volume velocity, etc.) for the actuators?
- What is the number of sensor channels required?
- Where should sensors typically be located?
- What control algorithm/architecture can be used to design control filters that will maximize achievable system performance?
- Is it likely that the program goals can be met (at least throughout the frequency range of the available models) with a reasonable number of actuator and sensor channels and with a causal controller?

These questions will be addressed within the context of the technical approach illustrated in the flow diagram of Fig. 18.74. As shown along the left side, the approach involves three sequential studies:

- Controllability: where to place the actuators.
- Observability: where to place the sensors.
- Realizability: how to design causal control filters.

Number, Location, and Sizing of Actuators

Actuator and sensor placement studies require either a model of the system to be controlled [e.g., finite-element model (FEM), lumped-parameter model] or access to experimental data from the system itself. The first questions to be addressed are where actuators should be located, how many are necessary as a function of achievable performance, and what size of actuator is needed (shaker maximum force output, speaker maximum volume velocity, etc.) to effectively drive the system and provide control.

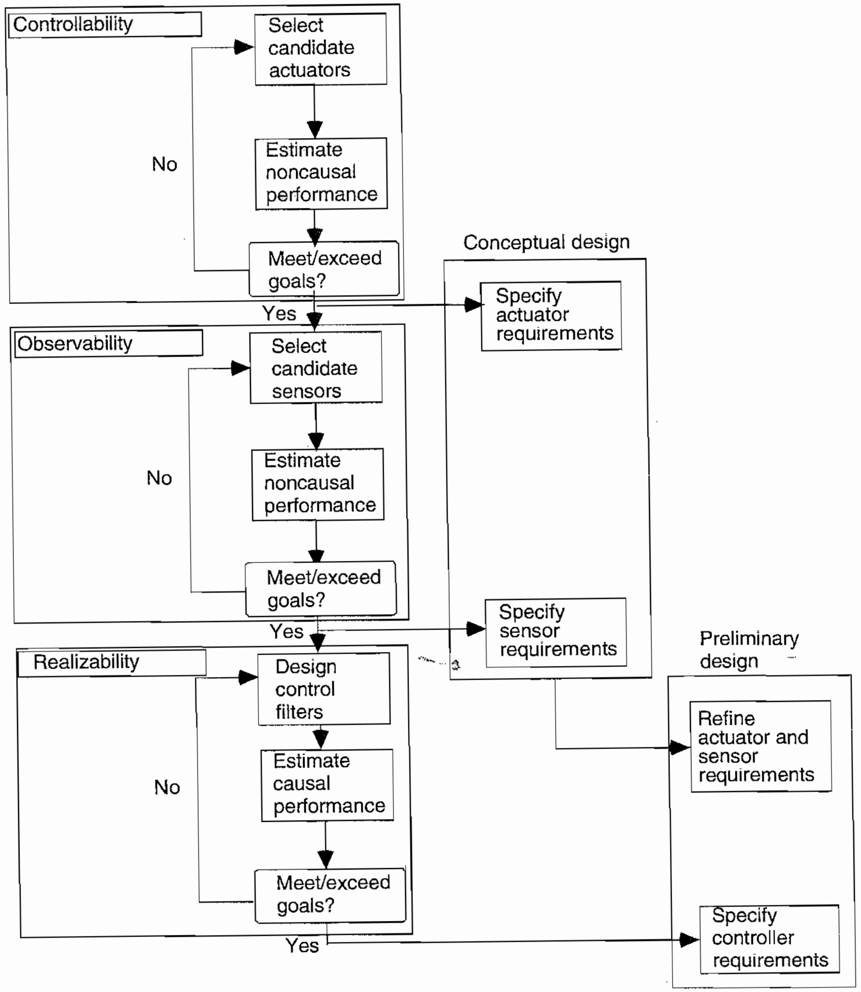

FIGURE 18.74 Flow diagram for ANVC strategy selection.

Number of Actuators. The question of how many actuator channels are required can be roughly estimated from experimental data or model results of the response to be controlled. For example, suppose that the response to be controlled is the mean-square vibration response on a component that is characterized by L point response measurements. The minimum number of actuator channels is equal to the number of independent ways the system is responding at the L measurement locations (referred to as *response dimensionality*) on a frequency-by-frequency basis. The response dimensionality can be estimated by computing the singular-valued decomposition (SVD) of the cross-spectral density (CSD)

matrix of the L responses. We can express this CSD matrix as

$$[\mathbf{S_{ee}}] = [\mathbf{T}][\mathbf{S_{dd}}][\mathbf{T}]^H \tag{18.70}$$

where $[\mathbf{S_{dd}}]$ = cross-spectral density matrix of disturbance
$[\mathbf{T}]$ = transfer function matrix from source(s) to L response locations
$[\cdot]^H$ = conjugate transpose of matrix

Note that $[\mathbf{S_{ee}}]$ can be evaluated directly by measuring the CSD matrix of a number of sensors at candidate locations. As an alternate approach analytical/numerical models of the system to be controlled can be used to estimate $[\mathbf{T}]$ along with approximations to $[\mathbf{S_{dd}}]$* in Eq. (18.70) to estimate $[\mathbf{S_{ee}}]$.

The SVD of a matrix $[\mathbf{A}]$ is defined as

$$\text{svd}\{[\mathbf{A}]\} = [\mathbf{U_A}][\boldsymbol{\lambda}_\mathbf{A}][\mathbf{V_A}]^T \tag{18.71}$$

where $[\mathbf{U_A}]$ and $[\mathbf{V_A}]$ are unitary matrices containing the left and right singular vectors of $[\mathbf{A}]$ and $[\boldsymbol{\lambda}_\mathbf{A}]$ is a diagonal matrix containing the singular values for $[\mathbf{A}]$ ranked from largest to smallest.[60] A typical plot of the singular values of $[\mathbf{S_{ee}}]$ (i.e., diagonal elements of $[\boldsymbol{\lambda}_\mathbf{e}]$) at a particular frequency will reveal several large (i.e., significant) singular values followed by a transition to a region containing smaller (i.e., less significant) singular values. An example of this type of plot, where the singular values are normalized by the largest, is shown in Fig. 18.75. These types of plots can be conveniently generated using the svd function in MATLAB.

The number of large singular values of $[\mathbf{S_{ee}}]$ at a given frequency indicates the number of significant and independent ways in which the disturbances on the system express themselves at the L measurement locations. At any frequency, the number of significant singular values is equal to the minimum of

- the number of independent disturbances acting on the structure (termed *source dimensionality*),
- the number of structural degrees of freedom (i.e., modes),
- the number of measurement responses (ie, sensors), and
- degrees of freedom of spectral estimates (i.e., number of ensemble averages in estimating the CSD matrix from experimental data).

As such, care must be taken to ensure that the estimated response dimensionality is not limited by using too few sensors, by insufficient averaging if $[\mathbf{S_{ee}}]$ is measured, or by too few sources and sensors if analytical models are used to estimate $[\mathbf{S_{ee}}]$. We note that controlling the response characterized by the L measurement

*For analytical/numerical simulations, where the CSD of the disturbances may be unknown, it is often sufficient to assume a large number of candidate disturbance locations and use a disturbance CSD matrix in Eq. (18.70) equal to the identity matrix at all frequencies of interest. This corresponds to the case where the sources are statistically independent with unit variance at each frequency.

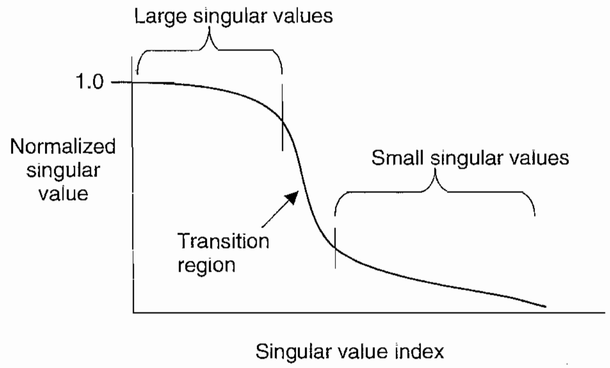

FIGURE 18.75 Typical decay of singular values of a sensor CSD matrix, normalized by the largest singular value.

locations will require at least as many actuator *channels** as significant singular values of $[\mathbf{S_{ee}}]$. Thus, this approach establishes a lower bound on the number of required actuator channels.

Finally, we make two remarks concerning the use of SVD spectra to determine lower bounds on the number of actuator channels. First, since the number of significant singular values will typically increase as a function of frequency (because the number of modes supported by the system increases with frequency), the number of required actuator channels is often dictated by the singular-value spectra at high frequency. Second, the transition region in Fig. 18.75 may be gradual rather than showing a distinct "knee." For those cases, a useful "rule of thumb" is that the number of significant singular values at a given frequency is equal to the number of singular values whose magnitude is within, say, 30 dB of the largest singular value.

Actuator Locations. The selection of specific actuator locations is typically the result of an optimization procedure to select the best K locations from a set of M possible locations ($M > K$). This procedure requires the response CSD discussed above as well as the $L \times M$ transfer function matrix $[\mathbf{P}]$ between the M possible actuator locations and the L sensor responses. An exhaustive search over all combinations to determine the optimal set of K actuator locations would require a search of $\dfrac{M!}{[K!(M-K)!]}$ possibilities. This can be a daunting task for even modest values of K and M. When this is the case, it is often useful to invoke suboptimal techniques to choose a "good" set of actuators.

One suboptimal approach that has been used successfully is based on Gram–Schmidt orthogonalization.[60] Given M candidate actuator locations,

*The term *actuator channels* is not necessarily the same as the number of actuators. For instance, a group of 10 actuators driven coherently requires only a single output channel from a controller.

choose the one that maximizes reductions in the trace of $[\mathbf{S_{ee}}]$. In this context, the best candidate is the column of $[\mathbf{P}]$ that is "most parallel" to the L sensor responses caused by the disturbances, integrated across frequency. Once an actuator (i.e., column of $[\mathbf{P}]$) is chosen, components of $[\mathbf{S_{ee}}]$ and remaining columns of $[\mathbf{P}]$ in the direction of the chosen column of $[\mathbf{P}]$ are removed. The process is repeated K times, where the value of K is estimated from SVD spectra of $[\mathbf{S_{ee}}]$. Variants of this procedure are discussed by LePage et al.[42] and Heck et al.[83] An interesting comparison of alternative procedures for selecting source locations based on using genetic algorithms and simulated annealing is discussed by Elliott.[58]

Regardless of the selection procedure, the mean-square response of the L sensors can be estimated assuming all actuators chosen so far can be used in an optimal, unconstrained sense. That is, we assume a controller can be developed to produce the required magnitude and phase spectra to drive each output channel. At each frequency, the L *vector* of residual responses $\boldsymbol{\varepsilon}$ can be expressed in terms of the L *vector* of uncontrolled responses $\mathbf{e}$ and the k *vector* of actuator drive signals $\mathbf{a}$ (for $k \le K$) acting though the $L \times k$ plant transfer function matrix $[\mathbf{P}]$:

$$\boldsymbol{\varepsilon} = [\mathbf{T}]\mathbf{d} + [\mathbf{P}]\mathbf{a} = \mathbf{e} + [\mathbf{P}]\mathbf{a} \tag{18.72}$$

The optimal solution for $\mathbf{a}$ to reduce the residual mean-square response $\mathrm{tr}\{[\mathbf{S_{ee}}]\}$ at each frequency is

$$\mathbf{a} = -[\mathbf{P}]^{\#}\mathbf{e} \tag{18.73}$$

where # signifies the pseudoinverse, which can be conveniently computed using the pinv function in MATLAB or by the expression defined in Section 18.4 under Extension to MIMO Systems.

As a consequence, the optimal noise reduction (NR, in decibels) of the mean-square response using the selected actuators is

$$\mathrm{NR} = -10 \log_{10}\left(\frac{\mathrm{tr}\{[\mathbf{S}_{\boldsymbol{\varepsilon\varepsilon}}]\}}{\mathrm{tr}\{[\mathbf{S_{ee}}]\}}\right) \tag{18.74}$$

where

$$[\mathbf{S_{ee}}] = E\{\mathbf{e}\mathbf{e}^{\mathbf{H}}\} = [\mathbf{T}][\mathbf{S_{dd}}][\mathbf{T}]^{\mathbf{H}}$$
$$[\mathbf{S}_{\boldsymbol{\varepsilon\varepsilon}}] = [\mathbf{I} - \mathbf{PP}^{\#}][\mathbf{S_{ee}}][\mathbf{I} - \mathbf{PP}^{\#}]^{\mathbf{H}} \tag{18.75}$$

In Eq. (18.75), $[\mathbf{S_{ee}}]$ is the CSD matrix of the *uncontrolled* responses at the L residual sensor locations. This can be estimated from experimental data (i.e., $E\{\mathbf{e}\mathbf{e}^{\mathbf{H}}\}$) or can be computed using transfer functions from source-to-residual locations, $[\mathbf{T}]$, based on analytical models (i.e., lumped-parameter or FEM), and an assumed CSD matrix of the sources, $[\mathbf{S_{dd}}]$, for example, the unit matrix as described above.

Equation (18.74) can be plotted frequency by frequency (or integrated across the frequency bandwidth of concern) to determine an upper bound on system performance, parameterized by the number of assumed actuators, as shown in Fig. 18.76. These performance predictions represent upper bounds because at this point we have not placed any causality constraints on the control filter, and we have not identified what sensor signals will be used as inputs to the controller. As such, these predictions are referred to as noncausal predictions, corresponding to those identified in Fig. (18.74) pertaining to controllability. Since Eq. (18.74) represents an upper bound on achievable performance as a function of frequency for the selected actuator set, it provides a first-order assessment as to whether the identified performance goals are achievable.

Actuator Sizing. A critical issue in the design of an active control system is the sizing of the actuators. Actuators with too little drive capacity will result in an underperforming control system, while actuators with too much capacity may impose excessive weight or cost penalties. A rough guide is that the actuators must be able to create response levels at the residual sensors that are comparable to the levels observed there due to the disturbance. A more precise estimate of the required drive levels from the actuators can be determined from the diagonal elements of $[\mathbf{S_{aa}}]=[\mathbf{P}]^{\#}[\mathbf{S_{ee}}][\mathbf{P}^{\#}]^{\mathbf{H}}$, which correspond to the power spectra of the required drive signals to each actuator. For this calculation $[\mathbf{S_{ee}}]$ should be based on measurements unless good analytical models of the disturbances and their CSD matrix, $[\mathbf{S_{dd}}]$, are available. The square root of the integrated mean-square levels of each diagonal term across frequency provides an estimate of the rms levels for each drive signal. Peak drive requirements can be estimated from these

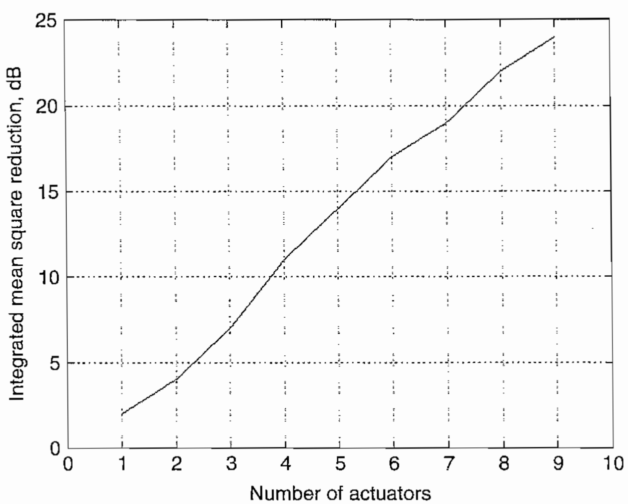

FIGURE 18.76 Example of noncausal performance versus number of actuator channels.

rms levels by applying an appropriate crest factor (i.e., ratio of the peak value of a waveform to its rms value). For pure-tone cases, the crest factor is 1.41; for broadband noise, the crest factor will depend on the statistics of the disturbance. A useful approximation to the crest factor for random noise is 4.

Note that if the plant [**P**] used in the equations above relates actuator output (force, volume velocity, etc.) to the residual channel responses, then the diagonal elements of $[\mathbf{S_{aa}}]$ (and the associated rms and peak levels) correspond to the actual actuator drive level (e.g., pounds, cubic feet per minute) that must be delivered to the structure by the actuators to produce the predicted performance. As such, these predictions provide initial actuator sizing information.

Number and Location of Sensors

The goals and requirements for selecting residual and reference channels are summarized below.

Residual Sensor Channel Selections for Feedforward and Feedback Strategies. The goal is to determine a minimal set of measurable responses that are

- well correlated with the radiated noise or vibration response to be controlled,
- nominally colocated with actuators for feedback control, and
- consistent with satisfying "obvious" causal constraints*: at or "downstream" of actuators for feedforward control strategy.

Reference Sensor Channel Selection (for Only Feedforward Strategy). The goal is to determine a minimal set of measurable responses that are

- well correlated with the disturbance sources,
- well correlated with candidate residual channels,
- consistent with satisfying obvious causal constraints: with sufficient "lead time" to implement an effective causal controller (i.e., located sufficiently "upstream" of the actuators).

Approaches for determining sensor channels that meet these goals and requirements are presented below.

Number of Sensors. If the number of residual sensors is equal to the number of control actuators, it is theoretically possible to achieve infinite noise reduction in a feedforward system. Of course, very large noise reduction at residual

*By obvious causal constraints, we rule out consideration of residual sensors that are closer to the sources than the selected actuator locations (i.e., upstream of the actuator locations). Similarly, we rule out consideration of reference sensor locations that are downstream of (farther away from the sources than) the actuator locations.

sensors does not necessarily mean that the system will also provide good noise reduction globally. Alternatively, if the number of control actuators exceeds the number of residual sensors, the system is overdetermined and the control effort may be excessive with some actuators competing against others unless control effort weighting is carefully included in the control filter design algorithm. Most practical systems have more residual sensors than control actuators so that the noise reduction is less concentrated at the residual sensor locations, resulting in more uniform global control.

The selection of residual and reference sensors (when required or available) can be determined following similar procedures to those outlined for actuator selection. As before, it is advisable to perform SVD analyses of candidate residual and reference CSD matrices to determine the minimum number of channels necessary to characterize the response caused by the disturbances at those locations. Since response dimensionality will never increase as measurement locations move away from the sources, it is common that the response dimensionality at the reference sensor locations will exceed that at the residual sensor locations. We note, however, that the number of sensors necessary to characterize the response dimensionality may exceed the number of sensor channels determined by the dimensionality studies, as, for example, when arrays of sensors are processed to characterize modal responses of a system.

If the response to be controlled is already known, the choice of residual sensing may be relatively straightforward. For example, if the mean-square response of a plate structure on a machine is to be reduced, it may be sufficient to instrument that plate with L point sensors, where L exceeds the response dimensionality of the plate (e.g., number of significant modes). Subsets of these L sensors can also be considered to determine the sets that when minimized in an optimal sense will produce the largest mean-square reductions of the full set of L sensors. Again, either exhaustive or suboptimal search techniques can be used.

For cases where reducing radiated noise is the main objective, it may not be possible to use residual sensor inputs to the controller that directly measure the noise field. Instead, for these cases, residual sensors must be located on the machine or device to be controlled. Selection of these on-board sensors is typically the result of using detailed radiation models to determine which on-board sensor responses are highly correlated with the radiated noise. If models or experimental data that include radiated noise information are available for this purpose, then candidate residual sensors can be selected using the exhaustive or suboptimal search techniques discussed above.

Residual Sensor Evaluation. As was done when considering actuator selection, the resulting sets of residual sensors obtained at each step can be evaluated to assess the maximum achievable performance as a function of the number of residual channels. In particular, reductions in the mean-square response of the selected residual channels can be determined using Eq. (18.74), where the optimal drive vector $\mathbf{a}$ in Eq. (18.73) is chosen to minimize only the candidate set of residual channels. These drives are then used in Eq. (18.72) to estimate the

reductions in mean-square performance across a larger and more complete set of residual channels, or the radiated noise response. Again, these predictions represent upper bounds on achievable noncausal performance assuming fixed sets of actuators and residual sensors. That is, we again assume that a controller can be developed to produce the spectral magnitudes and phases that are necessary to drive each output channel to reduce the mean-square residual response in an optimal sense.

Alternatively, residual sensors can be selected simultaneously with implementing the procedure for estimating performance. A similar approach can be used to select reference sensors for a feedforward system. Details of this approach are discussed below with respect to evaluating reference and residual sensors for the case where residual sensors cannot directly measure radiated noise.

Assuming statistical quantities, we define the following frequency domain relationships between the vectors of radiated pressures (or some other desired residual which cannot be measured directly by the control system) $\mathbf{p}$, residual channels $\mathbf{e}$, and reference channels $\mathbf{r}$ and the vector of disturbances $\mathbf{d}$,

$$\mathbf{p} = [\mathbf{Q}]\mathbf{d} \qquad \mathbf{e} = [\mathbf{T}]\mathbf{d} \qquad \mathbf{r} = [\mathbf{R}]\mathbf{d} \tag{18.76}$$

where $[\mathbf{Q}]$, $[\mathbf{T}]$, and $[\mathbf{R}]$ are the transfer function matrices relating the disturbances to the radiated pressure, residual channels, and reference channels, respectively. For purposes of the discussion below, we assume that either the transfer functions $[\mathbf{Q}]$, $[\mathbf{T}]$, and $[\mathbf{R}]$ are available from analytical models (e.g., lumped-parameter or FEM) or the response vectors $\mathbf{p}$, $\mathbf{e}$, and $\mathbf{r}$ are available from experimental data.

The radiated pressure can be related to the residual channels as

$$\mathbf{p} = [\mathbf{H_e}]\mathbf{e} + \mathbf{n} \tag{18.77}$$

where $\mathbf{n}$ represents the radiated pressure response that is uncorrelated with (or unobserved by) the residual channels. Assuming that $\mathbf{e}$ and $\mathbf{n}$ are independent statistical responses, we can obtain an expression for $[\mathbf{H_e}]$ in terms of the CSD matrix of the uncontrolled residual $[\mathbf{S_{ee}}]$ and the CSD matrix between the pressure and residual channels $[\mathbf{S_{ep}}]$:

$$[\mathbf{H_e}] = [\mathbf{S_{ep}}][\mathbf{S_{ee}}]^{-1} \tag{18.78}$$

As discussed earlier with regards to Eq. (18.75), $[\mathbf{S_{ee}}]$ is the CSD matrix of the *uncontrolled* responses at the L residual sensor locations and can be estimated from experimental data (i.e., $E\{\mathbf{ee^H}\}$) or can be computed by using transfer functions from source-to-residual locations, $[\mathbf{T}]$, based on analytical models (i.e., lumped-parameter or FEM), and an assumed CSD matrix of the sources, $[\mathbf{S_{dd}}]$. Similarly, $[\mathbf{S_{ep}}]$ is the CSD matrix of the uncontrolled responses of the pressure and residual sensors. It can be estimated from experimental data (i.e., $E\{\mathbf{pe^H}\}$) or be computed from analytical models for [**T**] and [**Q**] together with an assumed CSD matrix of the sources, [$\mathbf{S_{dd}}$]:

$$[\mathbf{S_{ep}}] = [\mathbf{Q}][\mathbf{S_{dd}}][\mathbf{T^H}] \tag{18.79}$$

We can now write an expression for the maximum noise reduction, at each frequency, that can be achieved by eliminating the response in the radiated pressure that is correlated with the chosen set of residual channels:

$$\mathrm{NR}_p = 10\log_{10}\left(\frac{\mathrm{tr}\{[\mathbf{S_{pp}}] - [\mathbf{H_e}][\mathbf{S_{ee}}][\mathbf{H_e^H}]\}}{\mathrm{tr}\{[\mathbf{S_{pp}}]\}}\right) \tag{18.80}$$

where

$$[\mathbf{S_{pp}}] = [\mathbf{Q}][\mathbf{S_{dd}}][\mathbf{Q^H}] \qquad [\mathbf{S_{ee}}] = [\mathbf{T}][\mathbf{S_{dd}}][\mathbf{T^H}] \tag{18.81}$$

Note that if there is no correlation between the residual sensors and radiated pressure, then NR_p will equal 0 dB. If the output is entirely due to the input (i.e., the residual sensors are perfectly correlated with the radiated pressure, then NR_p will be infinite (i.e., $-\infty$ decibels).

The evaluation of Eq. (18.80) requires either measured data or analytical/numerical models of the system to be controlled. If *simultaneous* measurements of the residual sensors, **e**, and the desired residual, **p**, are available, then the data can be processed to generate the cross-spectra density matrices [$\mathbf{S_{ep}}$], [$\mathbf{S_{ee}}$], and [$\mathbf{S_{pp}}$]. Equation (18.78) can then be used to determine [$\mathbf{H_e}$], which can then be substituted along with [$\mathbf{S_{ee}}$] and [$\mathbf{S_{pp}}$] into Eq. (18.80). If, on the other hand, analytical/numerical models are available, they can be used to estimate the transfer function matrices [**Q**] and [**T**]. If the CSD of the disturbance [$\mathbf{S_{dd}}$] is then taken to be the unit matrix as described earlier, then [$\mathbf{S_{ep}}$], [$\mathbf{S_{ee}}$], and [$\mathbf{S_{pp}}$] can be easily estimated from the equations given above, allowing the evaluation of Eq. (18.80) as if measured data were available.

Reference Sensor Evaluation. In a similar fashion, the procedure outlined above can be used to select reference sensors that are highly correlated with the residual and/or radiated pressure. The residual channels can be related to the reference channels as

$$\mathbf{e} = [\mathbf{H_r}]\mathbf{r} + \mathbf{m} \tag{18.82}$$

where **m** represents the response in the residual channels that is uncorrelated with (or unobserved by) the reference channels. Following the procedure outlined above, the maximum reduction in the mean-square response of the residual channels, **e**, assuming a set of reference sensors **r** is given by

$$\mathrm{NR}_e = 10\log_{10}\left(\frac{\mathrm{tr}([\mathbf{S_{ee}}] - [\mathbf{H_r}][\mathbf{S_{rr}}][\mathbf{H_r^H}])}{\mathrm{tr}([\mathbf{S_{ee}}])}\right) \tag{18.83}$$

where

$$[\mathbf{S_{ee}}] = [\mathbf{T}][\mathbf{S_{dd}}][\mathbf{T^H}] \qquad [\mathbf{S_{rr}}] = [\mathbf{R}][\mathbf{S_{dd}}][\mathbf{R^H}] \tag{18.84}$$

and

$$[\mathbf{H_r}] = \mathbf{S_{re}}[\mathbf{S_{rr}}]^{-1} \tag{18.85}$$

The expression given in Eq. (18.83) represents the maximum reduction, at each frequency, that can be achieved by eliminating the response in the residual channels that is correlated with the chosen reference channels. If there is no correlation between the residual sensors and radiated pressure, then NR_e will equal 0 dB. If the output is entirely due to the input (i.e., the residual sensors are perfectly correlated with the radiated pressure, then NR_e will be infinite.

As with the residual sensors the evaluation of Eq. (18.83) requires either measured data or analytical/numerical models of the system to be controlled. If simultaneous measurements of the residual sensors, **e**, and the reference sensors, **r**, are available, then the data can be processed to generate the cross-spectra density matrices [$\mathbf{S_{er}}$], [$\mathbf{S_{ee}}$], and [$\mathbf{S_{rr}}$]. Equation (18.85) can then be used to determine [$\mathbf{H_r}$], which can then be substituted along with [$\mathbf{S_{ee}}$] and [$\mathbf{S_{rr}}$] into Eq. (18.83). If, on the other hand, analytical/numerical models are available, they can be used to estimate the transfer function matrices [**R**] and [**T**]. If the CSD of the disturbance [$\mathbf{S_{dd}}$] is then taken to be the unit matrix as described earlier, then [$\mathbf{S_{er}}$], [$\mathbf{S_{ee}}$], and [$\mathbf{S_{rr}}$] can be easily estimated from the equations given above, allowing the evaluation of Eq. (18.83) as if measured data were available.

Sensor Selection and Noncausal Performance. Choices for candidate residual and reference sensors are typically guided by an understanding of the physics of energy propagation for the system to be controlled as well as guidance on the required number of channels required based on SVD analyses. Assuming candidate actuator, reference, and residual locations have been identified using the procedures discussed above, an upper bound on achievable performance for this set of transducers can be obtained by estimating the noncausal performance. These predictions correspond to those identified in Fig. 18.74 under the observability phase. For a feedforward system, this means that we assume the controller can implement whatever filter is necessary to relate the reference sensor responses to the required actuator drive signals to minimize the mean-square residual response. For this case, the uncontrolled and controlled mean-square residual responses are given by

$$\mathrm{tr}([\mathbf{S_{ee}}]) = \mathrm{tr}([\mathbf{T}][\mathbf{S_{dd}}][\mathbf{T^H}]) \tag{18.86}$$

and

$$\mathrm{tr}([\mathbf{S}_{\varepsilon\varepsilon}]) = \mathrm{tr}(\{\mathbf{I}-[\mathbf{P}][\mathbf{P}^{\#}]\}[\mathbf{H_r}][\mathbf{S_{rr}}][\mathbf{H_r}]^{\mathbf{H}}\{\mathbf{I}-[\mathbf{P}][\mathbf{P}^{\#}]\}^{\mathbf{H}}) \tag{18.87}$$

where $[\mathbf{S_{ee}}]$ and $[\mathbf{S_{rr}}]$ are defined in Eq. (18.84), $[\mathbf{H_r}]$ is defined in Eq. (18.85), and the noise reduction is given by

$$\mathrm{NR} = 10 \log_{10} \left(\frac{\mathrm{tr}([\mathbf{S}_{\varepsilon\varepsilon}])}{\mathrm{tr}([\mathbf{S_{ee}}])} \right) \tag{18.88}$$

As described in the above discussion for the residual and reference sensors, Eq. (18.88) can be evaluated using either measured data or analytical/numerical models. The one difference here is that measurements or analytical/numerical predictions of the plant transfer function matrix $[\mathbf{P}]$ are also required.

On a final note, we remark that while the required numbers of reference and residual channels are typically determined by the system response at the highest frequency of interest, they may be more than is necessary at lower frequencies. As a consequence, the CSD matrices of the reference and residual sensors (and the plant matrix) may be ill-conditioned (i.e., noninvertible) at low frequencies, which may impact the matrix inverses in Eqs. (18.78), (18.85), and (18.87). For these situations, it may be necessary to add small values to the diagonal elements of these matrices before computing the inverse. This procedure is referred to as "regularization." The values added are ideally a function of frequency and will have a larger influence at low frequencies (where the matrices are ill-conditioned) than at high (where the matrices are not ill-conditioned). One procedure that satisfies this requirement (and has been used successfully in many ANVC applications) is to add a scalar times the maximum singular value of the matrix to each diagonal element of the matrix on a frequency-by-frequency basis.

Controller Architecture and Performance Simulations

The upper bound predictions given in the sections above on the number, location, and sizing of sensors and actuators provide a series of tools for bounding system performance as more of the control system is defined. As more realism is included (e.g., identifying both actuator and sensor numbers and locations), the bounds on achievable performance typically get smaller but also more realistic. Comparisons of these bounds with performance goals can be made at each step to determine if the control system under consideration is likely to meet its objectives. Should the system still appear feasible after selecting both actuator and sensor locations [i.e., from Eqs. (18.86) and (18.87)], the next step is to add more realism related to the implementation of the controller.

In this section, we consider the impact of controller architecture on achievable performance. In particular, we discuss procedures to include effects of analog filtering, sample rate, and length of control filter.

As an introduction to these issues, consider the signal path from sensor inputs to actuator drive signals for a conventional digital controller as shown in Fig. 18.77. With reference to this figure, a digital controller requires that the analog signals from the sensors be sampled and digitized at the sample rate of the controller. The sample rate of the controller is usually expressed in terms of a sampling rate or frequency (f_s), which implies that the signals are sampled at a time interval (T_s) equal to the inverse of the sample rate. For example, a sample rate $f_s = 1000$ Hz corresponds to a sample interval $T_s = 0.001$ s. To satisfy Nyquist's sampling theorem,[57] the sample rate of the controller must be at least twice the highest frequency of interest for the controller. For feedforward systems, the sample rate may be a factor of 4 above the highest frequency to be controlled. For broadband feedback systems, as discussed in Section 18.5 under Alternate Suboptimum Control Filter Estimation, it is not uncommon for the controller sample rate to be a factor of 100 above the highest frequency to be controlled (to minimize the effects of time delay through the controller and quantization noise on system performance).

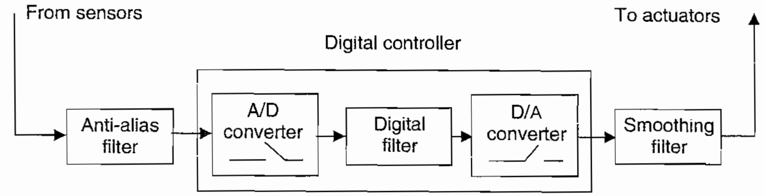

FIGURE 18.77 Signal path from sensor input to actuator drive signal for a digital controller.

Once the sample rate has been chosen, analog filters must be used to limit the frequency content of the analog sensor signals to below the Nyquist frequency of the controller, where

$$f_{\mathrm{nyq}} = \tfrac{1}{2} f_s \tag{18.89}$$

These filters are called "anti-alias" filters, and their output is passed to an A/D converter, which in turn samples and quantizes the signal. Similarly, the output of the digital controller is converted to an analog signal by a D/A converter. Before these output signals are sent to the actuators, however, they must be filtered to band limit the signals below the Nyquist frequency; otherwise signals above the Nyquist frequency will be sent to the actuators. These filters are referred to as "reconstruction" or "smoothing" filters

Although issues regarding the selection of anti-alias and smoothing filters are discussed in the next section, we note here that a major consequence of filtering is that it introduces a delay in the signal path, which is referred to as the "group delay" of the filter. This delay is related to the derivative of the phase response of the filter:

$$\tau_g(\omega) = \frac{d\varphi(\omega)}{d\omega} \tag{18.90}$$

In addition to the filters, delays in the signal path of Fig. 18.77 are also associated with the A/D converter, sample-and-hold functionality of the D/A, and the processing time associated with implementing the digital filter. With regards to the A/D converter, delays can be kept sufficiently small by choosing successive-approximation A/D converters. Issues related to A/D selection for applications where time delay is not a limiting factor in controller performance (e.g., tonal control systems or for residual sensing in some feedforward applications) are discussed in the next section. The delay associated with the sample and hold of the D/A converter $\tau_{D/A}$ is directly related to the sample rate of the controller:

$$\tau_{D/A} = \frac{1}{2f_s} \tag{18.91}$$

For efficient implementations, the delay (τ_{DSP}) associated with implementing the digital filter within a DSP chip can be limited typically to a few tens of microseconds. These implementations require that the sample clock controlling the D/A converters be offset relative to the sample clock for the A/D converters. As such, output samples can be sent to the D/A converters as soon as they are computed so that the processing delay can be held to a fraction of a sample interval. This sampling strategy is in contrast to one that waits until the next time step to output a sample. The latter approach imposes a minimum one-sample delay in the processing, which can be unacceptable for certain applications.

The total delay from analog signal input to analog signal output is termed the *latency* of the controller. Where appropriate, any delay associated with the amplifiers and actuators will also contribute to the latency. Latency is an important parameter since it can directly limit achievable performance of broadband feedforward and feedback systems. As such, it is important to limit overall latency in ANVC control systems consistent with achieving performance goals.

At this point, specific characteristics of the analog filtering, sampling, and control filter parameters can be merged with model or experimental results to make causal performance predictions. The steps involved are as follows:

- Specify a system sample rate based on control bandwidth and architecture (feedforward or feedback).
- Modify the transfer function matrices involving sensor inputs and actuator outputs to include
  - — transfer functions of anti-alias (AA) and smoothing filters (SF),
  - — delay associated with D/A converter sample and hold ($\tau_{D/A}$),
  - — controller processing delay (τ_{DSP}), and
  - — transfer functions of amplifiers and actuator (SH).
- Specify cost function (including control effort and robustness constraints) to be minimized.
- Specify number of control filter coefficients.
- Solve for control filter coefficients using the procedures outlined in Sections 18.4 and 18.5.
- Estimate causal mean-square residual performance and actuator output drive requirements: Compare estimated performance to performance goals.

If transfer functions of the filters, amplifiers, and actuators are not available, initial causal performance estimates can be made by assuming flat magnitude

spectra with linear phase spectra, which correspond to pure time delays that bound expected delays for those components. When this is the case, Elliott[58] suggests approximating the group delay of the anti-alias or smoothing filters as

$$\tau_g \approx \frac{n}{8f_c} \tag{18.92}$$

where n is the order of the filter and f_c is the cutoff frequency.

Hardware Selection

In this section, we discuss some of the practical issues related to selecting analog filters, A/D converters, and DSPs. Although a complete discussion of these issues is beyond the scope of this book, we present general guidelines and considerations. Detailed discussions of each of these issues can also be found in reference 58.

Anti-Alias and Reconstruction Filters. As discussed earlier, the main purpose of anti-alias and reconstruction filters is to attenuate signals above the Nyquist frequency. The anti-alias filters minimize contamination of frequencies below the Nyquist frequency by attenuating the spectral content of the signals above the Nyquist frequency. These higher frequencies are interpreted as lower frequencies because of the nonlinear sampling process of the A/D converter. This phenomenon is referred to as *aliasing*. Similarly, reconstruction filters attenuate components of the drive above the Nyquist frequency, which occur as a consequence of sampled signals at the output of the D/A converter. The benefits of using anti-alias and reconstruction filters in combination with A/D and D/A converters are discussed below

The amount of attenuation required from an anti-alias filter depends on the spectral shape of the sensor response and the desired bandwidth over which the controller needs an accurate representation of the signal. A sensor response that is inherently band limited below the Nyquist frequency may require only a low-order anti-alias filter or possibly none. Alternatively, a sensor response that is flat or increasing with frequency will require a higher order anti-alias filter. For purposes here, we assume that the sensor response is flat versus frequency. In addition, we impose a requirement of at least 40 dB attenuation of contributions from aliasing frequencies at the highest frequency that is important to the controller (f_a). From the context of controller implementation, however, we wish to achieve this attenuation while minimizing the group delay of the filter to acceptable levels.

There are two basic approaches to selecting the filter. The first is to use a low-order filter with a relatively low cutoff frequency. The second is to use a high-order filter with a higher cutoff frequency. Figure 18.78 compares the magnitude spectra and group delays for a fourth-order Butterworth filter and a sixth-order Cauer filter, both of which were designed to provide at least 40 dB of attenuation above $f_{40\ \mathrm{dB}} = 600$ Hz. Both filters will meet the attenuation requirements for

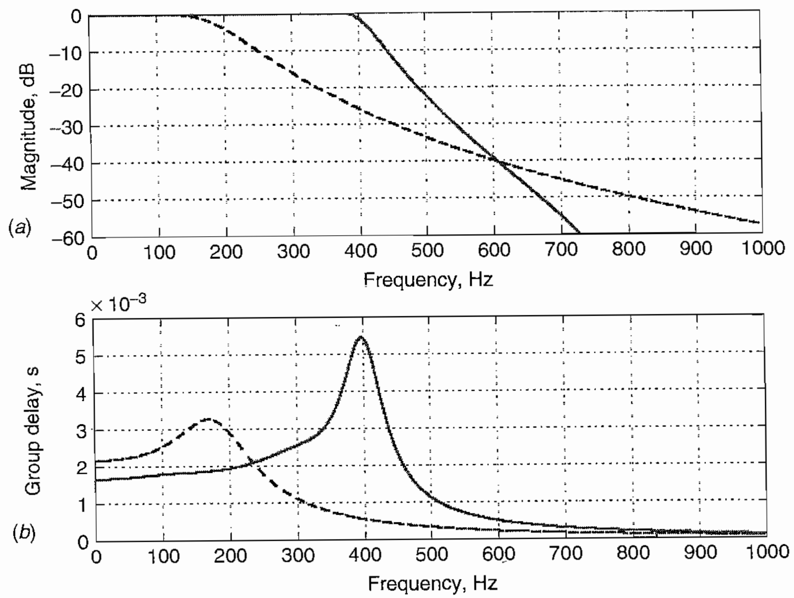

FIGURE 18.78 Comparison of (*a*) magnitude spectra and (*b*) group delay for fourth-order Butterworth (dashed curve) and sixth-order Cauer (solid curve) filters.

frequencies below their respective cutoff frequencies (i.e., $f_a < f_c$) provided that the system sample rate is chosen such that

$$f_s \geq f_a + f_{40\text{dB}} \tag{18.93}$$

Consider first the case with f_a less than the cutoff frequency of the Butterworth filter (nominally 200 Hz) and a sample rate of 800 Hz. For this case, attenuation of aliasing components is assessed by "folding" the magnitude response of the filters about the Nyquist frequency of $800/2 = 400$ Hz. As such, both filters provide the required attenuation of aliasing components in the frequency band below f_a. However, the group delay associated with the Cauer filter is less than that for the Butterworth for all frequencies below f_a, particularly near 200 Hz.

Now consider the case with $f_a = 350$ Hz and a sample rate of 950 Hz. For this case, attenuation of aliasing components is assessed by folding the magnitude response of the filters about the Nyquist frequency of $950/2 = 475$ Hz. The Cauer filter again satisfies the attenuation requirement because the sample rate satisfies Eq. (18.93). However, the attenuation requirement is not met by the Butterworth filter. In fact, less than 20 dB attenuation of aliasing components is achieved at 350 Hz (i.e., the difference in the magnitude responses at 350 Hz and $950 - 350 = 600$ Hz. Further, note that the maximum group delay of both filters in the frequency band below f_a is approximately the same.

The above comparisons suggest that using higher order filters with high cutoff frequencies is preferable to using low-order filters with low cutoff frequencies. Although the preceding discussion centered on selecting anti-alias filters, similar conclusions apply to reconstruction filters provided that the control filters are designed to reduce output levels above f_a. Unfortunately, the cost of implementing high-order filters will exceed the cost of using low-order filters. As a consequence, the performance benefits must be balanced against considerations of additional cost, as will be discussed further in the example ANVC system in Section 18.7 under MIMO Feedforward Active Locomotive Exhaust Noise Control System with Passive Component.

Analog-to-Digital and Digital-to-Analog Converters. A typical data path from sensor input to actuator drive signal was shown in Fig. 18.77. That figure illustrates the use of both types of data converters required for implementing digital controllers, namely A/D and D/A converters. The purpose of A/D converters is to sample the continuous-time signals from the sensors at uniform time intervals ($T_s = 1/f_s$) and quantize the amplitude to a discrete set of amplitude levels. Because the sampling process is a nonlinear operation, anti-alias filters are typically used to band limit the sensor signals below the Nyquist frequency ($f_s/2$) before sending the signals to the A/D converter. This minimizes the possibility that frequencies above Nyquist will contaminate the sensor response below Nyquist, which is referred to as aliasing.

Figure 18.79 shows a frequency domain schematic of how anti-aliasing filters are used in combination with A/D converters to minimize aliasing effects. The upper curve in Fig. 18.79*a* represents the spectrum of an unfiltered continuous-time signal presented at the input of an A/D converter. For an A/D converter operating at a sample rate of f_s, signals above the Nyquist frequency ($F_{\text{nyq}} = f_s/2$) will be interpreted as frequency below Nyquist. Fig. 18.79*a* illustrates schematically how frequencies above the Nyquist frequency will fold down into the frequency region below Nyquist. The estimated spectrum below Nyquist will be the sum of the true spectrum below Nyquist plus any aliasing components resulting from the frequency content of the signal that is above the Nyquist frequency. As a consequence, aliasing components can cause the estimated spectrum to differ from the true spectrum of the signal in the frequency region below Nyquist. Anti-alias filters are typically used to band limit the signals prior to the conversion process to reduce the magnitude of any aliasing components. Figure 18.79*b* is a plot of the magnitude response of an anti-alias filter designed to reject frequencies above the Nyquist frequency. When this filter is applied to the unfiltered signal of Fig. 18.79*a*, the resulting spectrum of the signal presented at the input to the A/D converter is that shown in Fig. 18.79*c*. As shown in this figure, much of the effects of aliasing components on the estimated spectrum are removed, thus ensuring that the estimated spectrum is a more accurate representation of the true spectrum of the signal below the Nyquist frequency.

Digital-to-analog converters are used to convert the digital sequences from the controller into analog signals that can ultimately be used as drive signals to actuator electronics. In the frequency domain, the sample output sequence

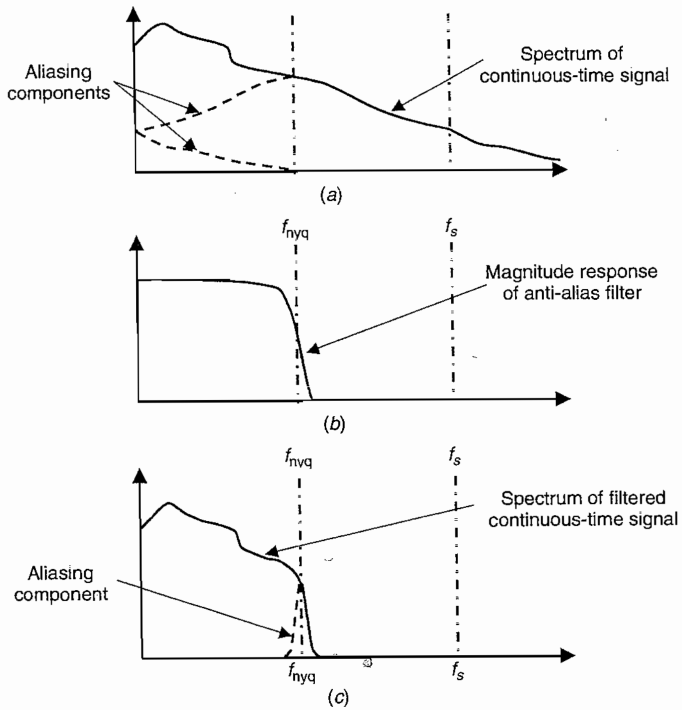

FIGURE 18.79 Use of anti-alias filters to minimize aliasing effects during A/D conversion: (*a*) aliasing components of an unfiltered continuous-time signal digitized at sample rate f_s; (*b*) magnitude spectrum of anti-alias filter; (*c*) aliasing components of filtered continuous-time signal digitized at sample rate f_s.

produces a spectrum that contains "images" of the signal spectrum below the Nyquist frequency, which occur at frequencies above the Nyquist frequency. These image spectra are shown schematically in Fig. 18.80. The effects of the images must be minimized. Otherwise, the controller will drive the actuators at frequencies above the Nyquist frequency, resulting in increased out-of-band noise amplification. These out-of-band effects are reduced to some extent by the sample-and-hold (S&H) functionality that is integral to most D/A converters. As discussed earlier, the S&H introduces a delay equal to one-half the sample interval ($T_s/2$). In addition, it provides some filtering of the output spectrum, as illustrated in Figs. 18.80*b* and 18.80*c*. To suppress the remaining signals above the Nyquist frequency, D/A converters are typically followed by smoothing or reconstruction filters. The effect of applying reconstruction filters on the D/A output signal is shown in Fig. 18.80*e*.

Two basic types of A/D converters are applicable for use in ANVC systems. The first type is referred to as "successive-approximation" (SA) A/D converters. The second type is referred to as "sigma–delta" ($\Sigma\Delta$) A/D converters. Table 18.1

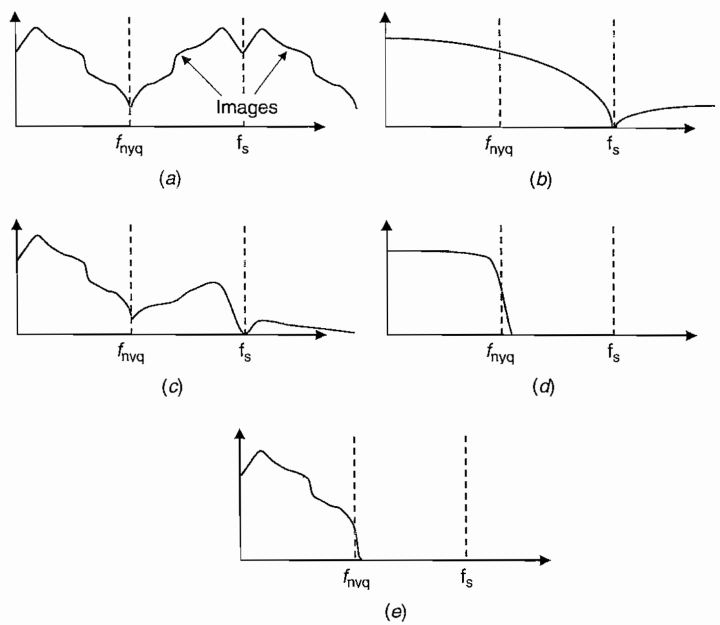

FIGURE 18.80 Use of reconstruction filters to reduce image spectra at the output of D/A converters: (*a*) spectrum of digitized output signal at sample rate f_s; (*b*) magnitude response of zero-order sample-and-hold integral to D/A converter; (*c*) spectrum of analog output of D/A converter prior to reconstruction filter; (*d*) magnitude response of reconstruction filter; (*e*) spectrum of analog signal at output of reconstruction filter.

compares some of the important features and differences between these two types of converters.

The choice of A/D converter for an ANVC application will depend on the control architecture (i.e., feedforward or feedback), the type of sensor signals (i.e., reference or residual sensors), and the performance goals. For broadband ANVC applications that require minimal latency through the controller (e.g., reference sensors in a feedforward system or residual sensors in a feedback system), the delay associated with $\Sigma\Delta$ A/D converters is unacceptable. As a consequence, SA A/D converters should be used for those applications, and the extra cost of the converters and anti-alias filtering should be included in the total cost of the ANVC system. We note, however, that low latency is not a necessary requirement for the residual sensors of a feedforward implementation. These sensor signals are used in the design of the control filters but are not themselves filtered by the control filter to produce output signals to the actuators. However, the latency associated with $\Sigma\Delta$ A/D converters used on the residual signals will be seen as a delay in the plant transfer functions. This added delay will in turn reduce allowable convergence coefficients for LMS-based algorithms[58] but does not preclude their use.

TABLE 18.1 Comparison of Successive-Approximation and Sigma-Delta A/D Converters

Successive-Approximation Converters	Sigma-Delta Converters
Sample input signal at rate f_s	Over sample input signal nominally at 64 times desired sample rate (i.e., $f_{\Sigma\Delta} = 64 f_s$)
Require use of relatively high-order anti alias filters to bandlimit signals below Nyquist frequency	Only low-order (if any) anti-alias filters required to bandlimit signals below $f_{\Sigma\Delta}/2$. Integral high-order (linear-phase) digital filters bandlimit signal below Nyquist frequency ($f_s/2$). Output is decimated (i.e., keep only every 64th sample) to produce sampled sequence at f_s sample rate.
Low latency (on the order of a few μs)	High throughput latency (typically $32T_s$, where $T_s = 1/f_s$)
Quantize signal at multiple bit levels (e.g., 12 or 16 bits)	One-bit quantization at oversampled rate to provide comparable multi-bit quantization (e.g., 12 or 16 bits) at f_s sample rate
Relatively expensive compared to $\Sigma\Delta$ converters	Relatively inexpensive compared to SA converters

When low latency is not required, the use of $\Sigma\Delta$ converters can significantly reduce the costs associated with digitizing the sensor signals. For example, a tonal feedforward ANVC system can use a $\Sigma\Delta$ A/D converter to digitize the reference signal. As before, digitization of the residual signals for this example can be done using $\Sigma\Delta$ A/D converters, provided that the extra delay is acceptable in terms of convergence rate (if adaptive algorithms are used). The choice of D/A converter is governed by similar arguments concerning allowable latency. For instance, when low latency is not required, $\Sigma\Delta$ D/A converters can be used. Alternatively, when latency must be minimized, conventional D/A converters should be used.

For most ANVC applications, it is desirable to initiate the sampling across all A/D converters using a common clock signal. In this way, all A/D inputs will be synchronously sampled. Similarly, it is advantageous to sample all the D/A converters using a common clock signal as well. The D/A converters could be clocked using the same clock pulse as for the A/D converters; however, to minimize latency through the controller, it is useful to offset the D/A clock relative to the A/D clock. In this way, subsample latency can be achieved by sending signals to the D/A when they are ready, as opposed to waiting for a full sample period.

The final aspect of converter selection is quantization noise. When analog signals are quantized to a finite number of amplitude values (e.g., 16-bit A/D converter), the errors in the conversion process can be thought of as noise. For the signals of interest for ANVC, this noise is modeled as uniformly distributed

from—LSB/2 to LSB/2. Here, LSB stands for the *least-significant bit* and is given by

$$\text{LSB} = \frac{V}{2^{M-1}} \tag{18.94}$$

where V corresponds to the voltage range of the converter (i.e., $\pm V$) and M is the number of resolution bits (e.g., 16 for a 16-bit converter). For the assumed uniform probability distribution of the noise, the rms of the quantization noise (QN_{rms}) is equal to

$$QN_{\text{rms}} = \frac{LSB}{\sqrt{12}} \tag{18.95}$$

For a sample rate f_s, the spectrum of the quantization noise ($QN_{\text{psd}}(f)$) is white (i.e., flat) with a power spectral density (PSD) amplitude given by

$$QN_{\text{psd}}(f) = \frac{LSB^2/12}{fs/2} \tag{18.96}$$

As an example, for a 16-bit converter with a voltage range of ± 10 V and a sample rate of 1 kHz, the rms quantization noise [from Eq. (18.95)] is 88 μV, and the PSD level is -108 dB re 1 V^2/Hz.

At this point, it is useful to compare plots of

- the expected signal levels (in volts from the sensor),
- electrical noise floors (associated with the sensors, analog filters, and gain), and
- quantization noise.

To support a common comparison, all of these voltage levels should be referenced to a common point in the signal path (e.g., the amplifier input). These plots should be generated corresponding to both open- and closed-loop sensor responses. Sensor sensitivities, signal gain, and quantization noise can then be assessed within a common framework. The goal is to choose each of these to ensure that sensor signals will have sufficient signal-to-noise ratio (SNR) throughout the bandwidth of interest.

To illustrate some of the issues related to A/D converter selection, consider the example shown in Fig. 18.81. The various curves grouped in the center of this plot correspond to the expected signal levels from multiple residual sensors, expressed in dB re V^2/Hz, referenced to the input of a bank of sixth-order Cauer filters. The filters are used to provide anti-alias filtering as well as programmable gain for these channels. The cutoff frequency is approximately 800 Hz. The power spectral density of the noise from the anti-aliasing filters at their input (labeled PFI *noise* in the figure) falls between -155 dB and -150 dB re 1 V^2/Hz. The spectral density of the sensor noise floor reference to the filter input is

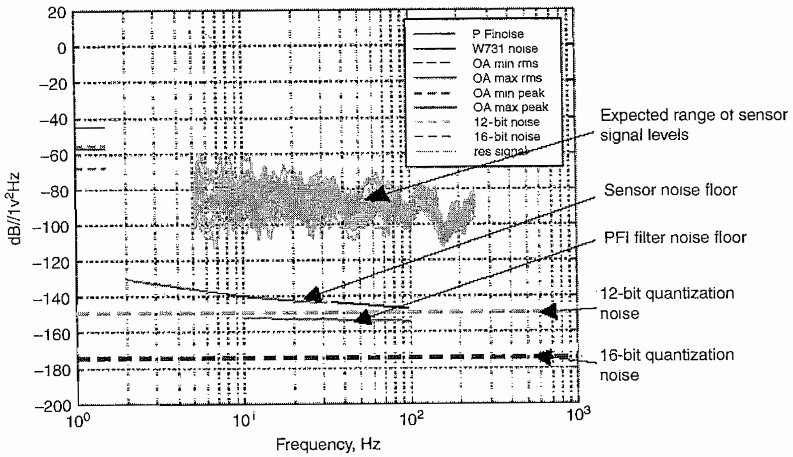

FIGURE 18.81 Comparison of signal level versus electrical and quantization noise.

approximately -130 dB re 1 V^2/Hz at 2 Hz and drops to -145 dB re 1 V^2/Hz at 100 Hz.

The rms levels for the sensor signals (needed for quantization noise estimates as indicated below) are determined by integrating the mean-square voltage responses across frequency and taking the square root. For these spectra, the largest rms level is approximately -57 dB re 1 V. Assuming the statistics of these responses is random (i.e., with a crest factor of 4 or 12 dB), a peak voltage response for this group of sensors is estimated to be approximately -45 dB re 1 V. The spectrum level of the digitization noise (at the filter input) can be estimated from Eq. (18.96), where the voltage V in Eq. (18.94) is taken (at the moment) to be the peak voltage of the sensor signals (i.e., -45 dB re 1 V $= 5.5$ mV). As such, the spectral levels of digitization noise for 12- and 16-bit converters, assuming a sample rate of 2 kHz, are -152 dB and -176 dB re 1 V^2/Hz, respectively. The SNR for these sensor measurements is a function of frequency and corresponds to the spread in decibels between the estimated signal responses and the maximum of the electrical noise (from filters and sensors) or the digitization noise. The SNR is nearly 30 dB throughout the frequency band of concern.

For the example shown in Fig. 18.81, it is sufficient to use a 12-bit converter since the SNR is limited by sensor noise as opposed to digitization noise up to about 100 Hz. Above that frequency, the SNR will be limited by digitization noise if a 12-bit converter is used or by PFI noise if a 16-bit converter is used. Further, if the converter (12- or 16-bit) has a voltage range of ± 1 V, the programmable gain should be set at approximately 33 dB to allow 1–2 bits of headroom to avoid clipping.

The example case in Fig. 18.81 illustrates the relatively complex interdependencies that must be considered when selecting ANVC hardware to ensure

adequate SNR, which in general will be a function of sensor noise and sensitivity, anti-alias filter noise, A/D converter quantization noise and voltage range, system gain, and sample rate.

Digital Signal Processors. As discussed earlier, the rapid growth in ANVC systems and applications over the past 25 years can be traced in large part to the advent of DSP chips. These chips are optimized to perform operations on a sample-by-sample basis. That is, these chips read in data one sample at a time, perform large numbers of computations, and then output a sample. This is in contrast to other central-processing units (CPUs) that read in groups (i.e., buffers or blocks) of data, operate on the entire buffer, and then output buffers of data. These later processors can often perform larger numbers of computations than DSP chips, but their latency is on the order of the block size.

Digital signal processors are ideally suited to perform the low-latency digital filtering required by ANVC algorithms. As such, they are widely used in the design of adaptive control systems based on the algorithms presented in this chapter. In addition, current DSP technology supports high-speed communication between DSPs to support applications with large numbers of inputs and outputs (e.g., many tens of inputs and outputs) as well as large digital filter sizes (e.g., IIR filters with over 5000 taps per filter). For these large-scale problems, efficient low-latency implementation of the digital filters can be achieved by combining DSPs with high-powered CPU compute engines such as PowerPC (PPC) chips. Further, the relatively large latency associated with the PPC chips may be acceptable to perform much of the "off-line" algorithms associated with system identification and control filter design when using direct estimation as opposed to adaptive filter algorithms.

Once the control algorithms have been selected, the computation and memory requirements can be determined for all "in-line" filtering and "off-line" processes. These requirements should then be mapped to DSPs and PPC chips, as necessary. Floating-point DSPs such as the TMS320C6701 are rated at 1 Gflop and include up to 128 MB of fast-access memory. Compute engines like the PPC7410 are rated at 2 Gflops with up to 512 MB of local memory. In addition, PC or VME (workstation) boards are currently available with up to four of each type of processor per board and support high-speed communications between processors on a given board as well as processors located on other boards. These processor-to-processor communications are supported by high-speed interconnect architectures such as Mercury RACE^{++}, Spectrum DSPLink, and SKYchannel.

As an example, Fig. 18.82 shows the hardware architecture for a large-scale ANVC system incorporating both DSPs and PPC chips, including high-speed communication over a Mercury RACEWAY interconnect. The signal path from the reference sensors to the actuator drive signals includes high-order anti-alias and reconstruction filters with cutoff frequencies near the Nyquist frequency. Successive-approximation converters are used to minimize latency associated with the conversion. A combination of DSPs and PPC chips are used to efficiently implement the digital control filters to minimize latency.[84] The residual sensor

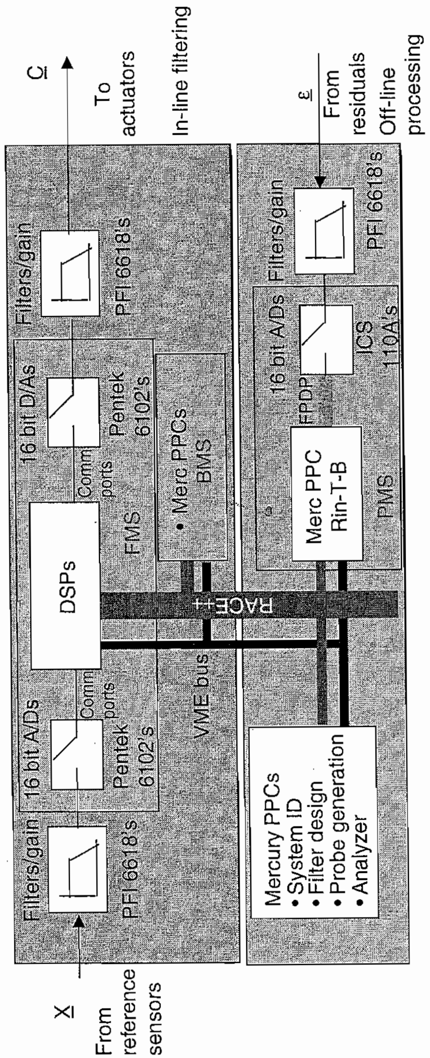

FIGURE 18.82 Control architecture using combination of DSPs and PPCs.

signals pass through anti-alias filters and are digitized using sigma–delta converters. These data support off-line functionality associated with system identification, control filter design, and probe-signal injection, which are performed on multiple PPC chips. Communications between the DSPs and PPC chips are primarily carried over Mercury's RACE^{++} interconnect bus, with additional communications occurring over the VME bus. In this way, the compute power associated with PPC chips can be used to efficiently perform off-line functions (e.g., direct estimation of plant and control filters), which can be passed to the in-line processors (DSPs and PPC chips) to support adaptation of the control filters.

Finally, we note that fixed-point DSPs as well as floating-point DSP devices are available. The floating-point devices are much easier to program and are often chosen for proof-of-principle systems or for final systems that are not highly cost sensitive. When cost is a driving issue, fixed-point devices should be considered. The final choice must balance the higher nonrecurring cost associated with programming fixed-point devices and the potential increased CPU overhead due to implementing floating-point arithmetic on a fixed-point device against the lower recurring per-unit cost

Control System Implementation and Testing

Once the simulations and hardware selections have been made, the control system is implemented and performance tests are conducted. In this section, we discuss the basic operating modes and features of a controller that should be considered during implementation to support the subsequent testing phase.

For each of the modes discussed below, parameters that can be changed during system operation (referred to as "soft" parameters) and those that cannot be changed during operation (referred to as "hard" parameters) must be identified. Soft parameters provide the flexibility to modify and tune certain parameters during system operation, which is often an invaluable feature in prototype systems. Allowing parameters to be changed "on-the-fly," however, adds complexity to the implementation. As such, lists of desired soft and hard parameters should be identified early on in the implementation phase so that the appropriate communications between a user interface and the embedded controller codes can be included. The typical operating modes and features of a controller are summarized in Table 18.2, including references to soft parameters that are useful in supporting each mode.

As indicated, an ANVC controller will typically have two primary operating modes, namely system identification and control. The purpose of system identification is to estimate the transfer functions (or equivalently impulse response functions) from the actuator control signals to sensor responses (both references and residuals). This identification is initially performed with the control filter set to zeros but can subsequently be performed during closed-loop operation, as discussed in Section 18.4 under System Identification. Once an initial plant estimate has been obtained, operational measurements of the system responses are obtained to characterize the "uncontrolled" (i.e., open-loop) response. These

TABLE 18.2 Controller Operating Modes and Features

Operating Mode	Description and Features
Open-loop characterization of system response	Collect measurement of residual sensors during normal "uncontrolled" (i.e., open-loop operation)
Open-loop system identification	Estimate plant models between actuator drive signals and sensors. Soft parameters include probe strength, adaptation coefficients, leakage coefficients, regularization parameters, and actuator channel selection.
Closed-loop operation with filter design based on open-loop response and system identification	Collect measurements of residual sensors during "controlled" (i.e., closed-loop) operation. Soft parameters include adaptation and leakage parameters, control effort and robustness weighting parameters, and regularization parameters.
Concurrent closed-loop system identification and control-filter adaptation	Collect measurements of residual sensors during "controlled" (i.e., closed-loop) operation, while probe signals are injected for the purpose of closed-loop system identification. Soft parameters include those cited above for system identification and closed-loop operation. In addition, software flags should be included to initiate use of updated plant models in the control filter design algorithm.
Save operational "state"	All controller information necessary to restart the controller should be saved. This includes, plant and control filter coefficients, all hard and soft parameters, operating mode, and probe signal path parameters.
Load saved "state" and restart controller	Load in a saved "state" and start operation using saved parameters and filters.

responses are also used to design control filters to support operation in the control mode. Once in the control mode, probe signals can be injected to support closed-loop system identification and to support adaptation of control filter coefficients. Soft parameters can be adjusted to optimize performance. Closed-loop system responses should then be collected and compared with open-loop responses to evaluate system performance versus performance objectives and goals.

The final two rows of Table 18.2 indicate the desire to be able to save the "state" of the controller at any point in time. By state, we mean all controller parameter values and filter coefficients are saved for the purpose of restarting the system at that state in the future. As such, the controller can be started from a closed-loop operating state or from some initial operating state (e.g., open loop). It is convenient for prototype systems to include a graphical user interface (GUI) through which operation mode, soft parameter values, performance assessments, and save/load state functionality can be monitored and controlled. Once an ANVC system has been successfully tested, values of soft parameters and logic for progressing from open-loop to closed-loop operation can be automated within the software, thus resulting in a stand-alone ANVC system.

18.7 EXAMPLES OF ANVC SYSTEMS

In this section we present three prototype active systems that illustrate the application of the principles outlined in the previous sections of this chapter. All of these systems were developed to demonstrate the technology and one is currently operational on a complete class of U.S. Navy ships. All three demonstrate the effectiveness of active noise and vibration control technology when appropriate design procedures are followed. The first example involves the synergistic application of a combination of active and passive noise reduction treatments. The example demonstrates the successful control of a source of noise that would have been difficult using only passive or only active approaches. The second example demonstrates the application of feedback technology to the control of both broadband and narrow-band vibration transmission through a vibration isolation mount. The final example illustrates the use of active noise control technology to generate a zone of silence in a noisy environment.

MIMO Feedforward Active Locomotive Exhaust Noise Control System with Passive Component

Problem Description. When operated at full power diesel-electric locomotives generate significant noise and can have a significant adverse impact on the quality of life near major railroad lines. The sources of noise are shown in Fig. 18.83.[85] As indicated in the figure, the primary sources of diesel-electric locomotive noise are the engine exhaust and the cooling fans, both of which must be reduced before significant noise reductions can be realized. The active noise control system developed for this application focused on just the exhaust noise, fully recognizing that later efforts would have to attack cooling-fan noise if significant overall locomotive noise reductions were to be achieved. Active technology was considered for this application because locomotive exhaust noise is significant at very low frequencies (below 40 Hz), and passive noise control treatments (e.g., dissipative or reactive mufflers) that could achieve the desired noise reduction would simply be too large to fit in the space available.

The basic concept for the system[86,87] is illustrated in Fig. 18.84, where a plan view of the top of the locomotive hood is shown near the exhaust stack. The figure shows a number of loudspeakers, the control actuators, surrounding the exhaust

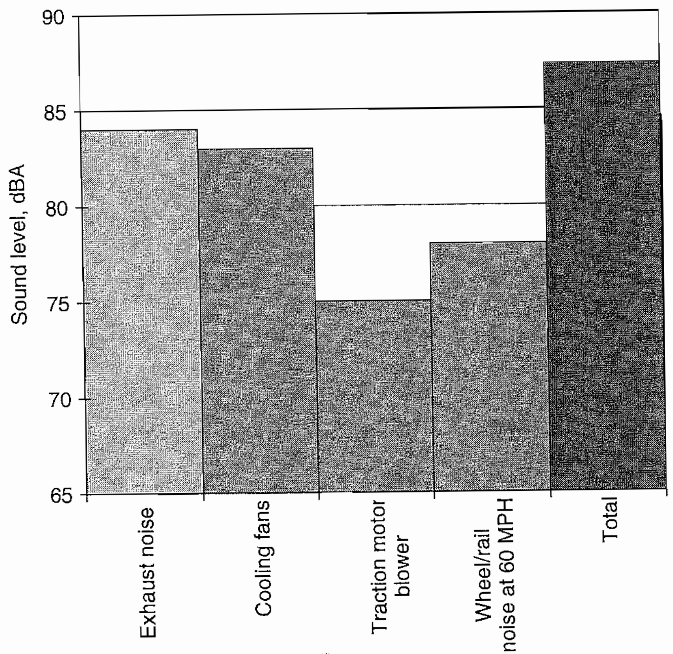

FIGURE 18.83 Noise sources on an SD40-2 diesel electric locomotive measured at 100 ft with the locomotive running at throttle 8 at full load.

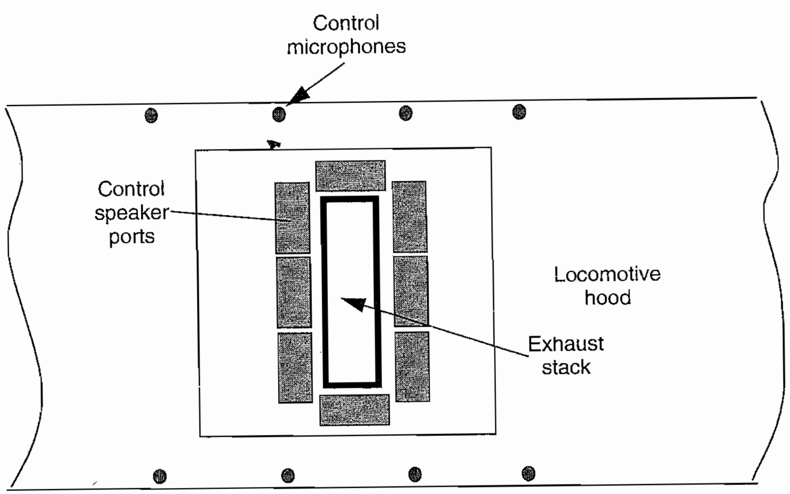

FIGURE 18.84 Plan view of the locomotive hood with the basic system concept.

stack and a number of control microphones located near the edge of the hood that will act as the residual sensors. It was determined based on exhaust noise measurements that at low frequencies where the active system would be designed to operate, the noise was primarily tonal and so a feedforward architecture was selected that used a tachometer on the locomotive diesel engine as the reference signal.

Performance Goals. Based on the source information in Fig. 18.83, it was decided that 10 dBA of overall reduction in exhaust noise would be desirable to have a significant impact on community noise (assuming of course that cooling-fan noise would eventually be similarly reduced). After examining the locomotive exhaust noise spectra we determined that to achieve 10 dBA of overall noise reduction would require that the exhaust noise be controlled out to at least 5 kHz. Since extending the bandwidth of the active system out to so high a frequency and requiring broadband control would place excessive demands on the technology, we decided on a hybrid approach. At low frequency where the noise is primarily tonal we decided to employ an active system. At high frequency where the noise is primarily broadband in character we determined that a passive silencer would be most advantageous. Such an approach is desirable because active technology is well developed for the control of low-frequency tonal noise and at high frequency passive silencers can be effective without having to be large in size. Both technologies were required because we found that

- active control of tones in the exhaust below 250 Hz with no broadband control at the higher frequencies would result in less than 1 dBA of noise reduction and
- no control of tones in the 0–250-Hz band would limit the maximum reduction of exhaust noise to ~5 dBA.

We ultimately decided that 10 dBA of exhaust noise reduction could be achieved with

- an active system providing 10 dB reduction of exhaust tones below 250 Hz along with
- a passive silencer providing 5 dB of broadband noise reduction from 250 to 500 Hz and 15 dB reduction from 500 to 5500 Hz.

Figure 18.85 shows the silencer designed to provide the above noise reduction performance. It is a very compact design with the center body and side chambers designed to provide the necessary insertion loss while maintaining the back pressure low enough to meet locomotive diesel engine specifications. The silencer was designed to allow the speaker enclosures to surround it, with the whole assembly fitting within a protective enclosure in the engine compartment. While the passive silencer was a critical component in the entire system design,

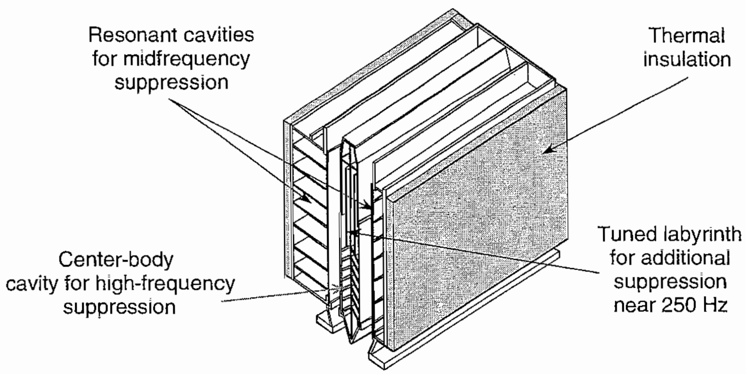

FIGURE 18.85 Compact passive silencer design.

we focus here only on the active system. Details on the passive silencer can be found in references 86 and 87.

Number and Location of Actuators. We began the design process by determining the number and location of control actuators (loudspeakers). Figure 18.86 shows a typical arrangement of actuators that we examined in simulations in which the exhaust stack and control actuators were treated as point sources. In the simulations we formed a matrix of transfer functions relating the sound pressure at 90 locations in the horizontal plane 30 m from the exhaust stack to the control speaker volume velocities at 32 speaker locations around the exhaust stack, as illustrated in Fig. 18.86. Figure 18.87 shows the ratio of the significant singular values to the largest singular value as a function of frequency for that transfer function matrix. In principle the number of significant singular values tells us the minimum number of actuators needed to provide significant control of the source. We found (not surprisingly), while carrying out calculations of this type, that the minimum number of singular values (control sources) was achieved when the control sources were placed as close as possible to the exhaust stack. Consequently, we carried out a preliminary design of the control speaker enclosures to determine a realistic minimum spacing between the exhaust stack and the enclosure outlets. The calculations in Fig. 18.87 were carried out for that minimum spacing. The figure shows that at 250 Hz eight singular values (including the largest) lie within 20 dB of the maximum. Since we are looking for only 10 dB reduction in noise, the use of eight actuators arranged as shown in Fig. 18.85 seemed to be a conservative choice. The performance predicted by this arrangement is shown in Fig. 18.88. While the noncausal noise reduction predicted by this calculation is much larger than we would expect to achieve, it was comforting to see that eight control actuators seemed to be more than adequate.

Number and Location of Control Sensors. The evaluations in the previous section placed the control sensors in the far field. In reality the microphones

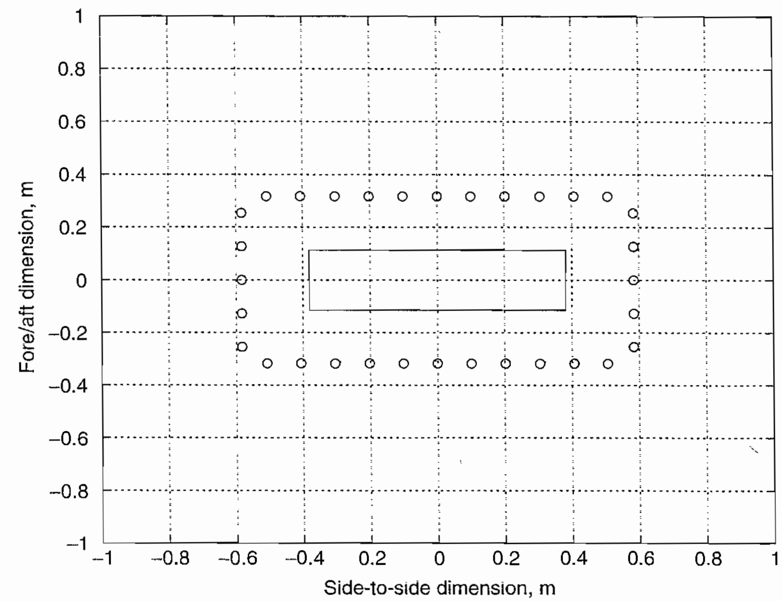

FIGURE 18.86 Candidate control source locations.

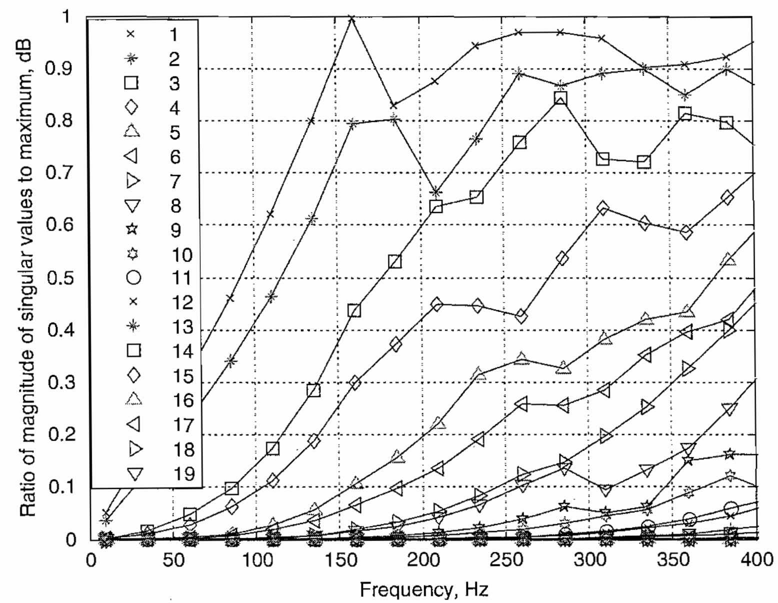

FIGURE 18.87 Ratio of each singular value to the largest singular value as a function of frequency.

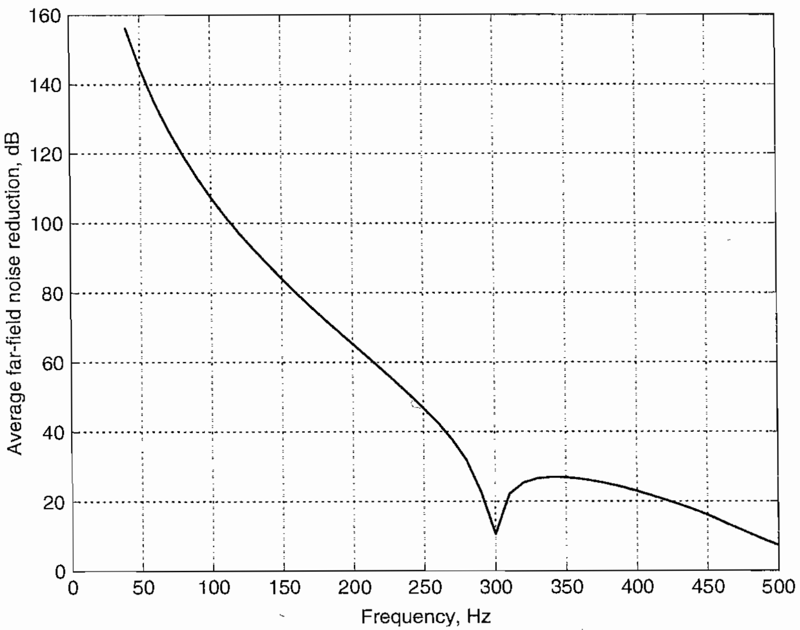

FIGURE 18.88 Predicted far-field performance of eight control actuators.

will have to be placed somewhere on the locomotive hood. Consequently, we developed an additional set of transfer function matrices relating the sound pressure at candidate control microphone locations on the locomotive hood to control speaker volume velocity at the previous 32 locations around the exhaust stack. We then determined the volume velocity required to minimize the pressure at the control microphones and then used those values with the previous transfer function matrix to predict the reduction in far-field pressure. Figure 18.89 shows the results of that calculation for a number of different control sensor locations. The solid curve in the figure is for the final control sensor placement, a line of four sensors along the two edges of the locomotive hood, similar to that shown in Fig. 18.84. A number of calculations of this type were used to help in the selection of control sensor locations. Other issues that came into play in the selection included the degree of dominance of exhaust noise over other sources at the candidate sensor locations, interference with other locomotive components, heat, and routing of cabling.

Control Actuator Design. The simulations for control sensor placement can provide, as part of the calculation, the estimated volume velocities required from the control speakers, provided realistic values of the uncontrolled sound pressure at the control sensors are used in the calculations. Measurements of the sound pressure at various locations on the hood of a test locomotive were acquired to

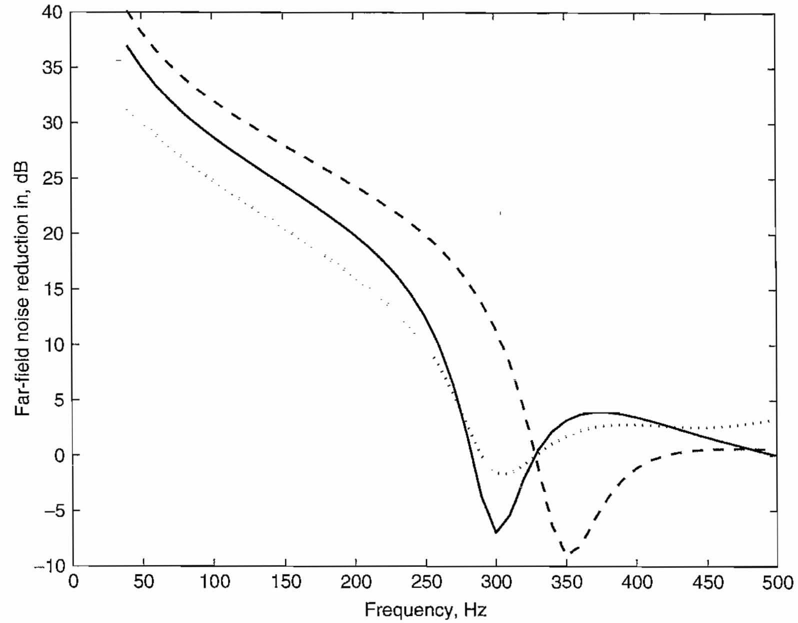

FIGURE 18.89 Predicted far-field noise reduction of eight control actuators with various configurations of eight control sensors.

provide those data. Simulations were then performed to determine the optimum control speaker volume velocities. That information was used in the selection of the control speakers and the design of the speaker enclosures. The enclosure design is shown in Fig. 18.90. Two different enclosure geometries were required to allow the necessary number of enclosures to fit in the space available around the exhaust duct. Each enclosure contains two 12-in.-diameter high-fidelity speakers and is designed to provide bandpass frequency response, enhancing the volume velocity in the 40–250-Hz frequency range. The enclosure–speaker system was designed using a commercially available computer program.

Figure 18.91 shows the arrangement of the control speaker enclosures around the exhaust stack. By careful design we were able to fit 10 enclosures in the space available. However, we retained only eight independent channels to drive the speakers. Because the simulations indicated that very high volume velocity would be required of the speakers on the centerline of the locomotive, we placed two speaker enclosures on each side of the centerline, as indicated in Fig. 18.91, rather than a single one on the centerline. We then drove each of the two pairs of enclosures with a single controller output channel.

Control Architecture. As indicated above, we decided early in the design process to use a feedforward control architecture since the technology is well

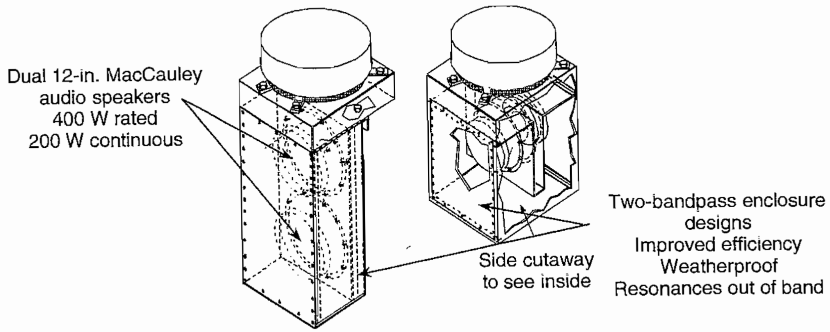

FIGURE 18.90 Control speaker enclosure design.

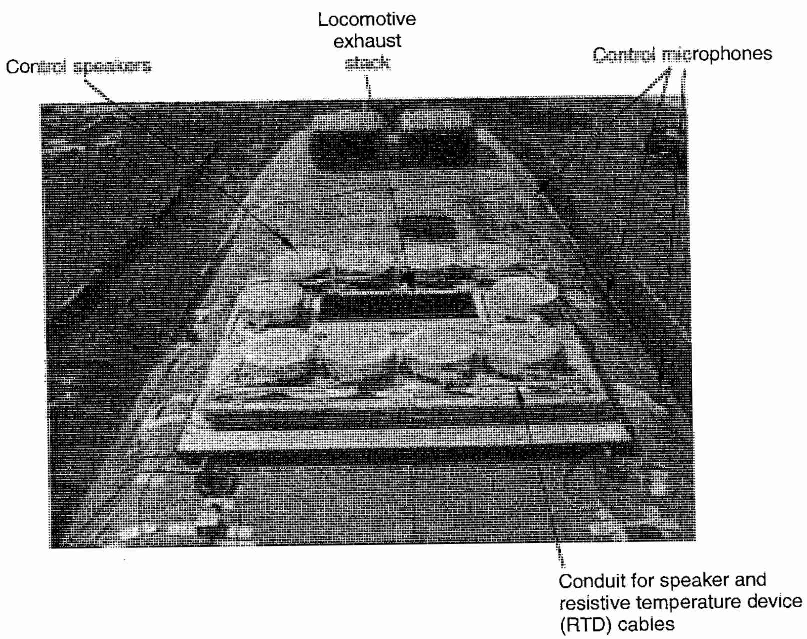

FIGURE 18.91 Control speaker arrangement in the locomotive.

developed for tonal control problems. A simplified control block diagram is shown in Fig. 18.92. The figure shows the typical adaptive MIMO LMS filtered-x architecture with eight control filters and an 8 × 8 plant transfer function matrix. A more detailed block diagram is shown in Fig. 18.93, where probe injection is shown for plant identification along with the additional LMS blocks for estimating the plant while minimizing the noise in the estimate.

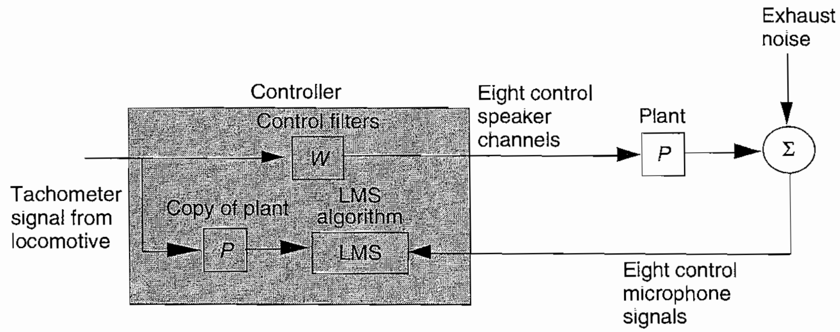

FIGURE 18.92 Simplified basic block diagram of the control architecture.

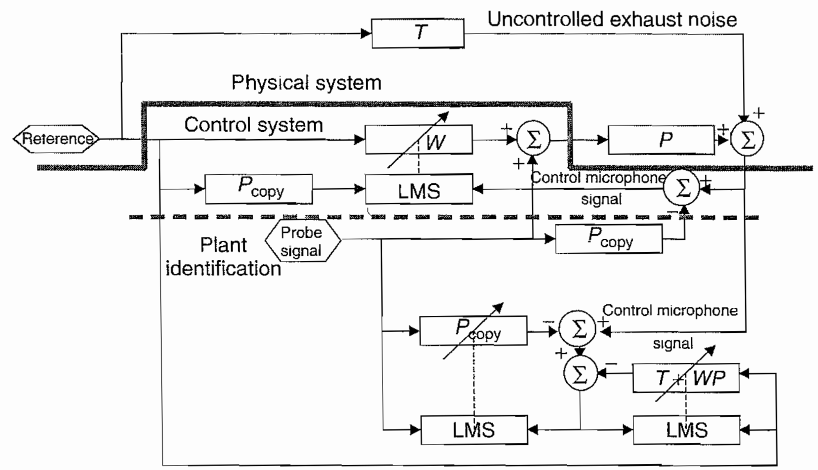

FIGURE 18.93 Detailed controller block diagram.

Hardware Selection. We decided early in the design process to use 12-bit successive-approximation A/D converters, since the lower discretization noise associated with 16-bit converters was not needed in this application. A commercially available input–output (I/O) board from Loughborough Sound Images was found that provided 16 input channels (A/D converters) and 8 output channels (sample-and-hold D/A converters) and in addition provided third-order low-pass Butterworth filters for anti-aliasing and reconstruction. We decided to use the on-board filters because providing a separate set of filters would have been too costly. Since these filters roll off very slowly with increasing frequency, we needed to use a sampling frequency much higher than would be needed to achieve the desired control bandwidth. Consequently, we sampled at 2000 Hz and set the cutoff frequency of the filters to 720 Hz; however, in the control computations we downsampled the digital signals by a factor of 4. This gave us an effective sampling rate of 500 Hz and a control bandwidth on the order of 250 Hz.

Estimates of computational load and memory requirements for the application are shown in Table 18.3. These estimates were based on up to 200 taps for each of the plant filters and 180 taps for each control filter. The table is divided into two functions: in-line control and system identification. In-line control is the function associated with implementing the control algorithm and system identification is the measurement of the plant transfer function, which must be updated periodically to maintain good control performance. It was decided to use two Texas Instruments TMS320C44 DSP chips available on a commercially available carrier board from Loughborough Sound Images. The board provided more than sufficient memory for the two operations. Each DSP chip is clocked at 60 MHz and is capable of up to 30 million floating-point operations per second (Mflops). It was decided to separate the two functions mentioned above with the primary DSP providing all of the control processing and the secondary DSP carrying out all of the system identifications tasks.

System Performance. The control system described above was implemented on an F40PH passenger locomotive operated by Chicago Metra, a commuter rail line in the Chicago metropolitan area. Testing was carried out at the 51st St. Rail Yard in Chicago. The microphone locations for the evaluation are shown in Fig. 18.94. The number of available microphone locations was limited because of the presence of other equipment and structures in the yard that would have interfered with the acoustical evaluation. Uncontrolled measurements were made before installation of the passive silencer. The performance of the system was then measured with the passive silencer in place and with the active system turned on and turned off.

Figure 18.95 shows the reduction of the tonal noise at microphone 5 on the roof of the locomotive due to the use of the active system for the locomotive operating loaded at throttle 4.* The figure shows significant reduction of all of the important tones with some amplification of the low-amplitude tones.

TABLE 18.3 DSP Computation Requirements for the Active System

Operation	MFLOPS	Memory (Kbytes)
Control	22.4	107
System identification	9.6	10
Total	32.0	117.0

*The locomotive diesel engine was loaded by passing the power from the alternator driven by the engine through the locomotive dynamic brake grids (large resistors cooled by the dynamic brake fan). The locomotive can be operated unloaded at idle and can be operated loaded or unloaded in any one of eight throttle setting. Throttle 1 corresponds to the lowest speed and lowest power and throttle 8 is the highest speed at full power.

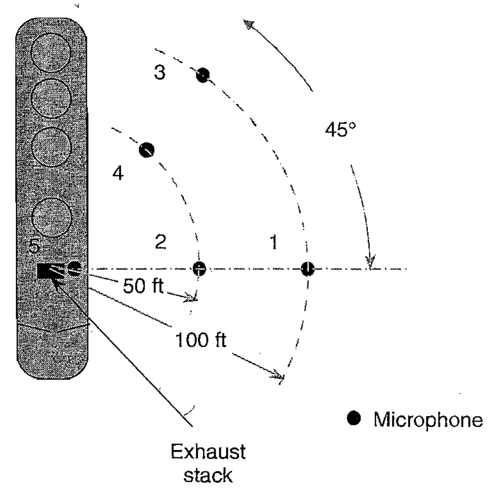

FIGURE 18.94 Microphone locations for the evaluation measurements.

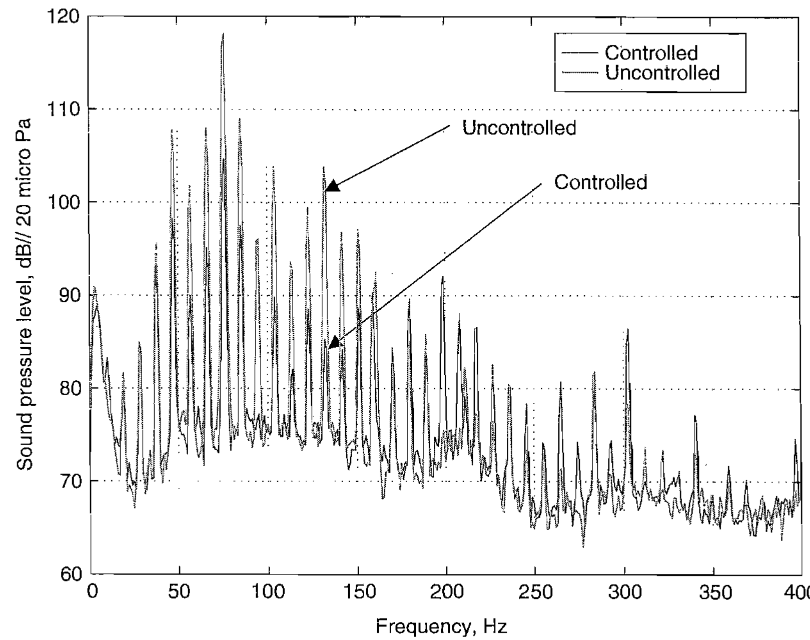

FIGURE 18.95 Noise reduction performance of the active system at throttle 4 loaded as measured at a microphone on the roof of the locomotive.

TABLE 18.4 Estimated Noise Reduction at the Far-Field Microphones

Throttle	Load	mic 5	mic 1	mic 2	mic 3	mic 4
idle	unloaded	5.1	5.2	6.5	6.1	6.4
hi idle	unloaded	8.7	6.5	8.9	5.8	7.4
t4	unloaded	6.9	5.2	4.1	5.6	5.4
t6	unloaded	7.7	6.6	5.6	6.4	6.0
t8	unloaded	5.8	−0.1	3.7	6.2	4.7
t4	loaded	6.4	5.2	4.1	4.7	4.6
t6	loaded	4.3	−1.9	1.2	2.8	1.7
t8	loaded	6.9	2.9	6.5	6.6	6.6

The reduction of the overall sound level below 250 Hz is in excess of 12 dB. Table 18.4 shows the overall A-weighted noise reduction due to the passive silencer and active system operating together. The reductions are somewhat less that the 10-dBA goal but are still significant for most operating conditions and for most microphone locations, showing that the hybrid active–passive system has provided significant broadband global noise reduction.

Active Machinery Isolation

Problem Description. It is difficult to achieve desired vibration isolation at low frequency using passive machinery mounts. Often, to achieve low-frequency isolation, two-stage isolators are employed, which incurs a very large weight penalty for the intermediate mass between the two isolators. In some applications, such as marine vessels or aircraft, the weight of the intermediate mass has an adverse economic and vehicle performance impact.

The forces transmitted into machinery foundations generally contain narrow-band and broadband components. Reduction of the continuous or broadband spectral components as well as the discrete or narrow-band spectral components is often necessary to meet noise or vibration goals. In addition, the tonal frequencies of the narrow-band excitation can change quite rapidly with time due to changes in operating speed. Further, the plant transfer function (i.e., the transfer function between the drive signal to the actuator and the sensor response) is expected to vary with time.

Finally, the machinery foundations of interest are often complex, large, distributed mechanical structures that are lightly damped and have a large number of resonant modes in the frequency range of interest. Thus, typically, plant transfer functions are of high order with high-Q response components. Moreover, the order (e.g., complexity) of the plant increases as the bandwidth of the controller is increased.

Based on the above observations, the control problem is defined as follows:

- Provide both narrow-band and broadband reduction of forces transmitted into the machinery foundation structures.

- Adapt rapidly to variations in the tonal frequencies of narrow-band excitations. Adapt at a relatively slower rate to variations in the plant.
- Minimize controller bandwidth to minimize complexity of the plant transfer function and consequently the controller.
- Provide the desired performance while avoiding out-of-band vibration amplification.

The final item is based on our experience with applications which require increased isolation performance within a certain frequency range but which will not tolerate significant degradation in isolation system performance outside the regulation bandwidth of the active system. Acceptable levels of out-of-band enhancement (i.e., noise amplification) are typically 2–3 dB.

In the following section, we describe an active isolation system designed to meet these requirements. We consider a feedback algorithm, because in general there is not a suitable reference sensor available to achieve broadband control using feedforward control. Although this discussion pertains to SISO control, the algorithms and control architecture are extensible to MIMO control.

Description of Control Strategy.

Real-Time Control Processing The basic real-time controller structure is shown in Fig. 18.96. This is the compensator-regulator architecture that was introduced in Section 18.5, where the plant, designated as $P(\omega)$ in Fig. 18.96, is the transfer function between the output of the controller and the net force transmitted to the foundation.

The controller is implemented as a cascade of two filters because we wish to adapt the low-order regulation filter coefficients quickly to track changes in the center frequency of narrow-band components of the disturbance. At the same time, we choose to adapt the relatively high-order compensation filter at a slower rate to track changes in the plant transfer function.

Adaptation Processing The full functionality of the adaptive controller is shown in Fig. 18.97. The "concurrent adaptation processing" block provides two types of adaptation:

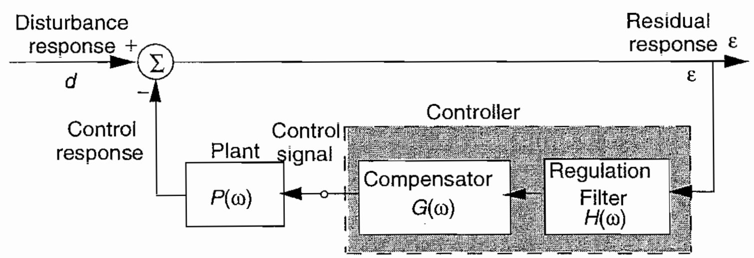

FIGURE 18.96 Feedback compensator regulator.

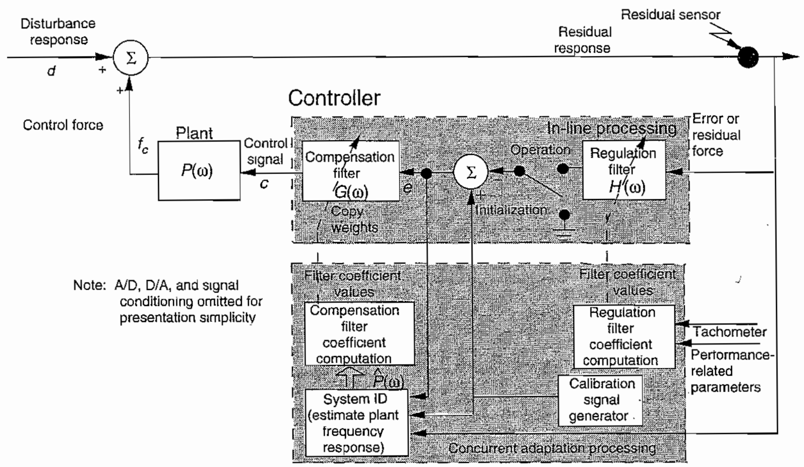

FIGURE 18.97 Controller functionality.

1. Variable narrow-band center frequency adaptation:
   - measurement via a tachometer (or other distinct speed or repetition rate measurement sensor) and a tracking filter of the center frequency of narrow-band response due to periodic excitation and
   - computation and updating of filter coefficients of the digital narrow-band regulation filters based on the currently measured center frequency and rate of change of the center frequency.
2. Variable plant adaptation:
   - system identification in the sense of plant frequency response estimation and
   - computation and updating of filter coefficients of the digital broadband compensation filter.

System identification is performed during closed-loop operation using the procedure outlined in Section 18.4. The major aspects of this procedure include (a) inserting a low-level calibration signal, which is uncorrelated with the external disturbance, into the compensation filter; (b) estimating the cross-spectra of the calibration signal with both the plant input and output; and (c) estimating the plant transfer function as the ratio of these two cross-spectra. Details of the processing of cross-spectra to estimate the plant as well as the design and injection of a covert probe signal are also discussed in Section 18.4 under System Identification.

The probe signal is sufficiently low in level that it does not add appreciably to the residual, and its bandwidth is matched to the full compensation band. Although it is low level, a good-quality estimate of the plant transfer function can be obtained with sufficient averaging time. In the performance plots that follow, estimates of the plant were updated approximately every 2 min.

Since we are concerned with a lightly damped mechanical structure and relatively large compensation bandwidths (e.g., 800 Hz), a FIR filter implementation of the compensation filters would have required a large number of coefficients. To reduce both the off-line and on-line computation load, we opted to use IIR filters designed by a multistep Yule–Walker method.

Hardware Description. Figure 18.98 presents a block diagram of the controller hardware. The algorithmic functionality of the controller is performed by four TMS320C30 DSP chips operating in parallel. The allocation of controller functionality to the individual DSP processors can be summarized as follows:

In-Line Processor. Performs the digital filtering of the regulation and compensation filters for the in-line data path.

Desamp Processor. Responsible for all off-line tasks associated with generating the desampled data buffers presented to the system identification algorithm. Replication filters and reference signal processing are also performed in this processor.

Sys_ID Processor. Performs the system identification and compensation filter weight algorithms. The compensation filter weights are then copied to the in-line processor.

Monitor Processor. Collects data from the other processors and uploads data to the host for monitoring and evaluating system performance.

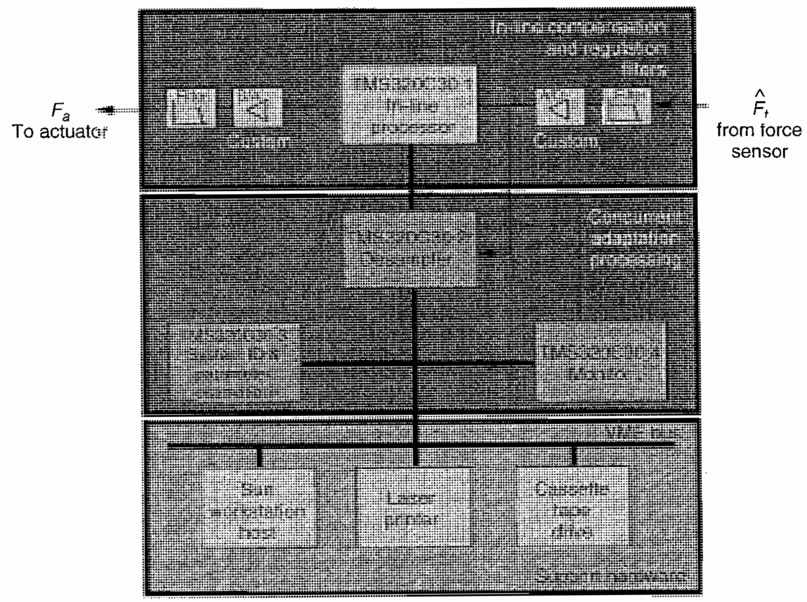

FIGURE 18.98 Controller hardware block diagram.

The controller implementation included custom-built A/D and D/A converter boards plus a logic controller board. The controller board provided a high-speed two-way interface between the DSP processors and the A/D and D/A boards. Two Sky Challenger boards, each of which contain two TMS320C30 chips per board, communicated with each other and the host computer over the VME bus and provide up to 132 Mflop computation rate. A SPARC workstation was chosen as the host computer.

Performance Example. The controller was connected to a prototype active/passive machinery mount located between one leg of a 1300-lb, 140 brake horsepower (BHP) at 2800 rpm, Detroit Diesel model 4–53 engine and a representative complex foundation structure. A picture of the active/passive mount and a schematic of the system are shown in Fig. 18.99. A detailed discussion of the engine, active/passive mount design, and test rig can be found in reference 88.

The test objectives were to provide at least 15 dB of narrow-band regulation at the fundamental and next four harmonics of the piston-firing frequency. In

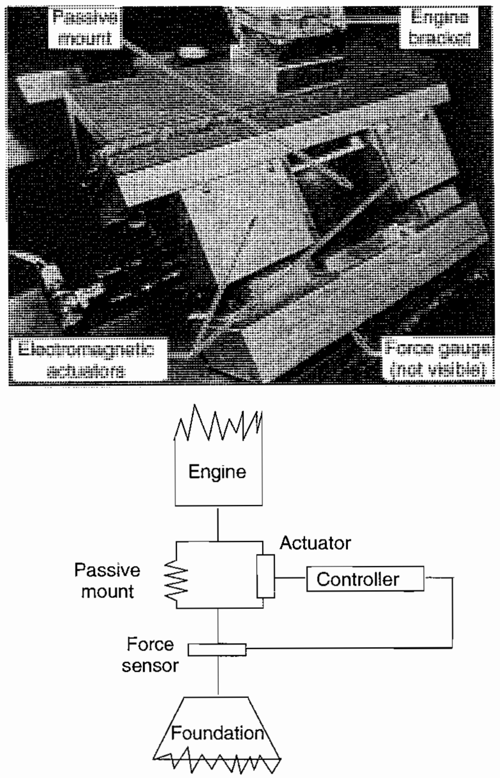

FIGURE 18.99 Active/passive mount and schematic of system.

addition, 10 dB of broadband regulation was desired over the frequency interval from 10 to 80 Hz while maintaining noise amplification below 5 dB outside the regulation bandwidth. To meet these objectives, a compensation bandwidth of 833 Hz and the system sample rate of 10 kHz were chosen. Latency of the digital system (including delay associated with the sample-and-hold on the D/A converter) was 60 μs.

The closed-loop performance of the active isolation system is shown in Fig. 18.100. This plot presents the ratio of the open- to closed-loop residual force transmitted into the foundation structure. As shown in this figure, narrow-band reductions in excess of 15 dB are achieved at the first five piston-firing tonals. In addition, approximately 10 dB of broadband regulation is achieved from about 15 to 80 Hz, which spans most of the frequency interval containing the tonals. Finally, this performance is achieved while limiting noise amplification to approximately 5 dB outside the regulation bandwidth. The very fine structure at higher frequencies of the measured ratio of open- to closed-loop forces, which sometimes goes below −5 dB, is due to harmonic distortion of the actuators (which were being driven very hard), rather than any shortcoming of the control processor.

Active Control of Airborne Noise in a High-Speed Patrol Craft

The Navy's new high-speed patrol crafts are powered by four main propulsion diesel engines that deliver a total of 13,000 shaft horsepower to a set of four propulsion shafts. The operation of these engines produces propeller blade rate tonal noise and broadband cavitation noise that propagate through the hull, producing high noise levels in the aft-crew berthing compartment, which is located

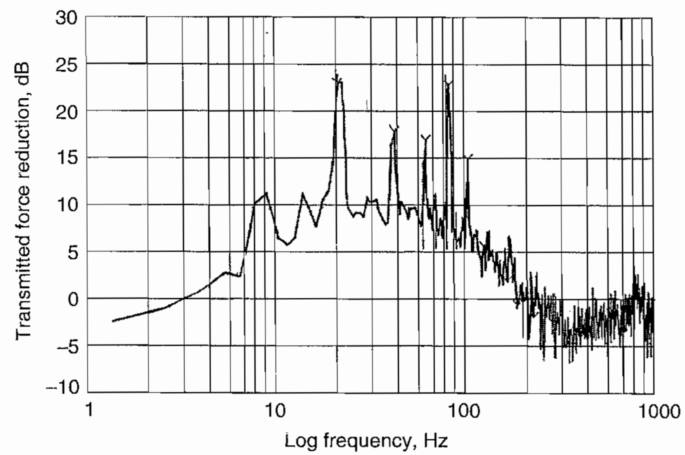

FIGURE 18.100 Reduction of transmitted force into foundation for active/passive mount relative to passive mount.

just forward of the propellers. Although extensive passive noise control treatments have been applied to reduce the noise in this compartment (including floating floors, double bulkheads, and constrained-layer damping), the 63- and 125-Hz octave-band and overall (dBA) airborne noise levels exceeded the Navy's acoustical habitability specifications. Table 18.5 compares measured third-octave-band and overall sound levels in the aft-crew berthing compartment for the first three ships of the class to the noise specification limits.[89] These measurements indicated that reductions in the 63- and 125-Hz octave bands were necessary to reduce overall A-weighted noise to acceptable levels.

To address this problem, several options were explored for reducing the low-frequency noise in the aft-crew compartment. Because passive treatments are least effective in this frequency region, several active noise and vibration control concepts were evaluated. These concepts included methods for both global and local control, using feedforward and feedback control strategies, and with digital and analog control hardware. To assess the benefits of each approach, a set of acoustical trials were conducted initially to measure the operational noise characteristics, path transfer functions, and compartment acoustical characteristics. These data were used to simulate performance of the various control options.

The approach chosen for implementation was local control of the sound field near the head of each bunk using a SISO feedback control strategy. This approach creates an effective "zone of silence" in the immediate vicinity of the occupant's head. This approach is shown schematically in Fig. 18.101. Laboratory simulations using measured data and a mock-up of one rack of bunks suggested that the necessary reductions at the occupant's head location could be achieved using this approach.

The active noise control system for a single bunk is contained within a single prismatic-shaped enclosure that is located in the upper corner of the bunk above and behind the occupant's head. Each unit contains a loudspeaker to create the cancellation noise, a pair of microphones to sense the noise field to be controlled, and a microprocessor to compute the cancellation signal in real time. The control algorithm implemented on the microprocessor was an adaptive feedback algorithm (based on the adaptive Youla transform discussed in Section 18.5) to reduce both narrow-band and broadband noise. The reading light originally placed in this location was incorporated into the active noise control (ANC) enclosure design.

TABLE 18.5 Average Aft Crew Berthing Octave-Band and A-Weighted Noise Levels at Full-Speed[89]

	31.5 Hz	63 Hz	125 Hz	250 Hz	A-Weighted
Noise Specification	105	100	95	90	82
Ship 1	98	113	100	88	87
Ship 2	97	104	94	85	85
Ship 3	95	111	96	86	86

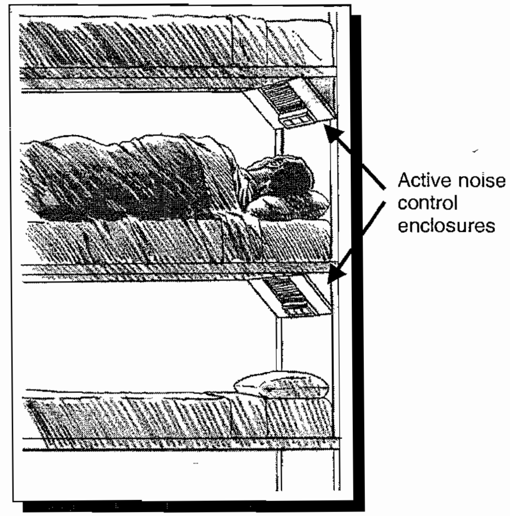

FIGURE 18.101 Schematic of active zone-of-silence approach.

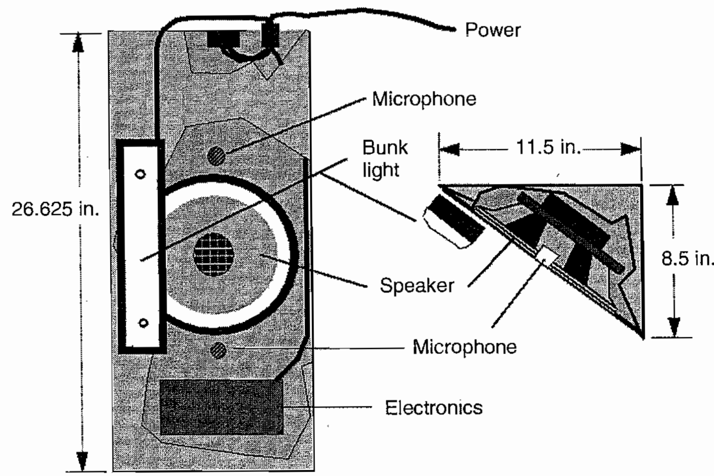

FIGURE 18.102 Components of the ANC enclosure.

The components of the ANC enclosure are illustrated in Fig. 18.102. Pictures of the actual implementation are contained in Figs. 18.103 and 18.104.

The prototype control system described above was evaluated during underway testing. A narrow-band plot of the measured noise reduction at the occupant's head location (not at the control microphones, where greater reductions were achieved) is shown in Fig. 18.105. This plot compares the noise spectra obtained

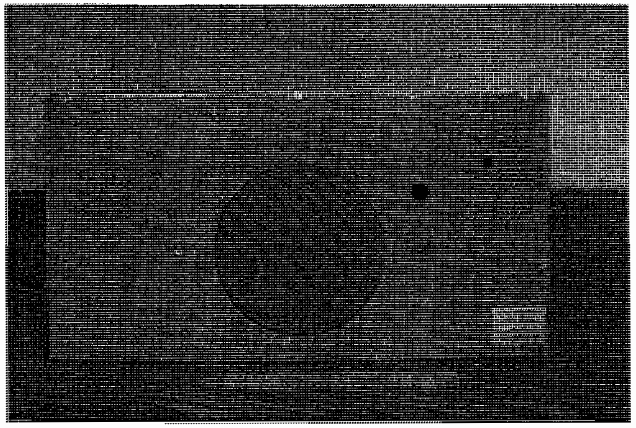

FIGURE 18.103 Faceplate of the ANC enclosure (integrated reading light not shown).

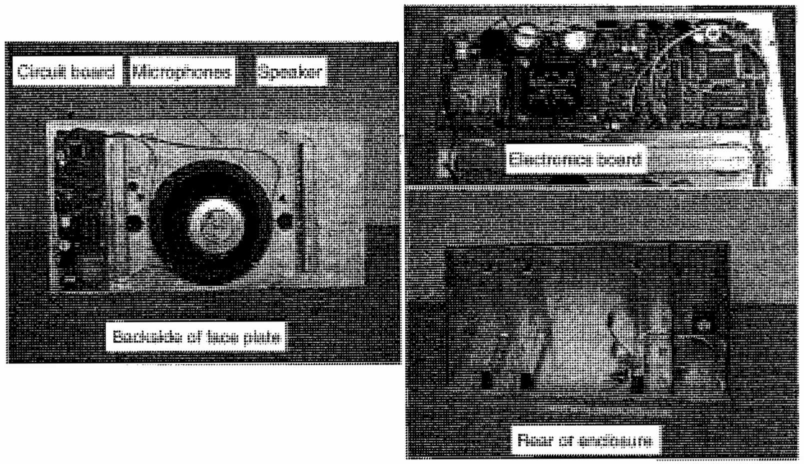

FIGURE 18.104 Pictures of the internal components of the ANC enclosure.

during full-speed operation when the control system was turned *off* to that when the control system was turned *on*. As shown in this plot, reductions at the dominant blade-rate tonals (at approximately 60 Hz) were greater than 15 dB, while 7–10 dB of broadband noise reduction was achieved between 30 and 85 Hz. Third-octave-band performance is summarized in Fig. 18.106. This summary shows that the system reduced the third-octave-band levels to below the limits of the Navy's acoustical habitability specifications, the goal of the program. Based on extensive testing of the prototype system on one patrol craft, the Navy contracted for production units for the entire class of PC1 patrol craft.

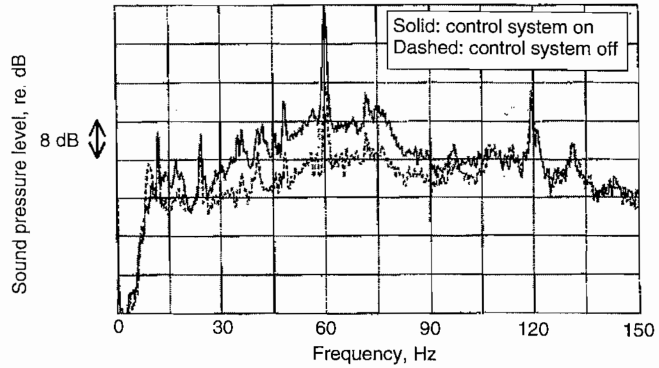

FIGURE 18.105 Narrow-band plot of noise reduction at occupant's head location during full-speed operation.

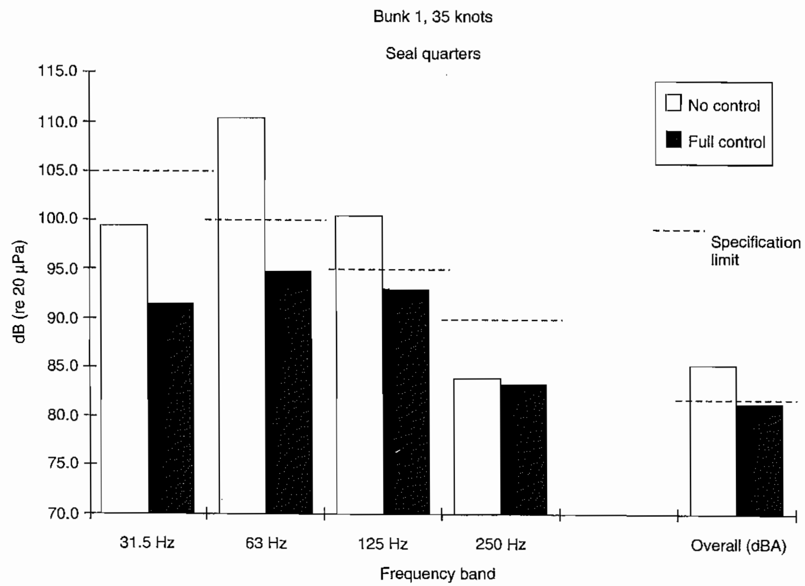

Acoustical data, dB re 20 μPa

Octave band	No control	Control	Attenuation
31.5	99.5	91.5	8
63	110.5	95	15.5
125	100.5	93	7.5
250	84	83.5	0.5
Overall dBA	85.5	81.5	4

19.1 INTRODUCTION

Noise and vibration are closely related biodynamic environments in terms of their origins, manifestations, and effects on people. Those effects on people that are undesirable are often threatening, induce fatigue, compromise working performance, modify physiological responses, and harm human systems. At the present time, avoidance of excessive noise and vibration exposure is the only assured way to prevent these major hazardous effects.

The practical alternative to complete avoidance is to limit exposures in these environments to those defined as acceptable by appropriate standards, guidelines, and damage risk criteria. Scientific exposure guidelines and criteria established to curtail these effects are vital parts of comprehensive protection programs of concern to governments, industry, and affected personnel. Most adverse effects of these commonly encountered mechanical forces on human systems can be minimized and controlled through engineering and design efforts. Central to these programs and actions are guidelines and criteria that describe potential damage risk and/or establish acceptable exposure limits.

Criteria and limits define conditions above which the risk of damage due to an exposure is considered substantial or unacceptable. Noise and vibration criteria describe exposure characteristics and corresponding undesirable effects such as noise-induced hearing loss, vibration-induced hand–arm vibration syndrome

(HAVS), and vibration-related spinal injury. Damage risk criteria have been developed and implemented worldwide. The basic exposure–effects relationships that underlie these criteria are reasonably well understood and are derived from observations and experience as well as good laboratory and field studies. The various criteria contain different limiting values because of variations in interpretations of the basic data and in the rationale used to establish them. The rationale may include practical, legal, and economic considerations as well as humanitarian concerns. It is very important that the rationale underlying damage risk criteria is fully understood by the user to ensure that the application is justified and accurate.

Estimates of noise and vibration exposures and of their probable effects on populations are usually expressed in terms of population distribution statistics. These group population effects are not precise descriptors, and they are not appropriate for evaluating an individual. Nevertheless, they are adopted by nations and incorporated into national regulations and laws. Many become mandatory requirements included in governmental and industrial activities involving exposure of people to noise and vibration environments.

This chapter presents contemporary regulatory and voluntary noise and vibration exposure standards and criteria along with background information that will facilitate their understanding and application in engineering control and design.

19.2 DAMAGE RISK CRITERIA FOR THE AUDITORY RANGE

Noise Factor

Permanent hearing loss and its associated problems are clearly the most critical and widespread of the various consequences of excessive noise exposure. The extent of damage to the hearing mechanism caused by noise is related to the amount of acoustical energy reaching the hearing mechanism. Such damage cannot be estimated accurately for an individual because of the variability of the noise and the susceptibility of the exposed ears. The primary factors in noise-induced hearing loss are the level of the noise, the frequency content or spectrum of the noise, the duration or time course of the noise exposure, and the susceptibility of the ear.

Exposure limits are defined in terms of level, spectrum, and duration of the noise. A-weighted sound energy of an exposure is directly related to noise-induced hearing loss. No other measure of noise exposure provides a better *cause–effect* relationship with hearing loss.[1] Impulse noise is also included in this measure for many criteria, as was concluded by a special workshop on impulse noise.[2] It was agreed that there is no convincing evidence against acceptance of A-weighting measurement of all noises from 20 to 20,000 Hz in determining their permanent threshold shift (noise-induced hearing loss that does not recover to preexposure levels after cessation of exposures) hazard except when their unweighted, instantaneous, peak-sound-pressure levels exceed approximately 145 dB. Consequently, exposures are typically described in terms of the average A-weighted levels, or the equivalent continuous A-weighted sound pressure level (L_{eq}), over an average workday.

Practical measures for the prevention of noise-induced hearing loss are centered in hearing conservation programs. These programs involve definitions of acceptable noise exposure, personal hearing protection, monitoring the hearing of the affected personnel, and appropriate administrative actions to minimize and eliminate identified temporary hearing problems before they become permanent. The basis of a hearing conservation program is the definition of acceptable noise exposure or exposure criteria that specify the acceptable exposure limits and the proportion of the population to be protected. The criteria of various hearing conservation programs and applications differ in their limiting values.

The parameters of particular exposure criteria are selected to satisfy the needs of the user. Factors that may influence these selections are various interpretations of available data, policies or requirements of organizations, and the remaining uncertainty in the noise exposure–hearing loss databases. Consequently, criteria may differ in such features as estimates of beginning hearing loss, corrections for nonnoise effects such as aging, percentage of the population to be protected, and the extent of protection to be provided.

The most obvious differences among noise exposure criteria are the sound level at which the implementation occurs and how the duration of the exposure and the sound level of the noise are combined.[3] The duration–sound level relationships are referred to as time–intensity trading rules, which assume that damage to hearing is related to total A-weighted sound level and the duration of exposure time. The equal energy relationship between these parameters results in the 3-dB rule. This and other relationships are shown in Table 19.1 which displays permissible noise exposures in A-weighted sound pressure levels for the cited criteria. The permissible A-weighted level for an 8-h exposure ranges from 75 dBA for the Environmental Protection Agency (EPA) to 90 dBA for the Occupational Safety and Health Administration (OSHA).

Most criteria utilize the 3-, 4-, or 5-dB rule. The 3-dB rule is based on the equal-energy concept and is the most conservative or protective of the three rules. The 4- and 5-dB rules assume that intermittency and interruptions of exposures reduce the risk to less than that expected from the total energy. Consequently, a 50% increase in exposure duration corresponds to sound-level decreases of 3 and 5 dB for the respective 3- and 5-dB rules (Table 19.1). Intermittency of exposure is discussed later in the chapter.

Hearing Sensitivity

The human ear is sensitive to a much wider range of sounds than the generally cited 20 Hz–20 kHz audio frequency range. A compilation of independent measurement studies by several investigators using a wide variety of instrumentation and methodologies shows very good agreement and provides confidence in the data summarized in Fig. 19.1 Infrasound (<20 Hz) and ultrasound (traditionally >20,000 Hz but practically above about 12,000 Hz) are normally detected by the ear only at very high sound pressure levels. The traditional audio frequency

region (20 Hz–20 kHz) is well defined for stimuli including discrete tones, bands of noise, speech materials, loudness, comfort, and acceptibility. These databases provide the information necessary to support the development of noise exposure criteria.

The sensitivity of human hearing for high-frequency sounds (3000–4000 Hz and above) gradually decreases with advancing age. This process is called *presbyacusis*. Auditory system components are affected in both the peripheral and the central nervous systems. Although individual patterns of presbyacusis vary widely, normative data describing hearing sensitivity as a function of age have been compiled for various segments of society (some are reported in ref. 5). Loss of sensitivity due to accident, disease, or substances toxic to the auditory system is called *nosoacusis* while that attributed to the noises of everyday living is *sociacusis*. The major high-level noises to which people are exposed are the occupational environments.

Environmental noise occurs over the full spectrum to which the human auditory system is sensitive. Exposure to various segments of this sensory continuum produces differential effects on humans. Limiting levels and durations of acoustical exposure are defined for a number of specific portions of this spectrum, which include infrasound (0.5–20 Hz), audio frequencies (20 to about 12,000 Hz), ultrasound (12,000 to about 40,000 Hz), and impulsive sounds (characterized by rapid onset and durations of less than 1 s) described in terms of peak sound pressure level and duration. Some of these limits are well substantiated by experience and experimental evidence while others remain tentative until more evidence is available.

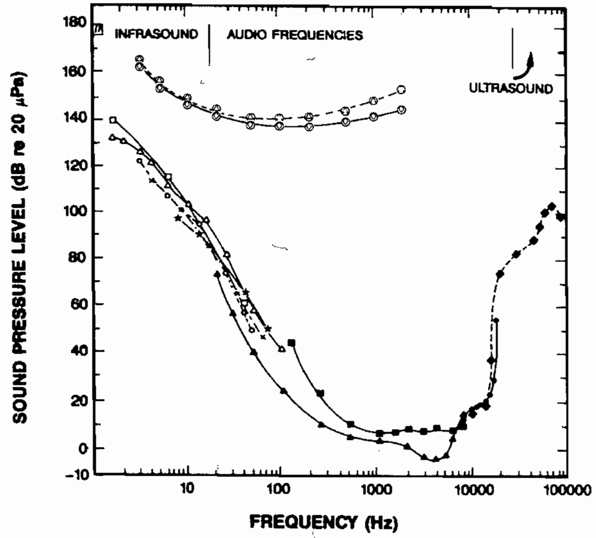

FIGURE 19.1 Human auditory sensitivity and pain thresholds for pure tones, octave bands of noise, and static pressure: (◬) BENOX (1953), pain MAP tones; (◬) pain static pressure; (◎) tickle, pain tones; (□) Bekesy (1960), MAP tones; (▲) ISO R226 (1961), MAF tones; (♦) Corso (1963) bone conduction minus 40-dB tones; (○) Yeowart, Bryan, and Tempest (1960), MAP tones; (×) MAP octave bands of noise; (■) standard reference threshold values (American National Standard on Specifications for Audiometers) (1969), MAP tones; (●) Northern et al. (1972), MAP tones; (△) Whittle, Collins, and Robinson (1972), MAP tones; (★) Yamada et al. (1986), MAF tones. (Data adapted from Ref. 4.) Minimum audible pressure (MAP) indicates that the sound was presented to the ears through earphones and the sound pressure levels were measured in an earphone–microphone coupler that approximated the cavity created by the earphone/pinna. Minimum audible field (MAF) indicates that the sound was presented to the listeners facing a loudspeaker and located in anechoic space. The sound pressure levels for MAF were measured at the location of the center of the head without the listener present. For the same listeners, MAP thresholds are generally several decibels higher than MAF thresholds.

19.3 AUDIO FREQUENCY REGION

CHABA

Noise exposure criteria for the audio frequency region (20–12,000 Hz) were developed by the National Academy of Sciences—National Research Council, Committee on Hearing, Bioacoustics and Biomechanics (CHABA) in 1965.[6] This method described noise exposure in terms of pure tones, third-octave, and octave bands of noise, and it includes the audio frequencies of 100–7000 Hz. Acceptable exposures to noise can be determined from 11 sets of curves. An environmental noise is considered acceptable if it produces, on average, a NIPTS after 10 years or more of near daily exposure of no more than 10 dB at 1000 Hz and below, 15 dB at 2000 Hz, and no more than 20 dB at 3000 Hz and above. These criteria are based on the assumption that noise exposures producing temporary threshold shifts (TTSs) would eventually produce permanent threshold shifts (PTSs). The possible relationship that TTS is a precursor to PTS is still an open question. The CHABA criteria have been widely used and are an excellent tool. However, they are not simple to use or to relate to current standards, regulations, and guidelines and are less preferred than criteria employing A-weighted sound level.

OSHA

The Occupational Safety and Health Administration has adopted a noise exposure limit of 90 dBA with a 5-dB trading relationship to control excessive noise exposure in industry (Table 19.1). When employees are exposed to noise at different levels during the day, ratios of the actual to the allowed duration for that level are computed and the fractions summed for the day. Total daily exposure calculated from these fractions or ratios must not exceed unity. No other corrections or adjustments are applied to these criteria.

The OSHA noise exposure criteria were verified in 1983 with the publication of "Occupational Noise Exposure; Hearing Conservation Amendment; Final Rule."[7] The basic conditions of the original OSHA noise exposure regulation remain the same with a few exceptions. Continuous A-weighted sound levels are not permitted above 115 dBA regardless of duration. A permissible exposure level (PEL) is defined as that noise dose that would result from a continuous 8-h exposure to a sound level of 90 dBA. The limit of 90 dBA is a dose of 100%, which is the basic criterion level. A *time-weighted average* (TWA) is the sound level that would produce a given noise dose when the employee is exposed to that level continuously over an 8-h workday regardless of the length of the work shift. Workday exposures of 4 h at 90 dB, 8 h at 85 dB, or 12 h at 82 dB all correspond to a TWA of 85 dBA and a noise dose of 50%. The Hearing Conservation Amendment includes computational formulas and tables showing the time–intensity relationships for the 5-dB rule and conversions of dose to time-weighted averages. Guidance is given on calculations of age corrections to audiograms. However, the use of age correction procedures is not required for compliance.

A noise dose of 50% or a TWA of 85 dB is the "action level" at which hearing conservation measures must be implemented. All workers receiving noise doses at or above the action level must be included in a hearing conservation program that requires noise monitoring, audiometric testing, hearing protection, employee training, and record keeping. A baseline audiogram is one taken within six months of the employee's first exposure above the action level, against which subsequent audiograms can be compared. An annual audiogram must be taken for each employee exposed at or above the action level. A *standard threshold shift* (STS) is a change in hearing sensitivity from the baseline audiogram that exceeds an average of 10 dB or more at 2000, 3000, and 4000 Hz in either ear. Appropriate action by the employer must be taken in response to the STS to ensure the continued protection of the hearing of the employee.

Environmental Protection Agency

The EPA published "Information on Levels of Environmental Noise Requisite to Protect Public Health and Welfare with an Adequate Margin of Safety"[1] in 1974 in response to the Noise Control Act of 1972. The objective was to identify levels of environmental noise required to protect the public from adverse health and welfare effects. The levels for noise-induced hearing loss described in this document were based upon reviews and analyses of scientific materials as well as consultations and interpretations of experts. It was concluded that an L_{eq} of 70 dB over a 24-h day (over a 40-year working life) would protect virtually the entire population (96th percentile) for hearing conservation purposes. An $L_{eq(8)}$ limit of 75 dB was considered appropriate protection for the typical 8-h daily work period. This criterion is considered to be very restrictive for most applications, and it has not been incorporated into any DRC for occupational noise exposures.

Air Force

The U.S. Air Force (USAF) hearing conservation criterion is 85 dBA for a maximum allowable 8-h daily exposure. The trading relationship of 3 dB allows such exposures as 16 h at 82 dBA and 4 h at 88 dBA. Higher level continuous exposures for shorter durations, such as 94 dBA for 1 h, are limited to a maximum level of 115 dBA. The ratios of the actual to the allowable daily exposure times are not to exceed unity. Air Force criteria also include limiting conditions for infrasound, ultrasound, and impulse noises.

Army

The U.S. Army (USA) hearing conservation program criterion is 85 dBA as the maximum allowable exposure regardless of duration. Personnel experiencing these exposures must be enrolled in the hearing conservation program. In training and noncombat scenarios single hearing protection will be worn in steady noises of 85–107 dBA and double hearing protection for 108–118 dBA. Protection requirements for unique military noise sources are determined individually. The Army criteria also include limiting exposures for impulsive noises.

Navy

All noise-exposed Navy personnel are required to wear hearing protection when exposed to environmental noise exceeding the criterion of 84 dBA or 140 dB peak, regardless of duration. Personnel are entered into the hearing conservation program based on the 84-dBA damage risk criterion for an 8-h work day, with a 4-dB exchange rate. Double hearing protection is required when sound levels exceed 104 dBA, which administratively assumes 20 dB of single protection from an approved earplug or earmuff.

ISO-1999

The International Organization for Standardization (ISO) standard ISO-1999 (1990), "Acoustics—Determination of Occupational Noise Exposure and Estimation of Noise-Induced Hearing Impairment,"[5] is a landmark document that establishes practical procedures for estimating noise-induced hearing loss in populations. Standard ISO-1999 does not provide a specific formula for assessing risk of hearing handicap, but it specifies uniform methods for the prediction of hearing impairment that can be used for assessment of handicap according to the formula stipulated in a specific nation. The procedures are based on the equal-energy, 3-dB rule (adopted by the ISO and member nations as a conservative criterion) and deal with the measurement and description of noise exposure, the prediction of effects of noise on hearing threshold, and the assessment of risk of noise-induced hearing impairment and handicap. Annexes, which are not part of the standard, provide calculation procedures, examples, tabular data used in the calculations, and a method for relating this information to that of the preceding standard, ISO-1999 (1975). These procedures allow agencies, industries, and governments to select parameters and establish criterion values according to their respective needs. This document will form the basis for legislation in many countries.

The ISO method describes all exposures during an average work day in terms of the A-weighted sound exposure or energy average. The integration period is taken as a working day or a working week. All noises are included in the exposure, ranging from steady state to impulses. Exposures that contain steady tonal noise or impulsive/impact noise are considered about as harmful as the same exposure without these components but about 5 dB higher in level. Exposure can be measured with personal noise dosimeters or an integrating-averaging sound-level meter. Direct and indirect methods for the determination of exposure level are discussed as well as sampling methods.

The only measure of environmental noise needed to calculate hearing impairment or risk of hearing handicap under the following conditions is the energy-averaged daily noise exposure. The maximum instantaneous sound pressure level must be less than 140 dB, the average 8-h daily exposure must not exceed 100 dBA, and the maximum individual daily exposure must not be more than 10 dB above the average of all daily exposures to permit this determination of energy-averaged daily exposure.

Implementation of this standard follows a well-defined series of operations. The first involves determination of the age-related hearing levels of the target population for all test frequencies (e.g., population of 50-year-old males, 90th percentile at 500–6000 Hz). The long-standing difficulties of defining a "normal" population for this purpose were overcome with the utilization of two databases. Database A contains standardized distributions of hearing threshold of an ideal "highly screened" population free from all signs of ear disease, obstructions of wax, and without undue history of noise exposure. Database B can be any carefully collected database covering an *occupationally non-noise-exposed population* considered to be a valid control for the noise-exposed population under consideration. Each user of the standard can select the subpopulation most appropriate for its analysis. As an example, for database B the standard provides the data from the U.S. Public Health Service Surveys reported in 1965.[8]

Next, the predicted NIPTS of the population is calculated for all test frequencies by considering both the number of years of exposure and the average daily noise exposure levels. Data in the standard for calculating NIPTS are valid for frequencies from 500 to 6000 Hz, exposure times of 0–40 years, and average daily noise exposure levels between 75 and 100 dB.

The hearing handicap or risk of hearing handicap may be calculated using the appropriate NIPTS values and a formula selected by the user or a member nation. The document contains nine formulas that are proposed or commonly used among nations for assessing hearing handicap by averaging hearing threshold levels at selected audiometric test frequencies. In the United States, hearing handicap for conversational speech is assessed using the average of the hearing levels at 500, 1000, 2000, and 4000 Hz. Other procedures are available for determining overall percentage of hearing loss for purposes of compensation.

Long-Duration Noise Exposure

Noise exposure durations that exceed 8 h may occur in some work assignments and when substantial nonoccupational noise is added to that received at work. These longer duration exposures are extended by noises from daily living activities, recreation, transportation, proximity to industry, and even other vocational activities. Although the baseline of most criteria is the allowable exposure for an 8-h day, many do extend their time–intensity trading relationship to 16 or 24 h as additional guidance.

Although the 8-h day, 5-day work week is considered standard, numerous variations are employed for many occupations. Some of these are four 10-h days with three days off, three 12-h days with three and four days off, and 12 h on and 12 h off. The noise exposure criteria do not cover these exposures with the same degree of accuracy as with the standard work week. However, it is reasonable to consider the exposure per work week as a basis for calculating noise exposure (i.e., the 3-dB rule).

An important discovery in studies of effects of long-duration exposure to continuous (nonimpulsive) noise of 24 h and longer on human hearing was the phenomenon represented in Fig. 19.2 and called asymptotic threshold shift (ATS).[9] Hearing threshold levels progressively increased with time until the exposure durations reached 8–16 h. Hearing threshold levels reached a plateau or asymptote between 8 and 16 h and did not increase further with continuation of the same exposure levels for 24 and 48 h. Recovery from these asymptotic levels to the preexposure threshold levels was related to exposure time. Even though the asymptotic levels were the same for 24- and 48-h exposures to a particular stimulus, the time needed to recover was significantly longer for the 48- than for the 24-h exposures. The longer period of time to recover is interpreted by

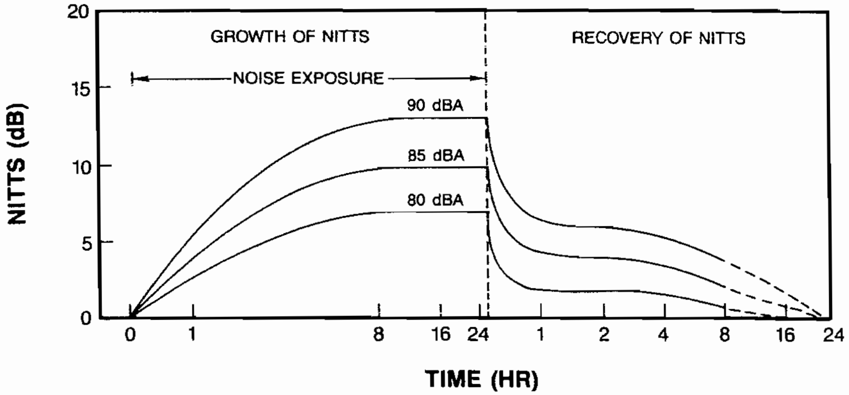

FIGURE 19.2 Growth recovery of noise-induced temporary threshold shift (NITTS) measured during and following the noise exposure at the times marked on the abscissa. The stimulus was a third-octave band of random noise centered on 1000 Hz presented at 80, 85, and 90 dBA. The curves represent the averages of the hearing levels (HLs) for the 1000-, 1500-, and 2000-Hz test frequencies $\frac{1}{3}(\mathrm{HL}_{1000} + \mathrm{HL}_{1500} + \mathrm{HL}_{2000})$.

some as an indication of greater risk to hearing from the same stimulus (same asymptotic threshold level) for 48 than for 24 h. On the basis of analyses of the actual recovery times the guideline was established that the period of time in effective quiet required for recovery should be at least as long as the duration of the exposure.

Audiometric data on the crew members and information on the internal noise levels of the *Voyager* lightweight aircraft (two 110-hp piston engines) during a practice (five days) and a round-the-world flight (nine days) have provided additional important data points. The overall noise environments at the crew locations ranged between 99 and 103 dBA. Crew members wore communications headset and earplug equipments that allowed estimations of the exposures at the ears to be between 84 and 95 dB for the octave band at 500 Hz. Comparisons of preflight and postflight audiograms for both flights revealed substantial shifts of hearing levels. The threshold shifts from the nine-day flight were no greater than those for the five-day flight. One week following the nine-day flight the hearing thresholds of both crew members had returned to their preflight levels.

The hearing level data on the five- and nine-day exposures is consistent with laboratory data derived from both human studies of shorter duration and animal studies of similar duration. It is considered acceptable by some criteria to extend the 8-h limits to as much as 24 h using appropriate trading relationships. Noise exposures of atypical work schedules such as four 10-h days with three days off and 12 h on, 12 h off might be calculated on the bases of work week. Although recovery of the hearing thresholds occurred prior to nine days for these crew members, it remains reasonable to have personnel remain in effective quiet for a period at least as long as the exposure prior to reentering the noise.

Music Exposure Criteria

The USAF has adopted music exposure criteria that consider customers or clients of military "clubs" to be "recreationally exposed" and employees to be "occupationally exposed." The occupationally exposed persons are governed by the same provisions as those of workers exposed in any other occupational noise. A separate set of criteria are used to control or limit the recreational exposures.

An average A-weighted sound level of 94 dB is considered acceptable when it does not exceed 2 h duration once a week. It is important to recognize that the 94-dBA guideline is not a peak of a maximum level value but is the average sound level. The average sound-level concept does not specify a fixed maximum level or eliminate crescendos and special effects or even some selections. It does permit these intermittent high levels of entertainment music to be averages in such a way that the overall performance is acceptable.

19.4 IMPULSE NOISE

Impulse or impact noise is a very brief sound or short burst of acoustical energy with a sound pressure rise of 40 dB in 0.5 s or faster that may occur singly or as a series of events. The noise may be treated as steady state when the repetition rate of a series of impulses exceeds 10 per second and the decay from the individual peaks to minima does not exceed 6 dB.

The effects on the auditory system have been examined for such characteristics of the impulsive stimulus as frequency spectrum, duration, peak pressure level, total energy, type of impulse, and rise time. Although work continues with some of these characteristics, present exposure criteria use only peak pressure level and duration and type of impulse to describe safe impulse exposures.

In 1968, CHABA developed exposure criteria for impulse noise[10] based on extensive work in the United Kingdom on firing small arms.[11] The limiting noise exposure values for the impulsive stimuli are summarized in Fig. 19.3. These criteria define exposures that should produce, on average, no more NITTS than 10 dB at 1000 Hz, 15 dB at 2000 Hz, and 20 dB at 3000 Hz and above in 95% of the exposed ears. The criteria provide for adjustments or corrections for exposure situations that vary from the basic condition. The criteria provide for a daily exposure of 100 impulses during any time period ranging from about 4 min to several hours. The values are increased for fewer and decreased for more than 100 impulses per day by a factor of 1.5 dB for each doubling or halving of the number of impulses. The allowable level must be decreased by 5 dB for impulses that strike the ear at perpendicular incidence.

Simple, nonreverberating impulses that occur in open spaces are evaluated using the A-duration or pressure wave duration, which is the time required for the initial or principal wave to reach peak pressure level and return momentarily to zero (Fig. 19.3). The B-duration or pressure envelope duration is used for impulses that occur under various reverberant conditions and is the total time that the envelope of the pressure fluctuations (positive and negative) is within 20 dB

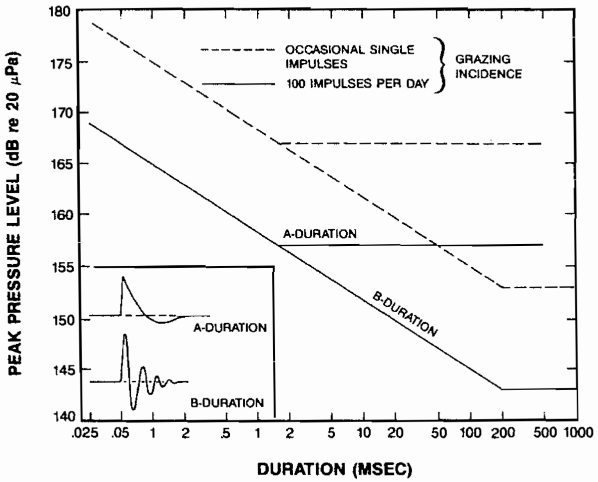

FIGURE 19.3 Proposed damage risk criteria for impulse noise arriving from the front or from behind (grazing incidence) exposed persons. The *A*-duration curve reflects the simple, nonfluctuating impulse that occurs in open areas. The *B*-duration curve reflects the pressure fluctuations of impulses that occur under various reverberant conditions.

of the peak pressure level, including reflected waves. The 143-dB floor of the B-duration curve represents the reduction of the energy entering the ear after 200 ms by action of the acoustic reflex (reflex contraction of the middle-ear muscles that reduces the transmission of energy to the inner ear). This comprehensive dose–response curve (DRC) for impulses continues to represent the present data and scientific understanding of impulse noise effects on hearing.

The OSHA amendment, the Air Force, and the Army, all limit exposure to impulse or impact noises to 140 dB peak sound pressure level. The Army has unique equipment that generates high-level impulse noises that are measured and treated individually.

Sonic booms do not constitute a threat of noise-induced hearing loss for human beings. Most of the energy in sonic booms generated by aircraft in supersonic flight is in the low and infrasonic frequency ranges and contributes little to the A-weighted sound level. Field and laboratory investigations with human exposures have revealed no significant effects on hearing from sonic booms at levels typically experienced in the community. One field study involving human exposures to extremely intense sonic booms ranging in level from about 50 to 144 lb/ft^2 observed no changes in the hearing levels of the participants.[12] Naturally, such intense sonic booms may generate higher A-weighted levels indoors than outdoors due to rattling of windows and doors.

Air bag systems are designed to provide crash protection of occupants during side and forward impacts of motor vehicles. These systems generate a loud, impulse noise inside the vehicle upon inflation of the air cushion. In an early study[13] of a prototype system, 91 volunteers experienced this air bag deployment inside a small automobile at a median peak pressure level of 168 dB. Some TTS was experienced by about 50% of the subjects. About 95% of those with TTS recovered preexposure hearing levels on the same day. About 5% required longer times for recovery with one subject showing a gradually returning shift at one frequency that persisted for several months.

19.5 INFRASOUND

Relationships among human exposures to infrasound (0.5–20 Hz) and resulting hearing loss are presently not sufficiently understood for the establishment of national (U.S.) or international standards on exposure limits. Few investigations have been conducted because of difficulties in measuring hearing thresholds for infrasound and in producing infrasound stimuli free from audible overtones that are required for exposure studies. Tentative criteria have been established on the basis of laboratory investigations and field experiences with noises containing intense infrasound components. These criteria have been incorporated in some Department of Defense regulations on hazardous noise exposure.[14]

Human whole-body vibration exposures in intense levels of infrasound that exceeded 150 dB sound pressure level were reported in a classic study.[15] The sample size was small. However, the subjects were highly experienced professionals. Relationships were observed between exposure levels and human tolerance as a function of subjective "symptoms." These symptoms are described in Section 19.8 for airborne vibration. Certain exposures were judged to be very close to tolerance limits. Hearing levels of the subjects were measured 3 min following termination of these very intense exposures and no changes were found in hearing sensitivity.

The absence of hearing sensitivity effects immediately following the intense infrasound exposures verifies laboratory findings that infrasound is not a major threat to hearing. The exposure criteria in Fig. 19.4 have been developed on the basis of data such as that in the cited report and that presented in Fig. 19.5.[16] Numerous experimental subjects experienced exposures to 10 Hz at 144 dB for 8 min with no adverse effects. This set of safe exposure conditions was accepted as a baseline exposure from which 8-h limits (136 dB at 1 Hz and 123 dB at 20 Hz) and 24-h limits (130 dB at 1 Hz and 118 dB at 20 Hz) were extrapolated. (Development of this sound pressure level formulation is described in ref. 16.)

19.6 ULTRASOUND

Ultrasound (~16–40 kHz) is widespread in our society due to sources such as ultrasonic cleaners, measuring devices, drilling and welding processes, animal repellants, alarm systems, and communications control applications as well as a wide range of medical applications. Although the number of people exposed to

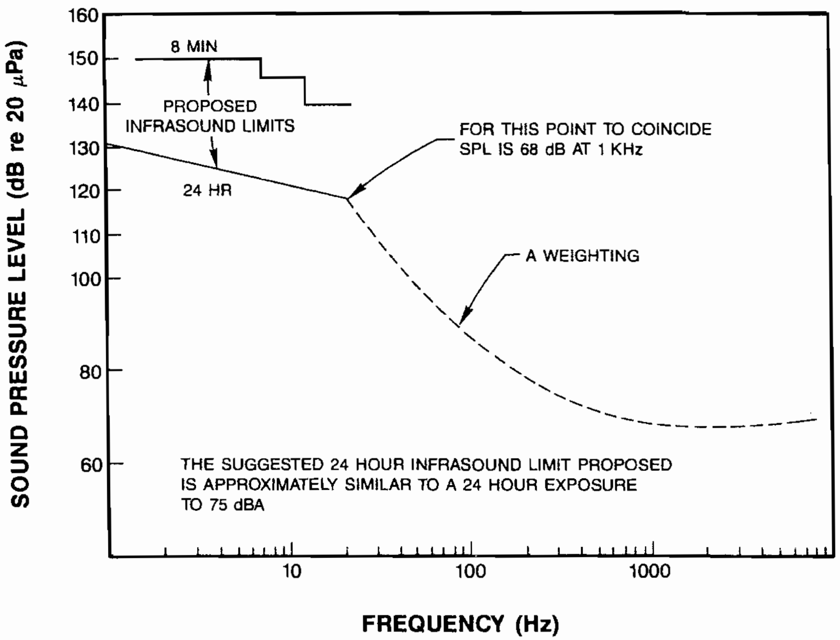

FIGURE 19.4 Infrasound 8-min and 24-h exposure limits.

ultrasound is large, it poses no threat to human hearing because neither temporary nor permanent hearing loss caused by ultrasound has been reported, with one exception. Temporary threshold shift was reported following experimental exposures to discrete tones in the region of 17–37 kHz at levels of 148–154 dB. The TTS occurred at subharmonics of the stimulus frequency and was likely caused by nonlinear distortion of the eardrum.

Nevertheless, ultrasound continues to be viewed as a threat to hearing as well as a cause of other subjective symptoms. Ultrasound is readily absorbed by air and its intensity diminishes rapidly with increasing distance from the source. The impedance match with human flesh is poor, and much energy is reflected away from the surface of the body. Consequently, the ear is the primary channel for transmitting airborne ultrasound to the internal systems.

Ultrasonic energy at frequencies above about 17 kHz and at levels in excess of about 70 dB may produce adverse subjective effects experienced as fullness in the ear, tinnitus, fatigue, headache, and malaise. These subjective effects are mediated through the hearing mechanism and are related to hearing ability. Persons who do not hear in this frequency region do not experience these subjective symptoms. Women experience the symptoms more often than men, and younger individuals report them more often than older ones. This reporting is consistent with the relative hearing abilities of the three groups. Neither disorientation nor loss of balance has been attributed to ordinary exposures to ultrasound.

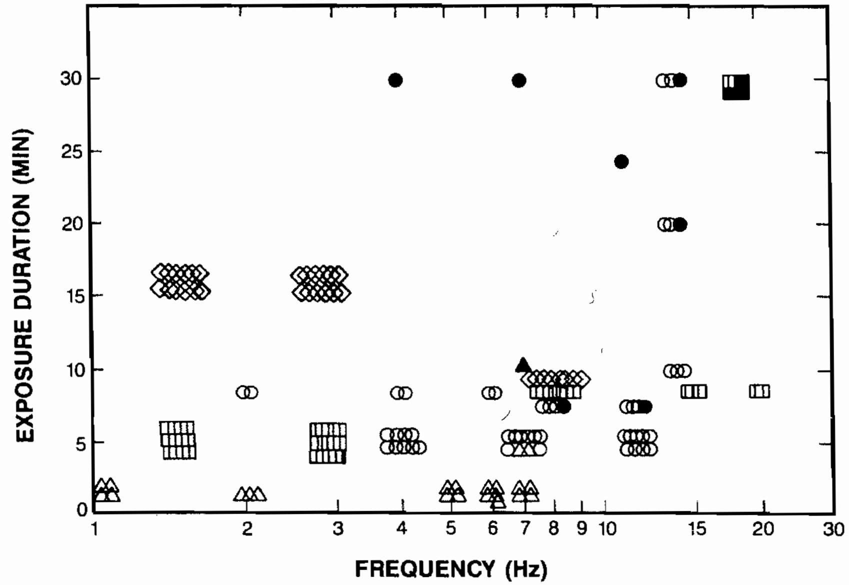

FIGURE 19.5 Infrasound exposure effects on hearing. Exposure levels (filled symbols indicate that some TTS has occurred): (△) > 150 dB; (○) 140–149 dB; (□) 130–139 dB; (◇) 120–129 dB.

Ultrasound exposures usually contain various amounts of high audio frequency energy (5–20 kHz). Subjective effects attributed to the ultrasound are usually caused by the audio frequency energy. Reducing the level of the audio frequency energy in the exposure usually results in the disappearance of the auditory and subjective symptoms.

Criteria for limiting the levels of ultrasound to control auditory and subjective effects are very similar. The data refer to the ultrasound levels at the head of the exposed person. The limiting levels at 20 kHz and above apply to protection from the subjective symptoms described earlier. Representative international and national criteria adopted by the World Health Organization (WHO), Norway, Sweden, and the American Conference of Governmental Industrial Hygienists (ACGIH) are displayed in Fig. 19.6. Norway accepts a level of 120 dB for frequencies higher that 22 kHz.

19.7 HEARING PROTECTION

The damage risk or noise exposure criteria presented above define allowable exposures for unprotected ears. These criteria are also used to identify exposure conditions above which personnel should be included in hearing conservation programs and where hearing protection should be worn. Hearing protection extends

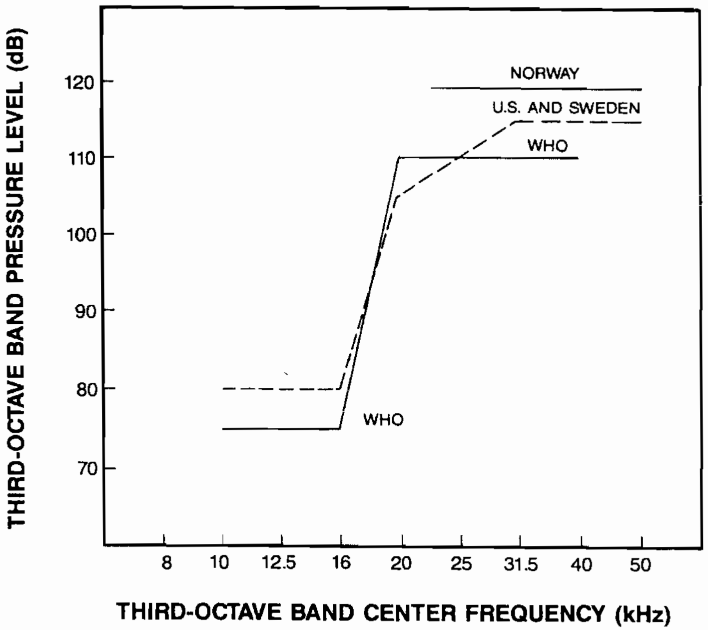

FIGURE 19.6 International and national criteria for exposure to airborne ultrasound.

the limits of allowable exposures by reducing the levels at the ear, allowing personnel to experience more intense and longer duration exposures than with unprotected ears and still remain within established whole-body exposure criteria.

Hearing protector performance is influenced by characteristics of the wearer, the protective device, and the noise exposure. Protection is best with devices that provide good attenuation, are comfortable, fit properly, are easy to use, are in a good state of repair, and are worn. Hearing protector effectiveness is reduced by air leaks, transmission properties of the materials, and noise-induced motion of the device that produces sound under the protector. A limit on performance of ideal devices is imposed by the sound conduction properties of the tissue and bone of the head. In high-level acoustical fields, sound travels "around" the protector to the inner ear through the tissue and bone of the head. The level of the sound reaching the ear by such means is about 50 dB below that of air conduction reaching the ear through an open ear canal. Bone-conducted sound is not a major concern for most noise environments. Total-head enclosures extend the tissue and bone limits by about 10 dB.

Infrasound

Good insert-type hearing protection devices should provide attenuation of infrasound approaching that observed at the 125-Hz third-octave band. Earmuff hearing protectors provide very little protection and may even amplify the sound at some of these infrasonic frequencies. Exposures to levels of infrasound above 150 dB should be avoided even with maximal hearing protection because of possible adverse nonauditory effects.

Audio Frequency Region

Hearing protection performance varies as a function of the frequency spectrum of the noise. In general, conventional earplugs and earmuffs provide good sound protection at higher frequencies (above 1000 Hz). Earplugs provide effective protection at both high and low frequencies. Ample protection is observed across all frequencies with certain foam insert earplugs. Earmuffs provide poor attenuation at the low frequencies.

A combination of earplug and earmuff is required when an individual protector is unable to reduce a noise to an acceptable level. The resulting attenuation is not the sum of the two protectors but an amount determined by the particular combination of devices. The attenuation of the combined units often reaches the bone conduction limits at the high frequencies. At the mid- and lower frequencies the amount of attenuation is determined primarily by the earplug. Selection of a good earplug for use with a muff will provide good double hearing protection at all frequencies.

Special earmuff hearing protectors called nonlinear devices allow face-to-face speech communication at low levels of noise and provide typical amounts of earmuff protection at high levels. Active noise reduction (ANR) earmuffs employ electronic (noise cancellation) and acoustical means of reducing low-frequency noise at the ears. This active earmuff can increase intelligibility and comfort and reportedly reduce fatigue when used with speech communication systems in noise. The ANR earmuffs are widely used in such areas as communications, private aircraft, entertainment, and sport activities and by passengers in commercial aircraft.

Hearing protection devices have the potential capability to reduce and eliminate most noise-induced hearing loss. However, issues such as comfort, selection, fit, training, use, motivation, and others limit the full-performance capability of the devices to be realized in the workplace.

Long-Duration Exposures

Long-duration noise exposures are typically steady state, continuous, and generally within the audio frequency range. The information on hearing protection for audio frequencies is also appropriate for long-duration noises.

Ultrasound

Conventional hearing protection devices, earplugs and earmuffs, provide good protection against airborne ultrasound at frequencies above about 20,000 Hz.

Attenuation exceeding 30 dB is generally provided for frequencies from about 10,000 to 20,000 Hz. Hearing protection is most effective in eliminating subjective symptoms that occur when protectors are not worn. Reduction and elimination of subjective symptoms is also a good indication of the effectiveness of the hearing protector.

Impulses

Earmuff and earplug protectors should provide adequate attenuation for impulses comprised primarily of high-frequency energy, such as small-arms fire. Earmuff attenuation decreases as the concentration of energy in the impulses moves to the lower frequencies, as with large-caliber weapons (the attenuation vs. frequency of the protectors is not changing, only the spectral distribution of the impulse is different). The reduction of the peak sound pressure level of a particular earmuff is about 30 dB for pistol fire, about 18 dB for rifle fire, and as little as 5 dB for cannon fire. The peak level of the impulses of most pistol and standard rifle shots is reduced to less than 140 dB by good earmuffs. A combination of earplugs and earmuffs should be used for impulses requiring good low-frequency attenuation.

The USAF and the USA require single hearing protection when impulses reach 140 dB peak positive pressure and double hearing protection when the levels reach 160 dB (USAF) and 165 dB (USA).

19.8 HUMAN VIBRATION RESPONSE

The human body is a dynamic system, possessing mass and the ability to achieve relative motion between parts of the body (elasticity). It can therefore be affected by exposure to oscillatory motion or vibration. Although the ear is the most sensitive body organ for the reception of vibratory energy in the auditory frequency range, structure-borne and airborne vibration occurring at lower frequencies can be transmitted to a variety of anatomical structures, including skin, bone, muscles, joints, and internal organs. Most of our population is exposed to occasionally moderate levels of vibration with relatively harmless effects. Occupational exposures to vibration are more severe than nonoccupational exposures and have been associated with biological, psychological, and human performance effects.

Vibration is transmitted to the human body via the oscillatory motion from vibrating structures in contact with the body surface (structure borne) or via the transmission of sound pressure waves in high-noise environments (airborne). In structure-borne whole-body vibration, oscillatory motions enter the body usually at the feet (standing) or buttocks (sitting) at the supporting surface and can be transmitted throughout the body to other anatomical structures (such as the head).[17] The major sources of nonoccupational whole-body exposures include transportation vehicles such as automobiles, buses, trains, airplanes, and boats. Whole-body occupational vibration is experienced by operators of agricultural and forestry tractors, earth-moving and construction equipment, all types of trucks, sea-going ships, airplanes and helicopters, as well as mining and factory workers on vibrating platforms. Structure-borne hand-transmitted vibration is isolated to a very specific anatomical region, primarily through the operation of vibrating hand tools such as jackhammers, chipping hammers, chain saws, grinders, and other types of pneumatic or electric hand-held devices. In airborne whole-body vibration, oscillatory motions enter the body via high levels of low-frequency sound pressure waves. Substantial airborne vibration occurs during aircraft engine run-ups and ground-based maneuvering, particularly in military environments where ground crews are required to work close to powerful aircraft in restrictive areas.

The absorption of vibratory energy by the body is determined by the body's characteristics as a mechanical system.[18] Engineering techniques (transfer function, power absorption) have been used and continue to be improved for defining these characteristics and for developing various models of the whole body and its subsystems (such as the hand–arm). These methods and models give insight into the energy transmission through the body and are useful tools for identifying the overall sensitivity of the body as well as for explaining the various effects on specific target organs and structures.

Whole-Body Vibration Effects

For whole-body vibration, the mechanical stresses imposed on the body can potentially lead to interference with bodily functions and tissue damage in practically all parts of the body. Historically, the major concern has focused on whole-body vertical vibration. More recent research includes multiaxis vibration effects. Figure 19.7 illustrates the short-time, 1-min, and 3-min tolerance limits reported by healthy adult male subjects exposed to vertical sinusoidal vibration.[19] Human tolerance to vibration tends to decrease with longer exposure periods. While acute exposures in the vicinity of human tolerance have not resulted in demonstrable harm or injury, prolonged and repeated exposures to these levels are considered to have a high potential for producing bodily damage. For vertical vibration, minimal tolerance occurs between 4 and 8 Hz.[19] This frequency range coincides with the major whole-body resonance observed in biodynamic data. Most physiologic effects in the region of 2–12 Hz are associated with excessive movement of the thoraco-abdominal viscera that can interfere with respiration and cause changes in cardiovascular functions that typically resemble the response to exercise.[20] Prolonged and repeated (chronic) occupational exposures, as they occur in drivers of tractors and earth-moving equipment, are implicated by many investigations in the development of spinal column and other joint disorders and pathologies and of stomach and duodenal diseases.[21,22] However, their causal relationship with vibration stress has not been clearly proven. For example, back pain and back disorders have been reported for other occupations with no vibration. These symptoms have also been associated with poor body posture. Studies, including the early study by Coermann,[23] have shown that body posture can affect whole-body vibration response.

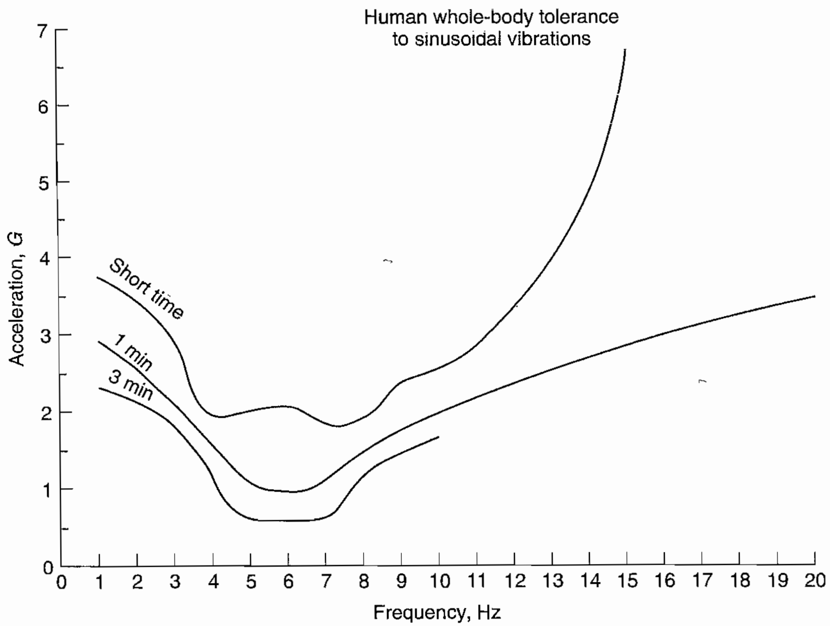

FIGURE 19.7 The short-time, 1-min, and 3-min tolerance limits reported during vertical sinusoidal vibration.[19]

Whole-body vibration can also influence working performance. It can cause involuntary body motions that interfere with the active motor control of the operator with undesirable effects. Relative motion of the eye with respect to an object or target can cause difficulty in reading instruments and performing visual searches.[24] This is particularly a concern at low frequencies where there is a high propensity for head movement in the region of whole-body resonance (below 10 Hz). Below about 20 Hz, compensatory eye movement aids in stabilizing the line of sight to a stationary object during head vibration.[25] When the image moves with the head, as occurs with a helmet-mounted display, compensatory eye movement becomes ineffective, increasing the potential for visual blurring.[26] Eye resonance has been reported to occur in a broad frequency range between 20 and 70 Hz.[25] Relatively high levels of whole-body vibration or direct contact of the head with the vibrating structure are necessary to induce visual blurring due to the body's damping effect at these higher frequencies.

With regard to airborne vibration, the mismatch between the acoustical impedance of air and the human body surfaces prevents significant amounts of acoustical energy from entering the body, particularly at higher frequencies.[27] With decreasing frequencies below 1000 Hz, more acoustical energy is absorbed in the form of transverse shear waves. With exposure to high-intensity noise levels [120 dB sound pressure level (SPL)] between 100 and 1000 Hz, tissue vibration

occurs and the noise is felt via the stimulation of somatic mechanoreceptors.[28] Below 100 Hz, intense noise can cause whole-body vibration that not only affects motion in the chest, abdominal wall, viscera, limbs, and head but also can generate motions in the body cavities and air-filled or gas-filled spaces.[28] Von Gierke and Nixon[27] reported that resonance of the chest wall and air-filled lungs occurs around 60 Hz. For noise exposures below 150 dB, the most common symptom reported by subjects was mild to moderate chest vibration.[15] Above 150 dB, symptoms included mild nausea, giddiness, subcostal discomfort, cutaneous flushing and tingling (around 100 Hz, 153 dB); coughing, severe substernal pressure, choking respiration, salivation, pain on swallowing, hypopharyngeal discomfort, and giddiness (60 Hz, 154 dB and 73 Hz, 150 dB); and headache (50 Hz, 153 dB).[15] More recent efforts have been made to measure the biodynamic response of the body to airborne vibration and compare the body acceleration spectra to the noise spectra.[29] The preliminary results for exposures to jet aircraft noise during engine run-ups confirm the upper torso resonance reported by von Gierke and Nixon.[27]

Hand-Transmitted Vibration Effects

Hand–arm vibration syndrome (HAVS) refers to the "complex of peripheral vascular, neurological, and musculoskeletal disorders associated with exposure to hand-transmitted vibration" (ref. 30, p. 11). HAVS is recognized worldwide as a health concern. Prolonged and repeated exposure to hand-transmitted vibration can lead to a very specific disease called vibration-induced white finger (VWF), or Raynaud's phenomenon. This impairment of the blood circulation of the hand progresses with exposure time from intermittent numbness and tingling in selected fingers to extensive blanching of most fingers, first only in combination with cold and finally at all environmental temperatures. In the final stages the disease interferes severely with social activities and continuation of the occupation. According to Taylor and Pelmear,[31] the clinical manifestations of the finger-blanching attacks progress in four stages, with stage 1 signaling the onset of the disease, mainly outdoors in winter. While symptoms of the first stages might still be reversible if vibration exposure is discontinued, the later stages are considered irreversible by most researchers. In later stages, the vascular manifestations are reported to be accompanied by nerve, bone, joint, and muscle involvement.[32] Studies have shown that HAVS, specifically VWF, is influenced by several factors, including the frequency, magnitude, and duration of the exposure, in addition to the type of tool. As with whole-body vibration, the symptoms of VWF appear to increase with exposure duration.

19.9 HUMAN VIBRATION EXPOSURE GUIDELINES

Extensive research over the last four decades has led to a reasonable understanding of the potential pathological and physiological effects of structure-borne whole-body as well as hand-transmitted vibration, although the mechanisms of these effects continue to be topics of research. Frequency-dependent sensitivity curves have been derived for the whole-body and for the hand–arm from both subjective and objective frequency response characteristics. These sensitivity curves form the basis for current whole-body and hand-transmitted vibration standards. There are major national and international standards that provide guidelines and recommended criteria for safe vibration exposure based on these curves and that are generally relied upon in designing vehicles, equipment, tools, and mitigation strategies for use in vibration environments. These standards are periodically revised as vibration research continues and new data become available.

Structure-Borne Whole-Body Vibration Criteria

The International Organization for Standardization (ISO) is the most widely recognized body for providing the basic guidelines for assessing the damage risk of structure-borne whole-body vibration (ISO 2631). As of 2004, the standard entitled "Mechanical Vibration and Shock—Evaluation of Human Exposure to Whole-Body Vibration" included three parts: ISO 2631-1:1997,[33] ISO 2631-2:2003,[34] ISO 2631-4:2001,[35] and ISO 2631-5:2004.[36] Part 1, entitled "General Requirements," describes the general methods for measuring whole-body vibration. Informative annexes are included that give guidance on possible effects of vibration on comfort, perception, health, and motion sickness based on current knowledge in these areas. In 2002, the American National Standards Institute (ANSI) accepted the ISO 2631-1:1997 as a nationally adopted international standard (ANSI S3.18–2002),[37] replacing the long-standing 1979 version. For whole-body vibration, the frequency range considered is 0.5–80 Hz although the range from 1 to 80 Hz can be used if appropriate. When the vibration is transmitted by a resilient structure, such as a seat cushion, a suitably shaped transducer support is interposed between the person and that structure. The standard recommends the collection of acceleration data between the body and three supporting surfaces for the seated occupant, including the seat pan or surface, seat back, and feet. For the recumbent occupant, the supporting surfaces include the pelvis, back, and head. Translational vibrations are typically measured in the three axes defined by an orthogonal coordinate system. For standing, seated, and recumbent whole-body vibration, the x axis is defined in the back-to-chest (fore-and-aft) direction, the y axis for the side-to-side (lateral) direction, and the z axis for the foot- (or buttocks-) to-head (vertical) directions.[33] Rotational vibration may also be measured or estimated. There are three primary frequency-weighting curves (including motion sickness) and three additional frequency-weighting curves that are applied to the acceleration–time histories or frequency response spectra depending on the measurement site and the particular effect being assessed. Figure 19.8 illustrates the two primary frequency weightings that reflect the sensitivity of the body in the respective directions.

The overall weighted root-mean-square (rms) acceleration is determined in the time or frequency domain in each axis. The assessment is made based on

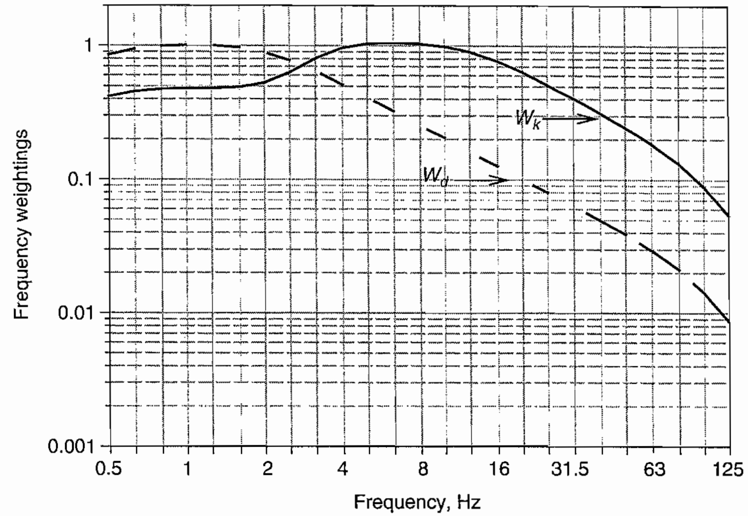

FIGURE 19.8 ISO 2631-1:1997[33] frequency-weighting curves for whole-body vibration in the horizontal (W_d) and vertical (W_k) directions. (Redrawn with permission. Copyright by the International Organization for Standardization. Standard can be obtained from any member body or directly from the ISO Central Secretariat, ISO, Casepostal 56, 1211 Geneva 20, Switzerland.)

the highest weighted acceleration level. If vibration in two or more directions is comparable, then additional direction-dependent multiplying factors are applied and the vibration total value (VTV) or vector sum is calculated.

Other methods are also described, including the running rms method and fourth-power vibration dose method (using the vibration dose value, or VDV). The VDV is more sensitive to peaks in the exposure. Figure 19.9 depicts the Health Guidance Caution Zones provided in the ISO 2631-1:1997 and ANSI S3.18–2002. These guidance zones apply to the overall weighted accelerations determined at the seat pan in the three translational directions. In the figure, the zones defined by the solid lines are applicable to the rms acceleration level. The zones defined by the dotted lines are applicable to the fourth-power vibration dose method. Below the zones, health effects have not been clearly documented or observed. Within the zones, caution is indicated for potential health risks. Above the zones, health risks are likely.[33]

For estimating the effects of structure-borne whole-body vibration on comfort and perception, rotational frequency weightings and multiplying factors are included for the seated occupant.[33] The VTV is recommended for assessing comfort. The standard ISO 2631-1:1997 provides six comfort reactions to vibration and the associated overall weighted acceleration levels ranging from "not uncomfortable" to "extremely uncomfortable." These reactions have no time dependency.

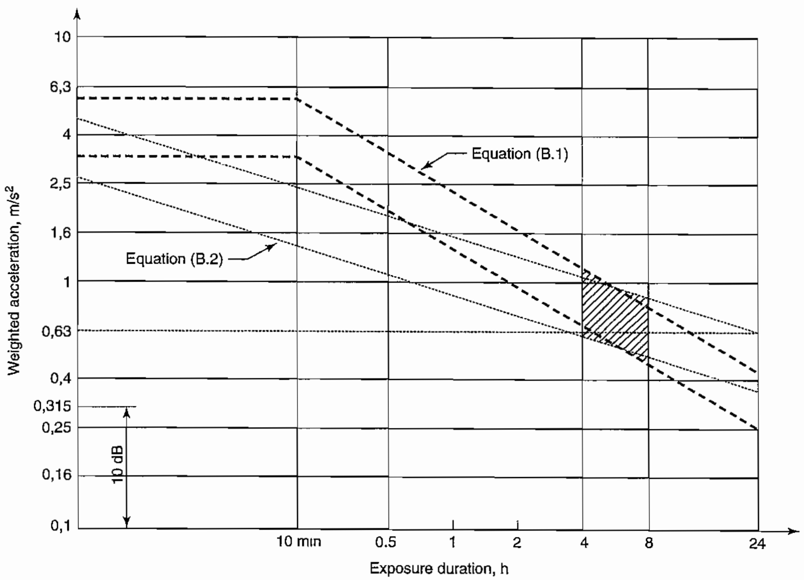

FIGURE 19.9 ISO 2631-1:1997 Health Guidance Caution Zones.[33] Equations (B.1) and (B.2) are defined in the standard. (Reprinted with permission. Copyright by the International Organization for Standardization. Standard can be obtained from any member body or directly from ISO Central Secretariat, ISO, Casepostal 56, 1211 Geneva 20, Switzerland.)

Guidelines on motion sickness are primarily applicable to ships and other sea vessels. The weighted rms acceleration is determined between 0.1 and 0.5 Hz in the vertical direction at the supporting surface. Two methods are given for calculating the motion sickness dose value ($MSDV_z$). An approximation of the percentage of individuals who may vomit is given by $K_m(MSDV_z)$, where $K_m = \frac{1}{3}$ for a population of unadapted male and female adults.[33]

The standard ISO 2631-2:2003, entitled "Part 2: Vibration in Buildings (1 Hz to 80 Hz)," is directed toward human exposure in buildings with respect to comfort and annoyance. A single frequency weighting, W_m, is defined that is related to the combined-response rating curve used in the older 1989 edition. The general guidelines for measuring the vibration are similar to those given in ISO 2631-1:1997. The vibration is measured in the three orthogonal axes with the directions relating to the structure and defined for the standing individual (Part 1). The measurements are made at a location where the highest frequency-weighted vibration occurs. Categories of sources are provided and include (a) continuous or semicontinuous processes (e.g., industry), (b) permanent intermittent activities (e.g., traffic), and (c) limited duration (nonpermanent activities, e.g., construction). The 2003 standard does not include acceptable levels of vibration. The consensus of opinion is that sufficient information was not available at the time for

establishing appropriate vibration levels given the complexity of human response to building vibration. The standard does indicate that adverse comments about residential building vibration may occur when the magnitudes or levels are only slightly higher than the perception levels (ISO 2631-1:1997, Annex C).[33] Other complaints may be due to secondary effects such as reradiated noise (ISO 2631-2:2003, Annex B).[34] There should be no reason to consult the Health Guidance Caution Zones in ISO 2631-1:1997, Annex B, except in an extremely rare building vibration environment.

The standard ISO 2631-5:2001,[36] entitled "Part 5: Method for Evaluation of Vibration Containing Multiple Shocks," directs attention to the health of the lumbar spine. Exposures to multiple shocks may occur in the operation of equipment and vehicles over rough terrain or rough seas. A biomechanical model is used to predict the response of the human spine to a given input and to generate an acceleration dose. The standard provides guidelines on using the acceleration dose to assess the health effects of multiple shocks based on the probability of an adverse health effect that depends on the relationship between the ultimate strength of the lumbar spine, the age of the person, and the number of years of exposure.

Airborne Whole-Body Vibration Criteria

Current guidelines for airborne vibration are given in terms of the noise exposure. The Air Force Occupational, Safety, and Health Standard AFOSHSTD 48-19[14] recommends that, for minimizing whole-body vibration effects, no octave- or one-third-octave-band noise level exceed 145 dB for frequencies in the range of 1–40,000 Hz and that the overall A-weighted sound pressure level be below 150 dBA with no time limits. The ACGIH[38] recommends that one-third-octave-band levels between 1 and 80 Hz should not exceed 145 dB, and the overall unweighted SPL should not exceed 150 dB. The assessment of airborne vibration exposure may differ depending on which guideline is used. Minimal research has been conducted on the physiological and pathological effects that may be associated with airborne vibration.

Hand-Transmitted Vibration Criteria

The ISO provides basic guidelines for assessing hand-transmitted vibration in ISO 5349, "Mechanical Vibration—Measurement and Evaluation of Human Exposure to Hand-Transmitted Vibration." The standard consists of two parts: Part 1: General Requirements (ISO 5349-1:2001)[30] and Part 2: Practical Guidance for Measurement at the Workplace (ISO 5349-2:2001).[39] For hand-transmitted vibration, the center of the coordinate system is the head of the third metacarpal with the z axis defined as the longitudinal axis of the third metacarpal, the y axis in the general direction of the tool handle (basicentric coordinate system), and the x axis passing from the top to the bottom of the hand. Figure 19.10 illustrates the frequency weightings or factors associated with the center frequencies of one-third-octave bands for assessing the effects of hand-transmitted vibration.

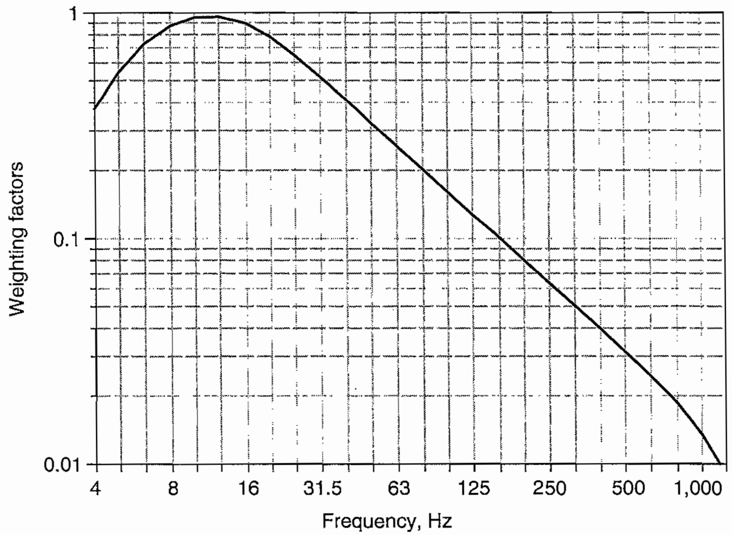

FIGURE 19.10 ISO 5349-1:2001 Frequency-weighting curve W_h for hand-transmitted vibration.[33] (Redrawn with permission. Copyright by the International Organization for Standardization. Standard can be obtained from any member body or directly from the ISO Central Secretariat, ISO, Casepostal 56, 1211 Geneva 20, Switzerland.)

The quantity used to assess health effects is the 8-hr energy-equivalent vibration total value [$A(8)$], or daily vibration exposure. It is assumed that the health risk for hand-transmitted vibration applies to all three orthogonal directions. Therefore, the same weighting curve (Fig. 19.10) is applied to vibration in each of the three orthogonal axes. The vector sum of the overall weighted accelerations estimated for each axis defines the vibration total value (a_{hv}). Figure 19.11 depicts the daily exposure values [$A(8)$] expected to produce vibration-induced white finger in 10% of persons exposed for a given number of years, D_y. The standard ISO 5349-2:2001[39] provides additional guidelines for measuring hand-transmitted vibration in the workplace, determining the daily vibration exposure, and selecting appropriate operations. The measurement of vibration entering the hand may not always be practical. Part 2 includes practical measurement locations for selected power tool types and summarizes the location of accelerometers used in vibration-type test standards for a variety of power tools. These locations are usually close to the hand.

Additional Exposure Standards and Guidelines

Other organizations and countries have generated standards and guidelines that compliment, supplement, or even differ from the human vibration standards described above, particularly the ISO 2631-1:1997. The ACGIH[38] provides guidelines for whole-body as well as hand-transmitted vibration. The European Union

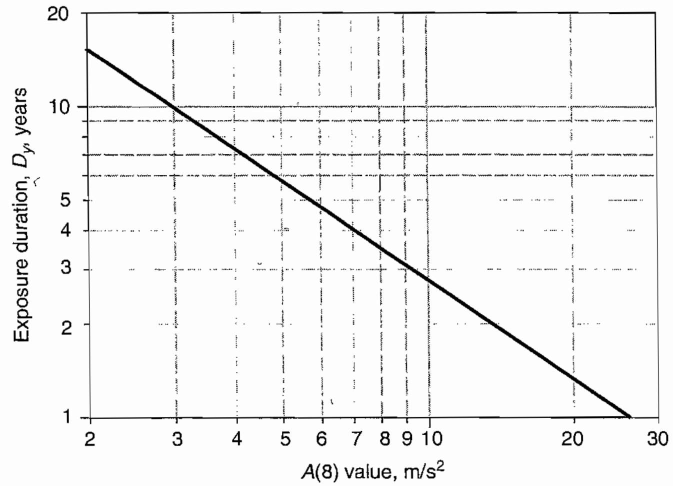

FIGURE 19.11 Vibration exposure for predicted 10% prevalence of vibration-induced white finger in a group of exposed persons. (Redrawn from ISO 5349-1:2001[30] with permission. Copyright by the International Organization for Standardization. Standard can be obtained from any member body or directly from the ISO Central Secretariat, ISO, Casepostal 56, 1211 Geneva 20, Switzerland.)

has recently published a directive on health and safety requirements for exposure to both whole-body and hand-transmitted vibration. It is important that designers and assessors understand the similarities and differences among the various standards and the appropriateness of their applicability. It is also critical to use current editions of these standards since new information could have significant influences on defining health risk.

CHAPTER 20

Criteria for Noise in Buildings and Communities

LEO L. BERANEK

Consultant
Cambridge, Massachusetts

One of the early steps in the architectural design of a building is the specification of acceptable noise levels in the spaces for occupancy by human beings. Noise sources in rooms include the air-handling and conditioning system (HVAC), the occupants themselves, machinery in the room, and vibration of the surfaces of the room by machinery outside. In this chapter, the sources of the noise in a space are, in general, not discussed. However, in many cases, such as in offices, dwellings, schools, auditoriums, and studios, it is generally true that the most likely annoying noise is created by the HVAC system. In those cases the criteria presented here apply to the HVAC noise alone as measured without the presence of people. In shops, manufacturing plants, and restaurants, the principal noise sources are machinery or large numbers of people. In such spaces the designer only has to make sure that the HVAC levels do not exceed the liberal limits suggested in this chapter.

20.1 SOUND LEVELS: DEFINITIONS

The sound (noise) levels, all in decibels, that are used in this chapter are taken from Chapter 1, which, in turn, were taken from U.S. and international standards:

- Sound pressure level (SPL) L_p [see Eq. (1.21)].
- A-weighted sound pressure level L_A [see Eq. (1.22)].
- The equivalent sound level L_{eq}, which is broadly defined by

$$L_{eq} = L_{av,T} = 10 \log(1/T) \frac{\int_0^T p_A^2(t)\, dt}{p_{ref}^2} \quad \text{dB} \tag{20.1}$$

where T is the time over which the averaging takes place and must be specified [see Eq. (1.23)].

CHAPTER 20

Criteria for Noise in Buildings and Communities

LEO L. BERANEK

Consultant
Cambridge, Massachusetts

One of the early steps in the architectural design of a building is the specification of acceptable noise levels in the spaces for occupancy by human beings. Noise sources in rooms include the air-handling and conditioning system (HVAC), the occupants themselves, machinery in the room, and vibration of the surfaces of the room by machinery outside. In this chapter, the sources of the noise in a space are, in general, not discussed. However, in many cases, such as in offices, dwellings, schools, auditoriums, and studios, it is generally true that the most likely annoying noise is created by the HVAC system. In those cases the criteria presented here apply to the HVAC noise alone as measured without the presence of people. In shops, manufacturing plants, and restaurants, the principal noise sources are machinery or large numbers of people. In such spaces the designer only has to make sure that the HVAC levels do not exceed the liberal limits suggested in this chapter.

20.1 SOUND LEVELS: DEFINITIONS

The sound (noise) levels, all in decibels, that are used in this chapter are taken from Chapter 1, which, in turn, were taken from U.S. and international standards:

- Sound pressure level (SPL) L_p [see Eq. (1.21)].
- A-weighted sound pressure level L_A [see Eq. (1.22)].
- The equivalent sound level L_{eq}, which is broadly defined by

$$L_{eq} = L_{av,T} = 10 \log(1/T) \frac{\int_0^T p_A^2(t)\,dt}{p_{ref}^2} \quad \text{dB} \qquad (20.1)$$

where T is the time over which the averaging takes place and must be specified [see Eq. (1.23)].

- A-weighted equivalent sound level $L_{eq,A}$ is that given by Eq. (20.1), but with the A-weighted frequency response in place in the measuring instrument. Often this quantity is simply labeled L_{eq} and the A weighting is known through its expression in dBA [see Eq. (1.24)].
- The band average sound level is that given in Eq. (19.1), but with the band width specified.
- The averaging time T can be a matter of fractional seconds, minutes, hours, days, or even a year. Always, it must be specified.
- Day–night sound level L_{dn} [see Eq. (1.25)]. Note, in some nations, the 24-h period is divided into three intervals, day, evening, and night, for which Eq. (1.25) must have three integrals with the interval times specified.
- A-weighted sound (noise) exposure $E_{A,T}$ (proportional to energy flow, intensity times time, in a sound wave in the time period T) [see Eq. (1.26)].
- A-weighted sound (noise) exposure level L_{EAT} [see Eq. (1.27)].
- Speech interference level SIL is the average of the sound pressure levels in the four octave bands, whose midfrequencies are 500, 1000, 2000, and 4000 Hz.

20.2 EVALUATION OF ROOM NOISE: SURVEY METHOD, ENGINEERING METHOD, AND PRECISION METHOD[1]

Current-Day Sound-Level Meters

Current-day sound-level meters are used to determine the sound levels in some or all of the ten octave bands with midfrequencies from 16 to 8000 Hz. The meter "speed" can be set to slow, fast, or impulse. When the meter speed is set to "fast," a running integration time of about 125 ms is achieved. The output of the meter can be set to read or store the following levels: L_{eq}, the equivalent noise level over the measurement time period; the peak level L_{max}; and the statistical levels L_{10}, L_{50}, L_{90}, and L_{95}, where the subscript means that level is exceeded 10, 50, 90, or 95% of the time. The 50% level is the median level. When measuring A-weighted sound levels, the meter speed is set at "slow." For monitoring, the meters usually have storage capacity from 1 s up to 24 h. The stored data can be sampled as often as every 100 ms. Acoustical consultants say that their measuring time of HVAC noise at a particular location in a room is usually under a minute.

Survey Method — L_A

An A-weighted sound level L_A is often used for surveying whether a measured noise level satisfies a specified noise criterion. It is readily measured with the simplest sound-level meters. The measurement of L_A is the average of the maximum meter readings, with the meter response set at slow, and obtained by moving the microphone about the room, avoiding positions near the surfaces or the geometric center. It is assumed that the measured noise is free of pure tones and HVAC surging. The presence of HVAC surging can usually be detected by listening or by observing the meter swings using the "flat" (or "C") frequency weighting and the fast meter response.

Because L_A lacks specific spectral information, it can be misleading in evaluating noise other than that arising from reasonably well-designed HVAC systems. The values given in Table 20.1 are recommended for estimating whether measured A-weighted levels may be suitable for the purposes indicated. The numbers presented in that table are largely influenced by the results of a request to a number of consulting firms for examples of excessive noise situations.[2] Fourteen firms responded. The acceptable and unacceptable octave-band levels in school rooms, auditoria, offices, and hotel rooms resulted. Those data indicated that the best method to use in writing specifications, where HVAC surging and large sound fluctuations are not expected, is to use noise criterion (NC) curves, described in the next section. (*Note*: The acceptable NC curves for various occupancies of the spaces are given in Table 20.2. Table 20.1 was determined from Table 20.2 and the NC curves of Fig. 20.1 as follows: For each of the NC curves the speech interference level (SIL) and the A-weighted effective level (L_A) were calculated and L_A − SIL found. These differences were added to the levels in Table 20.2 to obtain the levels of Table 20.1. For example, L_A − SIL for the NC-40 criterion curve is 8 dB, which means that where 40 dB appears in Table 20.2, 48 dB appears in Table 20.1. Also in reference 2, the octave-band levels for 14 cases of excessive noise at low frequencies revealed that L_A − SIL = 14 dB is clearly unacceptable, while in offices with acceptable noise levels L_A − SIL did not exceed approximately 7.5 dB.)

Engineering Method: NC Curves

The most widely used method today for evaluating the suitability of the noise in a space for human occupancy and for writing noise specifications employs the NC curves shown in Fig. 20.1.[3,4] The numerical values from which Fig. 20.1 was plotted are given in Table 20.2 (rounded to the nearest decibel). In measuring a noise the sound-level meter (with octave-band filtering) is set to yield L_{eq} with a slow meter, flat response. The integration time T can be of any desired length—seconds, hours, or months. If each octave-band meter reading slowly fluctuates over a small range, the average value is used.

For writing specifications, the suggested NC ratings for various occupancies are shown in Table 20.2. For example, for small offices, NC-35 to NC-40 is listed.

When evaluating a measured noise spectrum, the octave-band levels are plotted on the set of curves in Fig. 20.1. The rating given to the noise is set by the band level that "touches" the highest NC curve (interpolated to the nearest decibel). For example, assume that the levels in the eight bands from 31.5 to 4000 Hz were 68, 65, 61, 58, 50, 42, 37, and 30 dB, respectively. The highest NC rating

TABLE 20.1 Recommended A-Weighted Sound-Level Criteria for HVAC Systems for Rooms (Unoccupied) of Various Uses

Occupancy	A-Weighted Sound Level L_A in dBA
Small auditoriums	35–39
Large auditoriums, large drama theaters, and large churches (for very good speech articulation)	30–35
TV and broadcast studios (close microphone pickup only)	16–35
Legitimate theaters	30–35

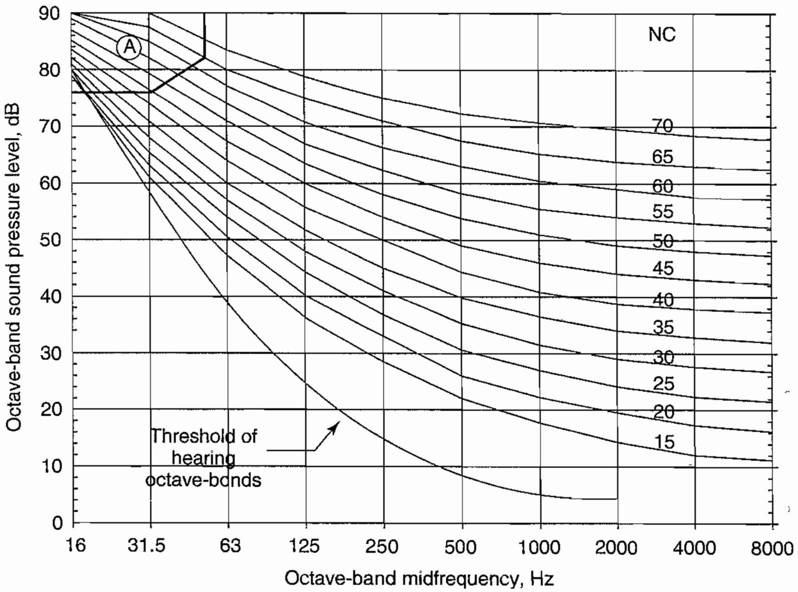

FIGURE 20.1 Noise criteria curves derived from interviews and simultaneous noise measurements extended to low frequencies by comparison with balanced NC (NCB) curves. These NC curves are used to rate noises by the "tangency method."[2,3,5,10] Region *A* indicates low-frequency levels that may produce feelable vibrations and rattles from lighting fixtures in lightweight constructions if fluctuations or surging is present. The threshold of hearing is taken from ANSI S12.2–1995.

curve "touched" by this spectrum is determined by the 58-dB level in the 250-Hz band and equals NC-50. This is the so-called tangency method of rating.

The NC curves were originally derived from a survey of noise in a large number of offices and spaces in a military Air Force base[5] and in several office buildings.[6] The surveys were conducted by asking occupants of rooms how they rated the noise both generally and at that instant (on a scale with six divisions from "very quiet" to "intolerably noisy") and then measuring the noise at that instant. It was determined that the activity most affected by the noise was speech communication both person to person and by telephone. However, it was also found that even though speech communication might be satisfactory in a space, the low-frequency noise levels could be so high as to be annoying. How much higher can the low-frequency noise be compared to the midfrequency noise? It was found that the overall loudness of the noise had to be taken into consideration. To answer this question, two quantities were measured, the SIL and the loudness level of the noise.

The SIL is a measure of the degree of interference of a noise with speech communication. It is standardized as the average sound pressure level, in decibels, in the four octave bands 500, 1000, 2000, and 4000 Hz.[7]

TABLE 20.3 Noise Criteria Curves from Fig. 20.1 to Nearest Decibel

	By Octave-Band Center Frequencies, Hz									
NC CURVE	16	31.5	63	125	250	500	1000	2000	4000	8000
NC-70	90	90	84	79	75	72	71	70	68	68
NC-65	90	88	80	75	71	68	65	64	63	62
NC-60	90	85	77	71	66	63	60	59	58	57
NC-55	89	82	74	67	62	58	56	54	53	52
NC-50	87	79	71	64	58	54	51	49	48	47
NC-45	85	76	67	60	54	49	46	44	43	42
NC-40	84	74	64	56	50	44	41	39	38	37
NC-35	82	71	60	52	45	40	36	34	33	32
NC-30	81	68	57	48	41	35	32	29	28	27
NC-25	80	65	54	44	37	31	27	24	22	22
NC-20	79	63	50	40	33	26	22	20	17	16
NC-15	78	61	47	36	28	22	18	14	12	11

The loudness level is determined by a standardized computational procedure which yields results in units called phons.[8] Needed are measured octave- or one-third-octave-band levels in all the frequency bands.

The studies revealed that the loudness level (in phons) should not exceed the SIL (in decibels) by more than about 24 units if the space is not to be annoying to the occupants. Because low-frequency sounds are less loud than high-frequency sounds, their levels can be higher. Thus with increasing frequency the NC curves slope downward monotonically and their shape is determined to resemble that of well-known "equal-loudness" curves.[9] The amount of slope and the shape of the spectrum are determined by the 24-unit difference just mentioned. (*Note*: The average of the levels in the four speech interference bands for each NC curve in Fig. 20.1 is between 0.25 and 1 dB higher than the designating number shown for the curve. The reason is that a shift in the frequency limits for the octave bands was standardized some years after these curves were developed. However, the decibel values for the points and the designating numbers on these curves are exactly the same as originally presented.)

It must be emphasized that the NC curves so derived give the upper permissible limit of the low-frequency noise once the SIL is known. Thus, the shape of a NC curve is not the shape of an ideal noise spectrum, but rather is the shape of a "not-to-be-exceeded" spectrum.

Two basic assumptions concerning the curves of Fig. 20.1 are that the noise contains no pure tones and there is no surging of the noise from fans that drive the HVAC system.

Concerning the measurement of sound levels at each point on a NC curve, the meter response is set to suit the desired result. If the equivalent noise level over a period of hours or days is decided, the slow meter response is selected. For short samples of the measured noise, the fast response is used. For example, a series of 100–1000 samples each 100 ms long requires fast response. The meter can show the equivalent level L_{eq} in decibels for the sequence, or the maximum level L_{max}, or the level above which 10% of the interval levels are found, called L_{10}, or the L_{50} level, which is the mean level, or the L_{90} level. Some consultants believe the L_{50} level correlates well with people's judgment of the acceptability of their noise environment, provided that the speech intelligibility requirement is met.

Comments about NC Curves. The NC curves as originally derived did not extend down to the 31.5- and 63-Hz octave bands. These two bands have been added by the author to the original curves, based on the studies that led to the balanced noise criterion (NCB) curves that are briefly discussed below. The revised curves of Fig. 20.1 have been shown in two studies to predict successfully all known cases of sizable complaints by occupants of existing building spaces.[10,11]* In none of these cases was surging detected.

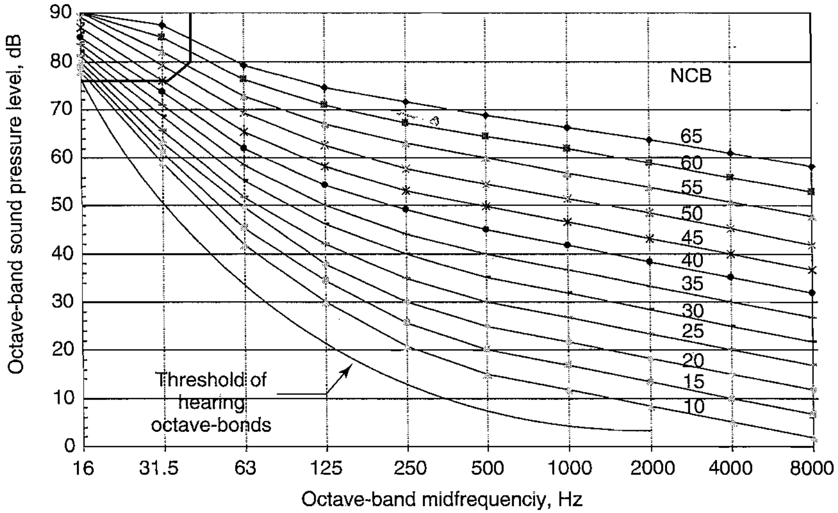

FIGURE 20.2 Balanced noise criteria curves, taken from ANSI S12.2–1995. These curves are used to rate noises with a procedure described in the standard and ref. 10.

*In ref. 11, 238 measured sound-pressure-level spectra were obtained from the consulting files of Cavanaugh Tocci Associates. Plots were made of the relation between NC (tangency method) and NCB (tangency method). The two were closely related with an $R^2 = 0.97$. Similarly, the NCB rating was plotted in relation to the RC or RC II rating, with a correlation of $R^2 = 0.98$, except that the RC values are about 2 dB greater than the NC values because the NC curves are based on the average of the levels in the 500-, 1000-, 2000-, and 4000-Hz bands, while the RC curves are labeled based on the average of the levels in the 500-, 1000-, and 2000-Hz bands.

NCB Curves

The NCB curves shown in Fig. 20.2[7] were derived from the following premises: (1) the rating number for each curve should equal its four-band SIL; (2) the calculated octave-band loudness for those bands from 125 to 8000 Hz should contain the same number of critical (hearing) bands, and for the two lower bands, the loudnesses should be weighted downward in proportion to the fraction of critical bands contained; and (3) the difference between the SIL (in decibels) and the loudness level (in phons) for a criterion curve should not exceed 24 units. The detailed method of applying NCB curves to the evaluation of HVAC noise is not discussed here, because they have not found widespread use, in spite of their being contained in ANSI S12.2–1995. As mentioned above, the NC curves have been extended to the 16- and 31.5-Hz bands by comparison with the rationale that led to the NCB curves. Except for the method of applying them to the rating of a noise, the NCB curves differ little from the NC curves of Fig. 20.1.

The levels taken from the NCB curves (rounded to the nearest decibel) are listed in Table 20.4.

RC (Originally Called "Revised Criteria") Curves

The RC criteria curves for evaluating noise in a room or for specifications were built around the point of view that sound levels lower than those shown by the NC curves of Fig. 20.1 should always be specified for the bottom three-octave frequency bands (31.5, 63, and 125 Hz). The primary reason given is that if there are strong fluctuations or surging in the HVAC noise, the specified low-frequency octave-band levels for the RC curves ought to be low enough so that the noise is not disturbing.

The basis for the RC curves was a set of measurements made in the early 1970s of the noise in 68 offices where the HVAC noise levels were judged satisfactory.

TABLE 20.4 Balanced Noise Criteria Curves from Fig. 20.2 to Nearest Decibel

	By Octave-Band Center Frequencies, Hz									
NCB CURVE	16	31.5	63	125	250	500	1000	2000	4000	8000
NCB-65	97	88	79	75	72	69	66	64	61	58
NCB-60	94	85	76	71	67	64	62	59	56	53
NCB-55	92	82	72	67	63	60	57	54	51	48
NCB-50	89	79	69	62	58	55	52	49	45	42
NCB-45	87	76	65	58	53	50	47	43	40	37
NCB-40	85	73	62	54	49	45	42	38	35	32
NCB-35	84	71	58	50	44	40	37	33	30	27
NCB-30	82	68	55	46	40	35	32	28	25	22
NCB-25	81	66	52	42	35	30	27	23	20	17
NCB-20	80	63	49	38	30	25	22	18	15	12
NCB-15	79	61	45	34	26	20	17	13	10	7
NCB-10	78	59	43	30	21	15	12	8	5	2

When plotted, those noise-level spectra, on average, sloped off linearly with frequency at the rate of 5 dB/octave in the bands from 63 to 4000 Hz. It was concluded that if the measured spectra in satisfactory office environments had that characteristic, the −5 dB/octave line is "optimum," but no comparisons with other spectra were made.

The RC curves are shown in Fig. 20.3 and the values are listed in Table 20.5.[12]

In this chapter, only the Mark II version of the RC method is employed, which differs from the original version in that the levels in the 16- and 31.5-Hz bands are equal instead of the 16-Hz band being 5 dB higher than the 31.5-Hz band. Also the procedure for evaluating measured data is different.

An RC curve suitable for a particular type of room may be determined from Table 20.6. The values there were chosen to permit satisfactory speech intelligibility, where that is important, or to provide noise levels that are not above normal activity sounds.

When evaluating a noise spectrum using the RC method, the first step is to determine the average of the measured sound levels in the 500-, 1000-, and 2000-Hz octave bands, the *midfrequency average*, which Reference 11 calls *level at midfrequencies* (LMF). This number identifies the level of the measured spectrum in the frequency region most important to speech communication, and it selects the reference RC curve used as a starting point for the analysis that follows. For example, if the LMF is 36 dB, the RC-36 becomes the reference curve. If that LMF is suited to the activities that take place in the space in which

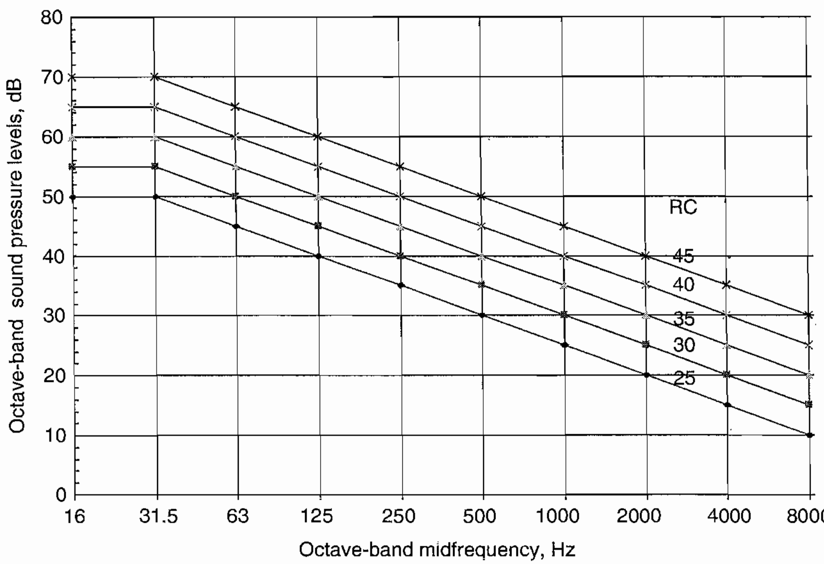

FIGURE 20.3 Noise criteria RC Mark II curves, derived from measurements of HVAC noise in offices. These RC curves are used to rate noises by a procedure detailed in ref. 12.

RC-45	70	70	65	60	55	50	45	40	35	30

the measurements were made (from Table 20.6), and if the spectrum closely approximates the reference curve, the noise is given a rating of "N," neutral.

If the measured spectrum is not "neutral," the RC (latest version, Mark II) rating procedure begins with the reference curve derived from it. Next, determination of three quantities is calculated from the measured spectrum, each called, *energy-average spectral deviation factor*. Three frequency regions are chosen for this analysis—low (16–63 Hz), middle (125–500 Hz), and high (1000–4000 Hz)—dubbed the LF, or "rumble," the MF, or "roar," and the HF, or "hiss," regions.

The procedure is as follows: First, for each octave-frequency band in the measured spectrum, the difference in decibels between that spectrum and the reference RC curve is found. The sign may be either positive or negative. For each of the three frequency regions, LF, MF and HF, the three octave-band differences therein are summed on an *energy basis*, which yields an energy-average spectral deviation factor for that region. For example, assume the three-octave-band differences in the LF region are 4, 5, and 9 dB, giving an averaged energy level of 4.54, and 10 log 4.54 = 6.57 dB. This factor is also determined for the MF and HF regions, which, as an example here, we shall assume are equal to 4.82 and −0.92 dB. Next, the *quality assessment index* QAI is defined

TABLE 20.6 Recommended RC Criteria for HVAC Systems for Rooms (Unoccupied) of Various Uses

Occupancy	RC Criterion Curve[a]
Private residences	
Bedrooms	25–30 (N)
Apartments	30–35 (N)
Family rooms and living rooms	30–40 (N)
Schools	
Lecture and classrooms	30–35 (N)
Open-plan classrooms	35–40 (N)
Hotels/motels	
Individual rooms or suites	30–35 (N)
Meeting/banquet rooms	30–35 (N)
Halls, corridors, lobbies	35–40 (N)
Service support areas	40–50 (N)
Office buildings	
Executive offices	25–35 (N)
Private offices	30–35 (N)
Private offices with conference tables	25–30 (N)
Conference rooms	25–30 (N)
Open-plan areas	35–40 (N)
Business machines/computers	40–45 (N)
Public circulation	40–50 (N)
Hospitals and clinics	
Private rooms	25–30 (N)
Wards	30–35 (N)
Operating rooms	25–35 (N)
Laboratories	35–45 (N)
Corridors	35–45 (N)
Public areas	40–45 (N)
Churches	30–35 (N)
Libraries	35–40 (N)
Courtrooms	30–40 (N)
Restaurants	40–45 (N)

[a]N = neutral spectrum.

as the difference (in decibels) between the maximum and minimum values of the three spectral deviation factors just determined. In our example QAI = 6.57 − (−0.92) = 7.5 dB.

By the RC Mark II procedure, a *neutral* spectrum is one for which QAI is less than 5 dB and L_{16} and $L_{31.5}$ are at most 65 dB. If the highest *positive* spectral deviation factor occurs in the LF region, the spectrum is evaluated as having (i) a "marginal rumble" if 5 dB < QAI ≤ 10 dB or (ii) an "objectionable rumble" if QAI > 10 dB. If the highest positive factor falls in the MF or the HF regions, the same decibel ranges for QAI are listed for evaluating a spectrum as having "marginal or objectionable roar or hiss." For example, a measured spectrum might be designated as RC-45 (i.e., reference curve), roar (i.e., MF region), and probably objectionable (i.e., QAI exceeds 10 dB).[12]

The RC procedure would seem to mean that in writing a specification, a particular RC curve would be specified, but with the understanding that the measured levels in *any one* of the three frequency regions can be exceeded by about 5 dB without penalty.

It must be noted that in the 68 offices originally studied, the A-weighted slow meter sound level only covered a range of 40 to 50 dB, and thus none of the sound levels were considered that are found in spaces like concert halls at one extreme or factory spaces at the other. Second, the RC spectra are typical of HVAC practice in quality offices of the 1970 period and may not be typical at any future time.

The difficulty with the undisciplined use of the RC curves is that they penalize those HVAC installations that are free of surging or of large low-frequency fluctuations. In concert halls or other sites where very low background noise is required, the HVAC systems must be of highest quality, free of surging or significant low-frequency fluctuations. The measured NC noise spectra for concert halls usually are specified to be in the range of NC-15 to NC-18 (See Fig. 20.1 and Table 20.2). The levels in the completed halls usually follow a NC curve down to the 63-Hz band or lower. If RC curves equal to RC-15 to RC-20 were to be specified at such a site, 15 or more decibels of noise reduction would be required in the lowest bands. The cost of such an unnecessary reduction at low frequencies would be prohibitive. Of course, the perceived danger, from the specification point of view, is that a supplier might be told to meet, say, the NC-20 criterion curve, but that he or she might, in fact, install a low-cost HVAC system whose air supply source exhibited surging and then insist that the system meets the specification based on measurements in the octave bands with the usual sound-level meter set to slow response. Advanced techniques for evaluating spectra to determine whether the HVAC noise exhibits surging or large random fluctuations are presented in the next section.

Precision Method — RNC Curves[13,14]

There is a need to evaluate HVAC systems in which surging from the driving fan(s) takes place and to write specifications for the design of HVAC systems to avoid the chance of surging. To listeners, surging is very apparent and disturbing, and it must be addressed both in the writing of specifications and when diagnosing the seriousness of the noise afterward. Surging cannot be determined by a conventional sound-level meter with the slow meter speed and "A" frequency-weighted response in place, partly because surging primarily affects the levels in the low-frequency bands and partly because surging may be averaged out if the slow speed is used.

HVAC: Well Behaved or Surging? Surging usually can be heard aurally or it can be seen visually on a standard sound-level meter by observing the levels in the 16-, 31-, and 63-Hz octave bands. The sound-level meter must be set for fast response and flat frequency characteristic (or C weighting). If surging is found from listening or observing the levels in the octave bands above, then the RNC method of evaluation should be used to determine the seriousness of the noise condition.

First, Some Psychoacoustics. In devising a more precise method of evaluating whether the HVAC noise in a room is intrusive for its primary use, one must turn to the field of psychoacoustics for help. First, the ear only integrates (lumps together) significant variations in the level of a sound provided they occur within a short time period, that is, if the variations occur within a time period that is less than about 125 ms. That is, any fluctuations in HVAC noise that occur within a time interval of about 100 ms are perceived as though the noise were continuous (with the same energy) in that period without fluctuations.

A second reality is that the ear integrates the sound energy that falls within frequency bands called *critical bands*. Critical bands increase in width at about the same rate as the widths of the octave frequency bands increase except at low frequencies. In the frequency region below 125 Hz, the critical bands are about 100 Hz wide. Hence, the 16-, 31.5-, and 63-Hz octave-band levels must be combined in some manner into one band centered, say, at 31.5 Hz, in order that it can be treated in the same way as the higher frequency bands.

A third fact arising from the properties of hearing involves the loudness of sounds at low frequencies, that is, at frequencies below about 200 Hz. For the three octave bands 16, 31.5, and 63 Hz, a change of approximately 5 dB in level creates a doubling in the subjective loudness of a sound. For the 125-Hz band, a change of about 8 dB causes a doubling of loudness. For octave bands with midfrequencies of 250 Hz and above, a change of 10 dB is necessary to create a doubling in loudness. Thus, variations in level of the successive 100-ms intervals for the four lowest frequency bands must be treated differently from variations in level of the 100-ms intervals for the higher frequency bands. The RNC procedures, about to be described, are designed to take into account these three characteristics of the hearing system when evaluating the noise of a space.

Large Random Fluctuations. Even though surging is not observed orally or visually, the presence of large random fluctuations at low frequencies is still a possibility. The simplest test for this requires the observation of the differences between the L_{max} and L_{eq} levels or the L_{10} and the L_{eq} levels in the 16-, 31-, 63-, and 125-Hz bands with the meter set on fast. If the difference between L_{max} and L_{eq} for any one of the three lowest bands (16-, 31-, and 63-Hz octave bands) is greater than 7 dB, or $L_{10} - L_{eq} > 4$ dB, or if the difference between L_{max} and L_{eq} for the 125-Hz band is greater than 6 dB, or $L_{10} - L_{eq} > 3$ dB, large random fluctuations are indicated and the full RNC method should be used.

Well-Behaved HVAC Noise — Use NC Curves. When no surging or large-scale fluctuations are observed, L_{eq} measurements (slow scale) can be made in all the octave bands for any length of time T (fractions of minutes or longer) and the results compared with the NC curves of Fig. 20.1. The microphone used for the decibel measurements can be at one place in the room if the noise field is uniform throughout, or by measuring at a number of points and averaging the results, or simply by rotating the microphone at arm's length (2-m-diameter circle) and taking the average of the results.

Again, it must be borne in mind that all of the methods described in this chapter assume that there are no pure tones audible in the noise. If a pure tone(s) is suspected, narrow-band measurements (one-third octave or less) should be made to determine its frequency and intensity. Then, the pure-tone source should be located and steps taken to reduce its level before evaluating the remaining HVAC noise.

Found or Suspected Surging or Large Low-Frequency Fluctuations in HVAC Noise — Use RNC Curves. When surging or large low-frequency fluctuations are found or suspected, the RNC procedure is recommended to determine the penalty. It requires the use of a contemporary sound-level meter and a computer. The method incorporates the psychoacoustic facts discussed above. The RNC curves are shown in Fig. 20.4. Each RNC-X curve (e.g., RNC-40, RNC-50)

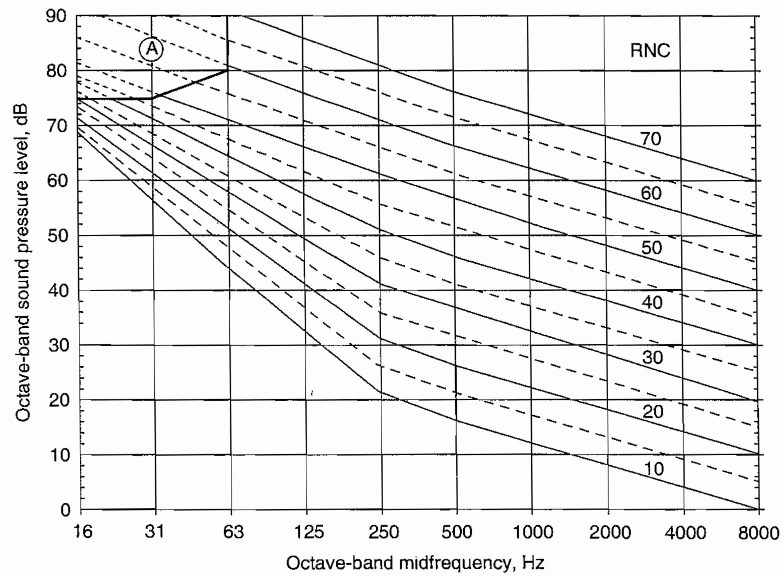

FIGURE 20.4 Balanced Noise criteria curves, devised in refs. 1,13, and 14 to rate noises that exhibit HVAC surging or large random fluctuations. In well-behaved HVAC systems the curves yield the same ratings as NC curves. When there are clearly audible HVAC surging or random vibrations, the curves yield ratings more like those of the RC curves—a penalty is imposed for surging that requires lower levels as measured with a "slow," sound-level meter setting.

TABLE 20.7 Coefficients Used in Eqs. (20.2) and (20.3) to Calculate RNC-X Curves of Fig. 20.4

Octave Band, Hz	Sound-Level Range, dB	K_{1ob}[a]	K_{2ob}
16	≤81	64.3333	3
	>81	31	1
31	≤76	51	2
	>76	26	1
63	≤71	37.6667	1.5
	>71	21	1
125	≤66	24.3333	1.2
	>66	16	1
250	All	11	1
500	All	6	1
1000	All	2	1
2000	All	−2	1
4000	All	−6	1
8000	All	−10	1

[a]The four-decimal figures are only to give calculated RNC-X even-decibel values.

can be derived from

$$L_{ob} = \frac{\text{RNC-}X}{K_{2ob}} + K_{1ob} \tag{20.2}$$

where RNC-X is the number on the curve, L_{ob} is the x-axis level for the particular octave band, and the constants K_{2ob} and K_{1ob} are taken from Table 20.7 for the particular octave bands.

Example 20.1. Calculate the SPL of the 63-Hz band for the RNC-20 curve of Fig. 20.4:

$$L_{ob} = (20/1.5) + 37.6667 = 13.3333 + 37.6667 = 51 \text{ dB}.$$

Conversely, the nearest RNC evaluation curve for a measured octave-band level can be obtained from

$$\text{RNC-}X = (L_{ob} - K_{1ob}) \times K_{2ob} \tag{20.3}$$

Example 20.2. Assume the measured level in the 125-Hz octave band L_{ob} is 55 dB. Determine which RNC curve (to nearest decibel) that measurement touches:

$$\text{RNC-X} = (55 - 24.3333) \times 1.2 = \text{RNC-37}$$

Recommended RNC Curves. The recommended RNC curves for spaces are the same as those for the NC curves and are given in Table 20.2.

If there is no surging or large scale-fluctuations, so that L_{eq} levels can be measured with the slow meter and flat frequency response, evaluation by the new RNC curves will yield results that are approximately equal to those from the NC curves. Therefore, the permissible L_{eq} levels at low frequencies compared to the SIL at midfrequencies will be as large as those shown in Fig. 20.1.

If surging and fluctuations exist, the RNC method "penalizes" the L_{eq} levels in the octave frequency bands below 300 Hz, so that if the disturbance in those frequency bands is large, the permissible L_{eq} levels may approach the low-frequency levels of the RC curves, as in Fig. 20.3.

Corrections to Measured Levels in Octave Bands at 16, 31.5, and 63 Hz When Surging or Large Fluctuations Exist. If surging and fluctuations exist, the RNC method penalizes the L_{eq} levels in the octave frequency bands below 300 Hz, so that if the disturbance in those frequency bands is large, the permissible L_{eq} levels may approach the low-frequency levels of the RC curves, as in Fig. 20.3. Contemporary sound-level meters can store up to 24 h of data for later downloading to a computer. The data should be recorded with a fast meter setting and a flat frequency response. The stored data (of whatever total time length) in bands or overall is sampled every 100 ms, forming the required octave-band time series for the RNC method. For the total time period, L_{peak}, L_{10}, and L_{50} are also available.

Each of the successive 100-ms samples is labeled i, where the ultimate i should be between 150 and 1000 depending on the suspected magnitude of the surging.

Because the loudness of a sound, at a given level, is considerably less at 16 Hz than at 31.5 Hz and, in turn, the loudness is considerably less at 31.5 Hz than that at 63 Hz, in the RNC method the three octave bands with midfrequencies at 16, 31.5, and 63 Hz are combined and replaced by a "three-band-sum" at 31.5 Hz. To do this, all of the measured 100-ms samples for the 16-Hz octave band are reduced by 14 dB and the samples for the 63-Hz octave band are increased by 14 dB. These adjusted levels for the 16- and 63-Hz bands are combined with the measured levels in the 31.5-Hz band on *an energy basis* and the new level (in decibels) is called a three-band-sum.

The ith 100-ms sample of this three-band-sum is called L_{LFi}. Calculate $L_{LF,eq}$ for the three-band-sum by summing the energies of the samples and dividing by the number of samples and taking 10 log of the result. Also, calculate L_{LFm}, the mean level of the set of three-band-sum samples.

The object now is to determine a correction K_{LFC} to be added to the *measured* L_{eq} at 31.5 Hz (not the three-band-sum) that takes into consideration both the L_{LFi} values and the fact that a change of only 5 dB is needed for a doubling of loudness at 31.5 Hz—and at 125 Hz, 8 dB is needed. Let δ stand for this change.

First calculate the correction at 31.5 Hz, K_{LFC}:

$$K_{LFC} = K_{LF\delta} - (L_{LF,eq} - L_{LFm}) \tag{20.4}$$

where

$$K_{LF\delta} = 10 \log \left(\frac{1}{N} \sum_{i=1}^{N} 10^{L\alpha/10} \right) \tag{20.5}$$

and where, at 31.5 Hz ($\delta = 5$ dB),

$$L\alpha = \frac{10}{\delta}(L_{LFi} - L_{LFm}) = 2(L_{LFi} - L_{LFm}) \tag{20.6}$$

The quantity K_{LFC} is added to the *measured* equivalent level L_{eq} (long time energy average) in the 31.5-Hz octave band and is plotted on Fig. 20.4 (no numbers are plotted in the 16- and 63-Hz bands). If data are not available for the 16-Hz band, the three-band-sum is determined for the 31.5- and 63-Hz bands.

Correction to Measured Level in Octave Band at 125 Hz If Surging Is Observed or Suspected. The level of each element of the 100-ms series at 125 Hz is called L_{125i}. Calculate L_{125eq} at 125 Hz by combining the energies of the samples and dividing by the number of samples and taking 10 log of the result. Also, calculate L_{125m}, the mean level of the set of samples at 31.5 Hz. The correction to be added to the *measured* 125-Hz octave-band L_{eq} is called K_{125C} and is given by

$$K_{125C} = K_{125\delta} - (L_{125eq} - L_{125m}) \tag{20.7}$$

where

$$K_{125\delta} = 10 \log\left(\frac{1}{N}\sum_{i=1}^{N} 10^{L\beta/10}\right) \tag{20.8}$$

and where, at 125 Hz ($\delta = 8$ dB),

$$L\beta = \frac{10}{\delta}(L_{125i} - L_{125m}) = 1.25(L_{125i} - L_{125m}) \tag{20.9}$$

Example for Surging. Used is a set of random data having a Gaussian distribution with a standard deviation of about 3 dB for the combined 16–31.5–63-Hz band. Superimposed is a sinusoidal variation with a peak-to-peak amplitude of 15 dB. Shown in Table 20.8 are 10 of the 1000 measured octave-band levels each 100 ms in length. The three-band-sum defined above is given in the last column.

The summary data for 1000 samples are listed in Table 20.9. The correction K_{LFC} to be added to the L_{eq} at 31.5 Hz comes from Eq. (20.4) and equals 11.5 dB, yielding the adjusted 31.5-dB band level equal to 73.1 dB. From Eq. (20.7), the correction K_{125C} is found to be 1.6 dB, yielding 44.7 dB. The corrected spectrum is shown in the last line of Table 20.9. When the corrected spectrum is plotted in Fig. 20.4 or is determined from Eq. (20.3), it is found that the highest RNC curve touched is RNC-44 (at 31.5 Hz). If there had been no correction, the highest curve touched would have been RNC-22. The strong surging and turbulence has changed the rating from RNC-22 to RNC-44.

TABLE 20.8 Ten 100-ms Samples from a Total of 1000 Samples[a]

ith Band Numbers	By Octave-Band Mid frequencies, Hz										L_{LFi} Three-Band-Sum, (dB)

Equivalent sound level L_{eq} of these 10 samples.											63.4

[a]Data Represent a Gaussian noise with a superimposed surge implemented by a sine wave with a 2-s period and a 15-dB peak-to-peak amplitude.

Simplified Method: Corrections to Measured Levels in 16–125-Hz Octave Bands When There Are Large Random Reflections and Not Strong Surging. By this method, the same equations are used to determine the corrections to the adjusted 31- and 125-Hz bands, that is, Eqs. (20.4) and (20.7), but the quantities $K_{LF\delta}$ and $K_{125\delta}$ are calculated from

$$K_{LF\delta} = 0.115\left(\frac{10}{\delta}\right)^2 \sigma_{LF}^2 = 0.115(2)^2\sigma_{LF}^2 = 0.46\sigma_{LF}^2 \tag{20.10}$$

where σ_{LF} is the standard deviation of the L_{LFi} (three-band-sum) series, and

$$K_{125\delta} = 0.115\left(\frac{10}{\delta}\right)^2 \sigma_{125}^2 = 0.115(1.2)^2\sigma_{125}^2 = 0.166\sigma_{125}^2 \tag{20.11}$$

where σ_{125} is the standard deviation of the L_{125i} series.

20.3 ACOUSTICALLY INDUCED VIBRATIONS AND RATTLES

From experience, primarily on the West Coast of the United States, an assessment has been made of the probability of acoustically induced vibration and rattles in lightweight wall and ceiling constructions (including light fixtures, windows, and some furnishings). Obviously, significant fluctuations or surging must be present in the HVAC noise. The region of likely probability where such vibrations in lightweight construction can be clearly felt is shown as A in Figs 20.1–20.4.[11] In

TABLE 20.9 Summary Data for RNC Example[a]

	Three-Band-Sum	Octave-Band Mid frequencies, Hz 16	31.5	63	125	250	500	1000	2000	4000	8000

[a]The L_{eq} is the energy average level in each octave band for all 1000 of the 100-ms samples. The three-band-sum correction of 11.3 dB is added to the L_{eq} of the 31.5-Hz octave band to give an adjusted (for surging) level of 73.1 dB. At 125 Hz the adjusted level is 44.8 dB, 1.6 dB above the L_{eq} level.

very well built structures, such as are expected in concert halls and opera houses, the sound levels can extend into region A without expectation of feelable surface vibrations or audible rattles. In office and school buildings attention should be paid to L_{eq} levels that reach 70 dB or more in the 16- and 31.5-Hz octave bands because of current trends in HVAC design and installation.

20.4 CRITERIA FOR NOISE ANNOYANCE IN COMMUNITIES

The major sources of noise in communities are road, rail and air traffic, industries, construction, and public works. The most common metric used in the United States for estimating the annoyance or disturbance of community noise is the A-weighted day–night sound level (L_{dn}) [see Eq. (1.25)] with slow meter response. The A weighting discriminates against low-frequency sound energy, similar to the way that the hearing apparatus judges loudness. The sound energy of each noise-producing event is summed separately into the total. All of the energy of a noise that rises and falls as a source approaches and departs is summed into the total. The sound energy of each event at night is multiplied by 10 before it is added into the total. This treatment means that a few aircraft fly-bys at night may be as annoying to residents as a large number in the daytime. The European Union countries, for the most part, use a day–evening–night level.

The day–night sound level (L_{dn}) that is agreed on by nearly all agencies, boards, and standards-setting bodies to be the threshold for noise impact in urban residential areas is $L_{dn} = 55$ dBA.[15] In other words, people will begin to complain seriously about the noise if the level is higher. Some agencies speak of this energy-average level as being determined over a period of 12 months. Only the U.S. Federal Aviation Administration (FAA) and the Department of Defense (DOD) speak of a L_{dn} equal to 65 dBA as being the level at which noise begins to impact unfavorably on people in residential areas. Some studies indicate that in urban communities just under half of the U.S. population is exposed to L_{dn} levels of 55 dBA or greater. The World Health Organization (WHO, 1999) has stated that serious annoyance may occur for a L_{dn} of approximately 55 dBA, while moderate annoyance will have a threshold of about 50 dBA. It further recommends that the maximum level L_{max} at night should not exceed 40 dBA.

A possible reason for the 65-dBA level used by the FAA and DOD is that people near airports, on average, have learned to accept higher noise levels or, if not, they have moved away. This also assumes that the airport's relations with the communities surrounding it are good. Quiet rural communities seem to demand lower (5–10 dBA) noise levels.

20.5 TYPICAL URBAN NOISE

A summary of A-weighted noise levels measured in U.S. city areas, daytime and nighttime, is given in Fig. 20.5. Trucks and buses are principal sources of

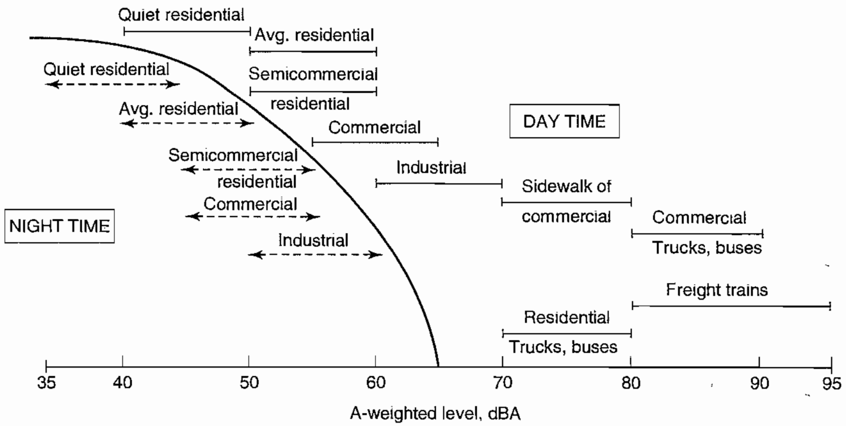

FIGURE 20.5 Schematic display of typical A-weighted noise levels by day and by night in different U.S. urban areas.[4] Noise around industrial areas is frequently caused by trucks.

noise. Parenthetically, the levels in this figure are not L_{dn}, but rather A-weighted levels in a residential area that vehicles produce when they travel on the streets surrounding that neighborhood. In urban residential areas, the noise is frequently the roar of traffic on thoroughfares that may be up to a kilometer away. Traffic noise is likely to be relatively steady and go on all night at a reduced level. If thoroughfares exist on two or more sides of an area, the noise is often nearly uniform over the area.

21.1 WHERE TO FIND AND HOW TO SELECT U.S. NATIONAL AND ISO STANDARDS

This chapter is arranged to provide the titles of North American and international (ISO) standards of interest to noise control engineers, according to specific noise control technology categories such as absorption and insulation (isolation). Acoustical terminology may be found in ANSI S1.1-1994 (R1999), *Acoustical Terminology* and ASTM C634, *Standard Terminology Relating to Environmental Acoustics*. The titles of some standards listed here are truncated to save space. Verbal descriptions, if offered, are brief. As with any technology, state-of-the-art advances bring updated versions of many of these documents. These standards are periodically reviewed and possibly revised by the responsible committees, often on a five-year cycle. A few ANSI standards have become an adoption of the corresponding ISO document, indicated as "Adoption" or "NAIS" (Nationally Adopted International Standard). The reader is encouraged to search anew for recent revisions of these documents. Be advised that some engineering applications may specify past versions, especially as part of a long procurement program or arbitrated contract. It is up to the reader to determine, in participation with interested parties as necessary, which version to use. For the latest standards version, often listed according to the standard's numeral title (e.g., ANSI S12.19 can be found by searching www.ansi.org for S12.19), see the public Internet web page listing by the providing agencies. Some of these agency pages are:

www.ANSI.org (ANSI)
www.ari.org (ARI—free downloads)
www.asastore.aip.org (ANSI + ISO standards available)
www.ashrae.com (ASHRAE)
www.asme.org (ASME)
www.astm.org (ASTM)
www.iec.ch (IEC)
www. iso.ch (ISO)
www.nssn.org (National Standards Systems Network, all standards available)
www.sae.org (SAE)

21.2 SOUND LEVEL MEASUREMENTS

Instrumentation

Standards for noise-measuring instruments, generally measuring sound pressure level (SPL) or "sound level," are listed separate from hearing-measuring instruments (audiometry). Common sound-measuring instruments include sound-level meters, calibrators, filters, and microphones. The most common sound measurement instruments for noise control are specified in ANSI S1.4. Such an instrument comprises a pressure sensor such as a condenser microphone, an amplifier with special wide-band and narrow-band filters, time-averaging circuits, a display, and some memory functions. The precision varies as type 0 (most accurate) to type 2 (least accurate). This entire system can be calibrated at any time with an appropriate calibrator. The acoustical velocity is rarely measured in practice, except for the use of dynamic (velocity) microphones for some audio purposes. The "intensity" method combines SPL and acoustical velocity measurements at a point to compute the intensity value at that point. Applicable standards are as follows:

ANSI S1.4-1983 (R2001), *Specification for Sound Level Meters*. Conforms closely to the IEC standard for sound-level meters, Publication 651, first edition, issued in 1979, but improved for measurement of transient sound signals and it permits the use of digital displays, rigorous definition of the fast and slow exponential time averaging, increase in the crest factor requirement to 10 for type 1 instruments, specification of a type 0 laboratory instrument with generally smaller tolerance limits than specified for type 1, and deletion of the type 3 survey instrument. The corresponding IEC standard (IEC 61672-1:2002 and IEC 61672-2:2003) contains more stringent environmental requirements. In 2003, ANSI S1.4 was under revision to better correspond.

ANSI S1.6-1984 (R2001), *Preferred Frequencies, Frequency Levels, and Band Numbers for Acoustical Measurements*.

ANSI S1.8-1989 (R2001), *Reference Quantities for Acoustical Levels*.

ANSI S1.9-1996 (R2001), *Instruments for the Measurement of Sound Intensity*. Requirements for instruments to measure sound intensity employing the two-microphone technique. Similar to IEC 1043.

ANSI S1.10-1966 (R2001), *Method for the Calibration of Microphones*.

ANSI S1.11-1986 (R1998), *Specification for Octave-Band and Fractional-Octave-Band Analog and Digital Filters*. Performance requirements for fractional-octave-band bandpass filters, in particular octave-band and one-third-octave-band filters, applicable to passive or active analog filters that operate on continuous-time signals to analog and digital filters that operate on discrete-time signals and to fractional-octave-band analyses synthesized from narrow-band spectral components. Four accuracy grades are allowed: the most accurate for precise analog and digital filters. The two least accurate grades meet the requirements of S1.11-1966. Also see IEC 61260:1995.

ANSI S1.14-1998, *Recommendations for Specifying and Testing the Susceptibility of Acoustical Instruments to Radiated Radio-Frequency Electromagnetic Fields, 25 MHz to 1 gHz*.

ANSI S1.15-1997/Part 1 (R2001), *Measurement Microphones*. Part 1: *Specifications for Laboratory Standard Microphones*. This is comparable to the international standard IEC 1094-1:1992, "Measurement Microphones—Part 1: Specifications for Laboratory Standard Microphones."

ANSI S1.16-2000, *Method for Measuring the Performance of Noise Discriminating and Noise Canceling Microphones*.

ANSI S1.17-2004/Part 1, *Measurement and Specifications of Insertion Loss of Wind Screens in Still or Slightly Moving Air*. Determines the insertion loss of wind screens when installed on measuring microphones over a defined frequency range.

ANSI S1.40-1984 (R2001), *Specification for Acoustical Calibrators*. Requirements for coupler-type acoustical calibrators, including the SPL in the coupler, the frequency of the sound, and the determination of the influence of atmospheric pressure, temperature, humidity, and magnetic fields on the pressure level and frequency of the sound produced by the calibrator. (Also see IEC 60942:2003.)

ANSI S1.42-2001, *Design Response of Weighting Networks for Acoustical Measurements*.

ANSI S1.43-1997 (R2002), *Specifications for Integrating Averaging Sound Level Meters*. Consistent with the relevant requirements of ANSI S1.4-1983 (R1997) but specifies additional characteristics needed to measure the time-average SPL of steady, intermittent, fluctuating, and impulsive sounds. (See also IEC 61672-1:2002 and IEC 61672-2:2003.)

ANSI S12.3-1985 (R2001), *Statistical Methods for Determining and Verifying Stated Noise Emission Values of Machinery and Equipment*. Preferred methods for determining and verifying noise emission values for machinery and equipment which are stated in product literature or labeled by other means.

SPL Measurement Techniques

ANSI S1.13-1995 (R1999), *Measurement of Sound Pressure Levels in Air*. Procedures for the measurement of sound levels in air at a single point indoors but may be utilized in outdoor measurements under specified conditions. Includes identification of prominent discrete tones.

ASTM E1014-2000. *Measurement of Outdoor A-Weighted Sound Levels.* A guide for measuring outdoor sound levels over various time periods, intended to be used by practitioners in the field as well as by members of the general public who have little or no special technical training in areas relating to acoustics.

ANSI S1.25-1991 (R2002), *Specification for Personal Noise Dosimeters.* Makes provision for three exchange rates: 3, 4, and 5 dB per doubling of exposure time. Provides tolerances for the entire instruments, parameters, including frequency response, exponential averaging employing slow and fast transient time response, threshold, and dynamic range, for SPL measurement in a random-incidence sound field without the presence of a person wearing the instrument.

ANSI S12.19-1996 (R2001), *Measurement of Occupational Noise Exposure.* Methods that can be used to measure a person's noise exposure received in a workplace. Provides uniform procedures and repeatable results for the measurement of occupational noise exposure.

ISO 11204:1995, *Noise Emitted by Machinery and Equipment—Measurement of Emission Sound Pressure Levels at a Work Station and at Other Specified Positions—Method Requiring Environmental Corrections.*

Intensity Instruments and Measurement Techniques

ANSI S1.9-1996 (R2001), *Instruments for the Measurement of Sound Intensity.* Requirements for instruments to measure sound intensity employing the two-microphone technique. Similar to IEC 1043.

ANSI S12.12-1992 (R2002), *Standard Engineering Method for the Determination of Sound Power Levels of Noise Sources Using Sound Intensity.* Measures the sound power level of noise sources in indoor or outdoor environments using sound intensity instrumentation.

ISO 9614-1:1993, *Determination of Sound Power Levels of Noise Sources Using Sound Intensity.* Part 1: *Measurement at Discrete Points.* Part 2: *Measurement by Scanning.*

21.3 SOUND POWER MEASUREMENT TECHNIQUES

ANSI S12.5-1990 (R1997), *Requirements for the Performance and Calibration of Reference Sound Sources.* Requirements, including free-field laboratory calibration above a reflecting plane, for reference sound sources used in the substitution measurement of sound power.

ANSI S12.11-1987 (R1997), *Method for the Measurement of Noise Emitted by Small Air-Moving Devices.* Measures sound power emitted by small air-moving devices, reported as the noise power emission level in bels. Includes device-mounting methods, test environmental conditions, and device operation method during the tests.

ISO 10302:1996, *Method for the Measurement of Airborne Noise Emitted by Small Air-Moving Devices.*

ANSI S12.15-1992 (R2002), *Measurement of Sound Emitted by Portable Electric Power Tools, Stationary and Fixed Electric Power Tools, and Gardening Appliances.* Methods for SPL measurement and the subsequent calculation of sound power levels.

ANSI S12.23-1989 (R2001), *Method for the Designation of Sound Power Emitted by Machinery and Equipment.* Expressing the noise emission of machinery and equipment as overall A-weighted sound power on labels or other noise emission documentation.

ANSI S12.30-1990 (R2002), *Guidelines for the Use of Sound Power Standards and for the Preparation of Noise Test Codes.* Six standards for determining the sound power levels of equipment for sound test codes for machines and equipment.

ANSI S12.35-1990 (R2001), *Precision Methods for the Determination of Sound Power Levels of Noise Sources in Anechoic and Hemi-Anechoic Rooms.* Determination of the sound power levels of noise sources in laboratory anechoic or hemi-anechoic room, the instrumentation, installation, source operation, SPL measurement surface; calculation of sound power level, directivity index, and directivity factor.

ANSI S12.44-1997 (R2002), *Methods for Calculation of Sound Emitted by Machinery and Equipment at Workstations and Other Specified Positions from Sound Power Level.* Determining emission SPLs from the sound power level values of machinery and equipment at workstations and other locations.

ANSI S12.50-2002 National Adopted International Standard (NAIS), *Determination of Sound Power Levels of Noise Sources—Guidelines for the Use of Basic Standards.* Adoption of ISO 3740:2000. Summaries of ISO 3741–3747 and selection of one or more standards appropriate to any particular type (Clause 6 and Annex D). Used in the preparation of noise test codes (see ISO 12001) and noise testing where no specific noise test code exists.

ANSI S12.51-2002 (including Corrigendum 1 : 2001) NAIS standard, *Acoustics—Determination of Sound Power Levels of Noise Sources Using Sound Pressure—Precision Method for Reverberation Rooms.* Adoption of ISO 3741:1999, a direct method and a comparison method for determining the sound power level produced by a source in a standard environment.

ANSI S12.53/1-1999 ISO 3743-1:1994, *Determination of Sound Power Levels of Noise Sources—Engineering Methods for Small, Movable Sources in Reverberant Fields.* Part 1: *Comparison Method for Hard-Walled Test rooms. (Adoption of ISO 3743-1.)* Part 2: *Methods of Special Reverberation Test Rooms. (Adoption of ISO 3743-2.)*

ANSI S12.54-1999 ISO 3744:1994, *Determination of Sound Power Levels of Noise Sources Using Sound Pressure—Engineering Method in an Essentially Free Field over a Reflecting Plane.* Adoption of ISO 3744, sound power engineering accuracy, measurement by the comparison method in an anechoic environment.

ANSI S12.56-1999 ISO 3746:1995, *Determination of Sound Power Levels of Noise Sources Using Sound Pressure—Survey Method Using an Enveloping Measurement Surface over a Reflecting Plane.* Adoption of ISO 3746, determining the sound power level of sound sources In Situ, especially if nonmovable, in octave bands from which the A-weighted sound power level is calculated. The accuracy will be that of either an engineering method or a survey method.

ARI 250-2001, *Performance and Calibration of Reference Sound Sources.*

ARI 280-95, *Requirements for the Qualification of Reverberant Rooms in the 63 Hz Octave Band.*

ASTM E1124-97, *Standard Test Method for Field Measurement of Sound Power Level by the Two-Surface Method.* An In Situ survey measurement of sound power level with sound pressure measurements at two concentric surfaces.

ISO 3740:2000, *Determination of Sound Power Levels of Noise Sources—Guidelines for the Use of Basic Standards.*

ISO 3741:1999, *Determination of Sound Power Levels of Noise Sources Using Sound Pressure—Precision Methods for Reverberation Rooms.*

ISO 3743-1:1994, *Determination of Sound Power Levels of Noise Sources—Engineering Methods for Small, Movable Sources in Reverberant Fields.* Part 1: *Comparison Method for Hard-Walled Test Rooms.* Part 2: *Methods for Special Reverberation Test Rooms.*

ISO 3744:1994, *Determination of Sound Power Levels of Noise Sources Using Sound Pressure—Engineering Method in an Essentially Free Field over a Reflecting Plane.*

ISO 3745:1977, *Determination of Sound Power Levels of Noise Sources—Precision Methods for Anechoic and Semi-Anechoic Rooms.*

ISO 3746:1995, *Determination of Sound Power Levels of Noise Sources Using Sound Pressure—Survey Method Using an Enveloping Measurement Surface over a Reflecting Plane.*

ISO 3747:2000, *Determination of Sound Power Levels of Noise Sources Using Sound Pressure—Comparison Method In Situ.*

ISO 5135:1997, *Determination of Sound Power Levels of Noise from Air-Terminal Devices, Air-Terminal Units, Dampers and Valves by Measurement in a Reverberation Room.*

ISO 5136:1990, *Determination of Sound Power Radiated into a Duct by Fans—In-Duct Method.*

ISO 6926:1999, *Requirements for the Performance and Calibration of Reference Sound Sources Used for the Determination of Sound Power Levels.*

21.4 MACHINERY NOISE EMISSION MEASUREMENT TECHNIQUES

ANSI S12.1-1983 (R2001), *Guidelines for the Preparation of Standard Procedures to Determine the Noise Emission from Sources.* Included are the general questions to be asked during development of a measurement procedure. Included are prefatory material, measurement conditions, measurement operations, data reduction, preparation of a test report, and guidelines for the selection of a descriptor for noise emission.

ANSI S12.10-2002 ISO 7779:1999 NAIS standard, *Measurement of Airborne Noise Emitted by Information Technology and Telecommunications Equipment.* Adoption of ISO 7779:1999 and its amendment ISO 7779: 1999/FDAM 1.

ANSI S12.16-1992 (R2002), *Guidelines for the Specification of Noise of New Machinery.* Methods to calculate workplace noise SPL from test data produced by manufacturers of stationary equipment. This references existing ANSI, trade, and professional association measurement standards and techniques to be used by manufacturers to produce individual raw machine sound power or SPL test data.

ANSI S12.43-1997 (R2002), *Methods for the Measurement of Sound Emitted by Machinery and Equipment at Workstations and Other Specified Positions.* Three methods to measure SPLs: (1) in a free field over a reflecting plane, (2) in normal operating environments, and (3) when operating in their normal environments when less accurate measurements are acceptable.

ARI 530-95, *Method of Measuring Sound and Vibration of Refrigerant Compressors.*

ARI 575-94, *Method of Measuring Machinery Sound within an Equipment Space.*

ISO 4412-1:1991, *Hydraulic Fluid Power—Test Code for Determination of Airborne Noise Levels.* Part 1: *Pumps.* Part 2: *Motors.* Part 3: *Pumps—Method Using a Parallelepiped Microphone Array.*

ISO 4871:1996, *Declaration and Verification of Noise Emission Values of Machinery and Equipment.*

ISO 7574-1:1985, *Statistical Methods for Determining and Verifying Stated Noise Emission Values of Machinery and Equipment.* Part 1: *General Considerations and Definitions.* Part 2: *Methods for Stated Values for Individual Machines.* Part 3: *Simple (Transition) Method for Stated Values for Batches of Machines.* Part 4: *Methods for Stated Values for Batches of Machines.*

ISO 7779:1999, *Measurement of Airborne Noise Emitted by Information Technology and Telecommunications Equipment.*

ISO 9295:1988, *Measurement of High-Frequency Noise Emitted by Computer and Business Equipment.*

ISO 9296:1988, *Declared Noise Emission Values of Computer and Business Equipment.*

ISO 9611:1996, *Characterization of Sources of Structure-Borne Sound with Respect to Sound Radiation from Connected Structures—Measurement of Velocity at the Contact Points of Machinery When Resiliently Mounted.*

ISO 11200:1995, *Noise Emitted by Machinery and Equipment—Guidelines for the Use of Basic Standards for the Determination of Emission Sound Pressure Levels at a Work Station and at Other Specified Positions.*

ISO 11201:1995, *Noise Emitted by Machinery and Equipment—Measurement of Emission Sound Pressure Levels at a Work Station and at Other Specified Positions—Engineering Method in an Essentially Free Field over a Reflecting Plane.*

ISO 11202:1995, *Noise Emitted by Machinery and Equipment—Measurement of Emission Sound Pressure Levels at a Work Station and at Other Specified Positions—Survey Method* In Situ.

ISO 11203:1995, *Noise Emitted by Machinery and Equipment—Determination of Emission Sound Pressure Levels at a Work Station and at Other Specified Positions from the Sound Power Level.*

ISO 10846, *Acoustics and Vibration—Laboratory Measurement of Vibro-Acoustic Transfer Properties of Resilient Elements.* Part 1—1997: *Principles and Guidelines.* Part 2—1997: *Dynamic Stiffness of Elastic Supports for Translatory Motion—Direct Method.* Part 3—2002: *Indirect Method for Determination of the Dynamic Stiffness of Resilient Supports for Translatory Motion.*

ISO 11690-1, *Recommended Practice for the Design of Low-Noise Workplaces Containing Machinery.* Part 1: *Noise Control Strategies.* Part 2: *Noise Control Measures.* Part 3: *Sound Propagation and Noise Prediction in Workrooms.*

21.5 IMPACT OF NOISE IN WORKPLACE

Two qualities of workplace noise are of concern as they affect damage to hearing and speech communication. Environmental noise includes vibration and infrasound. Hearing conservation measurements are of two forms: measurement of hearing acuity and measurement of noise levels in work and recreational environments.

Hearing Testing (Audiometry) Equipment and Procedures

ANSI S3.1-1999, *Maximum Permissible Ambient Noise Levels for Audiometric Test Rooms.* Specifies maximum permissible ambient noise levels (MPANLs) allowed in an audiometric test room.

ANSI S3.6-1996, *Specification for Audiometers.* The audiometers covered in this specification are devices designed for use in determining the hearing threshold of an individual in comparison with a chosen standard reference threshold level.

ANSI S3.21-1978 (R1997), *Methods for Manual Pure-Tone Threshold Audiometry.* Outlines the procedure for pure-tone threshold audiometry used in the assessment of an individual's threshold of hearing for pure tones.

ISO 226:1987, *Normal Equal-Loudness Level Contours.* Data in this standard formed the basis for the dBA and dBC curves used in noise measurement.

ISO 389, 1964 Acoustics, *Standard Reference Zero for the Calibration of Pure-Tone Audiometers.* Part 1: *Reference Equivalent Sound Pressure Levels for Pure Tones and Supra-Aural Earphones.* Part 2: *Reference Equivalent Threshold Sound Pressure Levels for Pure Tones and Insert Earphones.* These data are also shown in ANSI S3.6-1996.

ISO 6189:1983, *Pure Tone Air Conduction Threshold Audiometry for Hearing Conservation Purposes.* Outlines the procedure for testing hearing thresholds as well as describes the conditions of the testing. Part of this standard is similar to information found in ANSI S3.21-1978 (R1997).

ISO 7029:2000, *Statistical Distribution of Hearing Thresholds as a Function of Age.* Gives expected threshold values for men and women without a history of noise exposure. Data are utilized in ISO 1999 and ANSI S3.44-1996.

ISO 8253-1:1989, *Audiometric Test Methods*—Part 1: *Basic Pure Tone Air and Bone Conduction Threshold Audiometry.* Part 2: *Sound Field Audiometry with Pure Tone and Narrow-Band Test Signals.* Part 3: *Speech Audiometry.*

ISO 11904-1:2002, *Determination of Sound Immission from Sound Sources Placed Close to the Ear.* Part 1: *Technique Using a Microphone in a Real Ear (MIRE Technique).* Some of the data in this standard are similar to that in ANSI S12. 42-1995 (R1999).

IEC 60645-1 Ed 2.0 b: 2001, *Electroacoustics—Audiological Equipment.* Part I: *Pure-Tone Audiometers.* Has material also found in ANSI S3.6-1996.

Hearing Conservation Programs

ANSI S3.44-1996 (R2001), *Determination of Occupational Noise Exposure and Estimation of Noise-Induced Hearing Impairment.* Adoption of ISO 1999:1990(E) of the same name; however, S3.44 allows assessment of noise exposure using a time–intensity trading relation other than a 3-dB increase per halving of exposure time.

ANSI S12.6-1997 (R2002), *Methods for Measuring the Real-Ear Attenuation of Hearing Protectors.* Specifies laboratory-based procedures for measuring, analyzing, and reporting the noise-reducing capabilities of conventional passive hearing protection devices.

ANSI Technical Report S12.13 TR-2002, *Evaluating the Effectiveness of Hearing Conservation Programs through Audiometric Data Base Analysis.* Describes methods for evaluating the effectiveness of hearing conservation programs in preventing occupational noise-induced hearing loss by using techniques for audiometric database analysis.

ANSI S12.42-1995 (R1999), *Microphone-in-Real-Ear and Acoustic Test Fixture Methods for the Measurement of Insertion Loss of Circumaural Hearing Protection Devices.* Describes the microphone-in-real-ear and the acoustical test fixture methods for the measurement of the insertion loss of circumaural earmuffs, helmets, and communications headsets.

ISO 1999:1999, *Acoustics—Determination of Occupational Noise Exposure and Estimation of Noise-Induced Hearing Impairment.* Similar to ANSI S3.44-1996 except that ISO 1999 is more restrictive.

ISO 4869-1:1990, *Hearing Protectors*—Part 1: *Subjective Method for the Measurement of Sound Attenuation.* Part 2: *Estimation of Effective A-Weighted Sound Pressure Levels When Hearing Protectors Are Worn.* Part 3: *Simplified Method for the Measurement of Insertion Loss of Ear-Muff Type Protectors for Quality Inspection Purposes.* Part 4: *Measurement of Effective Sound Pressure Levels for Level-Dependent Sound-Restoration Ear-Muffs.*

ISO 7029:2000, *Statistical Distribution of Hearing Thresholds as a Function of Age.*

ISO 9612:1997, *Guidelines for the Measurement and Assessment of Exposure to Noise in a Working Environment.*

Speech Communication Metrics

ANSI S3.2-1989 (R1999), *Method for Measuring the Intelligibility of Speech over Communication Systems.* A revision of ANSI S3.2-1960 (R1982). Provides three alternative sets of lists of English words to be spoken by trained talkers over the speech communication system to be evaluated.

ANSI S3.4-1980 (R1997), *Procedure for the Computation of Loudness of Noise.* Specifies a procedure for calculating the loudness of certain classes of noise.

ANSI S3.5-1997 (R2002), *Methods of the Calculation of the Speech Intelligibility Index (SII).* Computation of the SII based on the intelligibility of speech as evaluated by speech perception tests given a group of talkers and listeners.

ASTM 1130-2002, *Objective Measurement of Speech Privacy in Open Offices Using Articulation Index (AI).* Computation of the Articulation Index (AI) from standard speech levels, ambient noise, and articulation weighting factors.

ANSI S3.14-1977 (R1997), *Rating Noise with Respect to Speech Interference.* Defines a simple numerical method for rating the expected speech-interfering aspect (Speech Interference Level, SIL) of noise using acoustical measurements of the noise.

ISO/TR 3352, 1974, *Acoustics—Assessment of Noise with Respect to Its Effect on the Intelligibility of Speech.* This technical report has never been approved as a standard in part because of the concern over whether the impact of noise is similar for each language.

ISO/TR 4870:1991, *The Construction and Calibration of Speech Intelligibility Tests.*

Environmental Noise SPL Measurement Methods

Environmental noise SPL measurements are typically made outdoors to mirror most regulations. Sound measurement locations are often near houses or in empty fields and near transportation and industrial noise sources. In addition to meeting all the requirements of ANSI S1.4, this acoustical equipment and its application must be tolerant of wind, rain, birds, insects, and mechanical abuse. Primary noise sources include transportation (aircraft, road traffic, trains, etc.), industrial facilities, neighborhood noise (pets, heating, ventilation, and air conditioning), recreational noise (shooting ranges, races, and music venues).

ANSI S12.18-1994 (R1999), *Procedures for Outdoor Measurement of Sound Pressure Level.* Procedures for the measurement of SPLs outdoors, considering ground effects and refraction due to wind and temperature gradients and to turbulence. Measurement of SPLs produced by specific sources outdoors. Method 1: general method, outlines conditions for routine measurements. Method 2: precision method, describes strict conditions for more accurate measurements, providing short-term A-weighted SPL or time-averaged SPL, A-weighted or in octave- or in one-third-octave or narrow-band SPL, but does not preclude determination of other sound descriptors.

ASTM E1014-84(2000), *Standard Guide for Measurement of Outdoor A-Weighted Sound Levels.* Basic technique for performing a reliable A-weighted sound-level measurement outdoors.

ASTM E1503-97, *Standard Test Method for Conducting Outdoor Sound Measurements Using a Digital Statistical Analysis System.* Covers the measurement of outdoor sound levels at specific locations using a digital statistical analyzer and a formal measurement plan.

ISO 7196: 1995, *Frequency-Weighting Characteristic for Infrasound Measurements.*

ISO 10843:1997, *Methods for the Description and Physical Measurement of Single Impulses or Series of Impulses.*

Environmental Noise Measurement Applications

ANSI S12.7-1986 (R1998), *Methods for Measurement of Impulse Noise.* Measures impulse noise from discrete events, such as quarry and mining explosions or sonic booms, or from multiple-event sources such as pile drivers, riveting, or machine-gun firing. Data may be reported as time variation of the sound pressure, with or without frequency weighting, and sound exposure level.

ANSI S12.8-1998 (R2003), *Methods for Determining the Insertion Loss of Outdoor Noise Barriers.* Determine the insertion loss of outdoor noise barriers, including direct before and after measurements, indirect before measurements at an "equivalent" site, and indirect predictions of "before" sound levels. Indirect before measurements and indirect before prediction methods require direct measurements of "after" sound levels. May use sound sources naturally present at a site, controlled natural sound sources, or controlled artificial sound sources. Receiver location and atmospheric, ground, and terrain conditions may be chosen. Worksheets are provided

ANSI S12.9-1988 (R2003), *Quantities and Procedures for Description and Measurement of Environmental Sound.* Part 1: *Basic Quantities for Description of Sound in Community Environments and General Procedures for Measurement of These Quantities.* Part 2: *Measurement of Long-Term, Wide Area Sound.* Part 3: *Short-Term Measurements with an Observer Present.* Part 4: *Noise Assessment and Prediction of Long-Term Community Response.* Part 5: *Sound Descriptors for Determination of Compatible Land Use.* Part 6: *Methods for Estimation of Awakenings Associated with Aircraft Noise Events Heard in Homes.*

ANSI/ASME PTC 36-1985 (R1998), *Measurement of Industrial Sound.* Procedures for measuring and reporting airborne sound emissions from mechanical equipment.

ARI 260-2001, *Sound Rating of Ducted Air Moving and Conditioning Equipment.*

ARI 270-95, *Sound Rating of Outdoor Unitary Equipment.*

ARI 275-97, *Application of Sound Rating Levels of Outdoor Unitary Equipment.*

ARI 300-2000, *Sound Rating and Sound Transmission Loss of Packaged Terminal Equipment.*

ARI 350-2000, *Sound Rating of Non-Ducted Indoor Air-Conditioning Equipment.*

ARI 370-2001, *Sound Rating of Large Outdoor Refrigerating and Air-Conditioning Equipment.*

ISO 1996, *Description and Measurement of Environmental Noise*. Part 1-2003: *Basic Quantities and Assessment Procedures.* Part 2-1987: *Acquisition of Data Pertinent to Land Use*. Part 3-1987: *Application to Noise Limits.*

ISO 3891:1978, *Procedure for Describing Aircraft Noise Heard on the Ground.*

ISO 8297:1994, *Determination of Sound Power Levels of Multisource Industrial Plants for Evaluation of Sound Pressure Levels in the Environment—Engineering Method.*

ISO 10847:1997, *In-Situ Determination of Insertion Loss of Outdoor Noise Barriers of All Types*. See also ANSI S12.8.

ISO/TS 13474:2003, *Impulse Sound Propagation for Environmental Noise Assessment.*

SAE J1075 (revised June 2000), *Surface Vehicle Standard (R) Sound Measurement—Construction Site*. Procedures and instrumentation to be used for determining a representative sound level during a representative time period at selected measurement locations on a construction site boundary.

Environmental Sound Propagation Outdoors

ANSI S1.18-1999, *Template Method for Ground Impedance*. Procedures for obtaining the real and imaginary parts of the specific acoustical impedance of natural ground surface outdoors.

ANSI S1.26-1995 (R1999), *Method for Calculation of the Absorption of Sound by the Atmosphere*. Still-atmosphere absorption losses of sound for a wide range of meteorological conditions.

ANSI S12.17-1996 (R2001), *Impulse Sound Propagation for Environmental Noise Assessment Response*. Engineering methods to calculate the propagation and attenuation of high-energy impulsive sounds through the atmosphere. It estimates the mean C-weighted sound exposure level of impulsive sound at distances ranging from 1 to 30 km, applicable for explosive masses between 50 and 1000 kg.

ISO 9613, *Attenuation of Sound during Propagation Outdoors*. Part 1-1993: *Calculation of the Absorption of Sound by the Atmosphere. Attenuation of Sound During Propagation Outdoors*. Part 2-1996: *General Method of Calculation*. Propagation attenuation, including barrier attenuation calculations, excess attenuation by hard and soft ground surfaces, and attenuation of sound by rows of buildings and by trees and shrubs.

ISO/TS 13474:2003, *Impulse Sound Propagation for Environmental Noise Assessment.*

Environmental Vibrations

ANSI S3.18-2002, *NAIS Standard Mechanical Vibration and Shock—Evaluation of Human Exposure to Whole-Body Vibration*. Part 1: *General Requirements*. Part of ISO 2631 defining methods for the measurement of periodic, random, and transient whole-body vibration. It indicates the principal factors that combine to determine the degree to which a vibration exposure will be acceptable.

ANSI S3.29-1983 (R2001), *Guide to the Evaluation of Human Exposure to Vibration in Buildings*. Reactions of humans to vibrations of 1–80 Hz inside buildings are assessed as degrees of perception and associated vibration levels and duration.

ANSI S3.34-1986 (R1997), *Guide for the Measurement and Evaluation of Human Exposure to Vibration Transmitted to the Hand*. The recommended method for the measurement, data analysis, and reporting of human exposure to hand-transmitted vibration.

ANSI S3.40-2002, *NAIS Standard Mechanical Vibration and Shock—Hand-Arm Vibration—Method for the Measurement and Evaluation of the Vibration Transmissibility of Gloves at the Palm of the Hand*. Adoption of ISO 10819:1996. A method for the laboratory measurement, data analysis, and reporting of the vibration transmissibility of gloves of vibrations from a handle to the palm of the hand in the frequency range 31.5–1250 Hz.

ISO 2631, *Mechanical Vibration and Shock—Evaluation of Human Exposure to Whole-Body Vibration*. Part 1-1997: *General Requirements*. Part 2-1989: *Continuous and Shock-Induced Vibrations in Buildings (1 to 80 Hz)*. Part 4-2001: *Guidelines for The evaluation of the Effects of Vibration and Rotational Motion on Passenger and Crew Comfort in Transport Systems.*

ISO 2671:1982, *Environmental Tests for Aircraft Equipment—Part 3.4: Acoustic Vibration.*

ISO 4866:1990, *Mechanical Vibration and Shock—Vibration of Buildings—Guidelines for the Measurement of Vibrations and Evaluation of Their Effects on Building.*

21.6 VEHICLE EXTERIOR AND INTERIOR NOISE

There are many SAE and ISO standards dealing with the source of noise emissions of various motor vehicles, including road vehicle (automobiles, trucks, buses, and motorcycles), trains, boats, aircraft, construction equipment (e.g., dozer), agricultural equipment (e.g., tractor), and small-engine equipment (e.g., lawn edger). Full listings of these standards are maintained at the SAE and ISO websites. The following is a sampling of these standards. Quite a few are identically SAE and ISO standards.

Vehicle Noise — Interior Noise Measurement Techniques

ISO 2923:1996, *Measurement of Noise on Board Vessels*.

ISO 3095:1975, *Measurement of Noise Emitted by Railbound Vehicles*.

ISO 3381:1976, *Measurement of Noise Inside Railbound Vehicles*.

ISO 5128:1980, *Measurement of Noise Inside Motor Vehicles*.

ISO 5129:2001, *Measurement of Sound Pressure Levels in the Interior of Aircraft During Flight*.

ISO 5130:1982, *Measurement of Noise Emitted by Stationary Road Vehicles—Survey Method*.

ISO 5131:1996, *Tractors and Machinery for Agriculture and Forestry—Measurement of Noise at the Operator's Position—Survey method*.

ISO 7188:1994, *Measurement of Noise Emitted by Passenger Cars under Conditions Representative of Urban Driving*.

ISO 11819-1:1997, *Measurement of the Influence of Road Surfaces on Traffic Noise*. Part 1: *Statistical Pass-By Method*.

Road Surface Sound Absorption

See ISO 13472 below under Sound Absorption.

Vehicle Noise — Exterior Noise Measurement (Noise Emission) Techniques

SAE J366, *Exterior Sound Level for Heavy Trucks and Buses (APR 2001)*. Test procedure, environment, and instrumentation for determining the maximum exterior sound level for highway motor trucks, truck tractors, and buses.

ISO 3095:1975, *Measurement of Noise Emitted by Railbound Vehicles*. Obtaining reproducible and comparable measurement results of levels and spectra of noise emitted by all kinds of vehicles operating on rails or other types of fixed track except for track maintenance vehicles in operation.

SAE J34 (June 2001), *Exterior Sound Level Measurement Procedure for Pleasure Motorboats*. Procedure for measuring the maximum exterior sound level of pleasure motorboats while being operated under wide open-throttle conditions.

ISO 362:1998, *Measurement of Noise Emitted by Accelerating Road Vehicles—Engineering Method*. (Available in English only.)

SAE J16395 (ISO 6395) (February 2003), *Measurement of Exterior Noise Emitted by Earth-Moving Machinery—Dynamic Test Conditions*. Determining the noise emitted to the environment by earth-moving machinery in terms of the A-weighted sound power level while the machine is working under dynamic test conditions.

SAE J17216 (ISO 7216) (February 2003), *Agricultural and Forestry Wheeled Tractors and Self-Propelled Machines—Measurement of Noise Emitted When in Motion*. Measuring the A-weighted SPL in an extensive open space of the noise emitted by agricultural and forestry wheeled tractors and self-propelled machines fitted with elastic tires while the vehicle is in motion. It is not applicable to special forestry machinery, for example, forwarders, skidders, etc., as defined in ISO 6814.

ISO 4872:1978, *Measurement of Airborne Noise Emitted by Construction Equipment Intended for Outdoor Use*. Method for determining compliance with noise limits

ISO 6393:1998, *Measurement of Exterior Noise Emitted by Earth-Moving Machinery—Stationary Test Conditions*. (Available in English only.)

ISO 6394:1998, *Measurement at the Operator's Position of Noise Emitted by Earth-Moving Machinery—Stationary Test Conditions*. (Available in English only.)

ISO 6395:1988, *Measurement of Exterior Noise Emitted by Earth-Moving Machinery—Dynamic Test Conditions*.

ISO 6396:1992, *Measurement at the Operator's Position of Noise Emitted by Earth-Moving Machinery—Dynamic Test Conditions*.

ISO 6798:1995, *Reciprocating Internal Combustion Engines—Measurement of Emitted Airborne Noise—Engineering Method and Survey Method*.

ISO 7216:1992, *Agricultural and Forestry Wheeled Tractors and Self-Propelled Machines—Measurement of Noise Emitted When in Motion*.

ISO 7182:1984, *Measurement at the Operator's Position of Airborne Noise Emitted by Chain Saws*.

ISO 9645:1990, *Measurement of Noise Emitted by Two-Wheeled Mopeds in Motion—Engineering Method.*

ISO 11094:1991, *Test Code for the Measurement of Airborne Noise Emitted by Power Lawn Mowers, Lawn Tractors, Lawn and Garden Tractors, Professional Mowers, and Lawn and Garden Tractors with Mowing Attachments.*

21.7 ARCHITECTURAL NOISE CONTROL IN BUILDINGS

There are three categories of sound control standards for buildings. The first is for testing materials that limit sound transmission from one room to another. The second is to test the sound absorption capability of materials. The third tests the general capabilities of rooms to cope with sounds within it for favorable (offices, classrooms, and auditoria) and unfavorable or noisy situations.

Sound Transmission

ASTM E90-02, *Standard Test Method for Laboratory Measurement of Airborne Sound Transmission Loss of Building Partitions and Elements.* Laboratory measurement of airborne sound transmission loss of building partitions such as walls of all kinds, operable partitions, floor–ceiling assemblies, doors, windows, roofs, panels, and other space-dividing elements.

ASTM E336-97, *Standard Test Method for Measurement of Airborne Sound Insulation in Buildings.* Determining the sound insulation in the field between two rooms in a building. The evaluation may be made including all paths by which sound is transmitted or attention may be focused only on the dividing partition. The word "partition" in this test method includes all types of walls, floors, or any other boundaries separating two spaces. The boundaries may be permanent, operable, or movable.

ASTM E413-87 (1999), *Classification for Rating Sound Insulation.* The method of calculating, from laboratory or field sound insulation measurements at frequencies from 125 to 4000 Hz the single-number acoustical rating called sound transmission class (STC) or field sound transmission class (FSTC) and the single-number rating between two spaces called the noise isolation class (NIC).

ASTM E497, *Practice for Installing Sound-Isolating Lightweight Partitions.* Preferred design methods for constructing high-noise-insulation walls and floor/ceilings.

ASTM E557, *Practice for Architectural Application and Installation of Operable Partitions.* Preferred design and installation methods for constructing high-noise-insulation operable partitions in the field.

ASTM E596-96 (2002), *Standard Test Method for Laboratory Measurement of Noise Reduction of Sound-Isolating Enclosures.* The reverberation room measurement of the noise reduction of sound-isolating enclosures.

ASTM E597, *Practice for Determining a Single-Number Rating of Airborne Sound Isolation for Use in Multi-Unit Building Specifications.* A short test method for field use where a sound source of a standard spectrum is used to test the noise insulation between two existing rooms in a building. Broadband A-weighted sound levels are measured. Computation provides a single number sound insulation value analogous to FSTC.

ASTM E966-02, *Standard Guide for Field Measurements of Airborne Sound Insulation of Building Facades and Facade Elements.* Procedures for measuring the sound insulation of an installed building facade or facade element (window, door). These values may be used separately to predict interior levels or combined into a single number such as by classification E 413 (STC with precautions) or classification E 1332 (outside–inside transmission class, OITC) for sound insulation against transportation noises.

ASTM E492-90 (1996), *Standard Test Method for Laboratory Measurement of Impact Sound Transmission through Floor-Ceiling Assemblies Using the Tapping Machine.* Measurement of impact sound levels (e.g., footfalls) produced by the ISO tapping machine. Results are used to determine the impact isolation class (IIC) by E989.

ASTM E989-89 (1999), *Standard Classification for Determination of Impact Insulation Class (IIC).* A single-number rating of data from ASTM E492 and E1007 for comparing floor–ceiling assemblies for general building design purposes. The rating is called an impact insulation class (IIC).

ASTM E1007-97, *Standard Test Method for Field Measurement of Tapping Machine Impact Sound Transmission through Floor-Ceiling Assemblies and Associated Support Structures.* A field measurement analogous to E492.

ASTM E1123-86 (1998), *Standard Practices for Mounting Test Specimens for Sound Transmission Loss Testing of Naval and Marine Ship Bulkhead Treatment Materials.* Describes test specimen mountings for test method E90, to be used for naval and marine ship bulkhead noise insulation measurement.

ASTM E1222-90 (2002), *Standard Test Method for Laboratory Measurement of the Insertion Loss of Pipe Lagging Systems.* Covers the measurement of the insertion loss of pipe lagging systems under laboratory conditions.

ASTM E1289-97, *Standard Specification for Reference Specimen for Sound Transmission Loss.* Construction and installation of a standard reference specimen for interlaboratory sound transmission loss measurement evaluation using test method E90.

ASTM E1332-90 (1998), *Standard Classification for Determination of Outdoor-Indoor Transmission Class.* A single-number rating for exterior doors, windows, and walls for their noise insulation against ground and air transportation noise, including aircraft roadway vehicles and trains.

ASTM E1408-91 (2000), *Standard Test Method for Laboratory Measurement of the Sound Transmission Loss of Door Panels and Door Systems.* Laboratory measurement of the sound transmission loss for door panels and door systems. It includes specimen-mounting instructions and the force required to close, latch, unlatch, and open a door.

ASTM E1414-00, *Standard Test Method for Airborne Sound Attenuation between Rooms Sharing a Common Ceiling Plenum.* Uses a special laboratory space to simulate a pair of adjacent offices or rooms separated by a partition and sharing a common plenum space (a common economical construction method used for walls between offices and classrooms). The only significant laboratory sound transmission path is by way of the ceiling structure and the plenum space.

ISO 140-1:1997, *Measurement of Sound Insulation in Buildings and of Building Elements*. Part 1: *Requirements for Laboratory Test Facilities with Suppressed Flanking Transmission*. Part 2: *Determination, Verification and Application of Precision Data*. Part 3: *Laboratory Measurements of Airborne Sound Insulation of Building Elements*. Part 4: *Field Measurements of Airborne Sound Insulation between Rooms*. Part 5: *Field Measurements of Airborne Sound Insulation of Façade Elements and Façades*. Part 6: *Laboratory Measurements of Impact Sound Insulation of Floors*. Part 7: *Field Measurements of Impact Sound Insulation of Floors*. Part 8: *Laboratory Measurements of the Reduction of Transmitted Impact Noise by Floor Coverings on a Heavyweight Standard Floor*. Part 9: *Laboratory Measurement of Room-to-Room Airborne Sound Insulation of a Suspended Ceiling with a Plenum Above It*. Part 10: *Laboratory Measurement of Airborne Sound Insulation of Small Building Elements*. Part 12: *Laboratory Measurement of Room-to-Room Airborne and Impact Sound Insulation of an Access Floor*. Part 13: *Guidelines*. (Available in English only.)

ISO 717-1:1996, *Rating of Sound Insulation in Buildings and of Building Elements*. Part 1: *Airborne Sound Insulation*. Part 2: *Impact Sound Insulation*.

ISO 9052-1:1989, *Determination of Dynamic Stiffness*. Part 1: *Materials Used under Floating Floors in dwellings*.

ISO 3822, *Laboratory Tests on Noise Emission from Appliances and Equipment Used in Water Supply Installations*. Part 1-1999: *Method of Measurement*. Part 2-1995: *Mounting and Operating Conditions for Draw-Off Taps and Mixing Valves*. Part 3-1997: *Mounting and Operating Conditions for In-Line Valves and Appliances*. Part 4-1997: *Mounting and Operating Conditions for Special Appliances*.

ISO 11546-1:1995, *Determination of Sound Insulation Performances of Enclosures*. Part 1: *Measurements under Laboratory Conditions (for Declaration Purposes)*. Part 2: *Measurements In Situ (for Acceptance and Verification Purposes)*.

ISO 11957:1996, *Determination of Sound Insulation Performance of Cabins—Laboratory and In Situ Measurements*.

ISO 15186-1:2000, *Measurement of Sound Insulation in Buildings and of Building Elements Using Sound Intensity*. Part 1: *Laboratory Measurements*.

Sound Absorption

ASTM C384-98, *Standard Test Method for Impedance and Absorption of Acoustical Materials by the Impedance Tube Method*. The use of an impedance tube (standing-wave apparatus) for the measurement of impedance ratios and the normal-incidence sound absorption coefficients of acoustical materials.

ASTM C423-02, *Standard Test Method for Sound Absorption and Sound Absorption Coefficients by the Reverberation Room Method*. Measures the random-incidence sound absorption coefficients of material test specimens, mounted according to ASTM E795, in a reverberation room by measuring sound decay rate.

ASTM E477, *Test Method for Measuring Acoustical and Airflow Performance of Duct Liner Materials and Prefabricated Silencers*. Laboratory measurement method for the sound insertion loss provided by duct sound attenuators.

ISO 7235:1991, *Measurement Procedures for Ducted Silencers—Insertion Loss, Flow Noise and Total Pressure Loss*.

ISO 11691:1995, *Measurement of Insertion Loss of Ducted Silencers without Flow—Laboratory Survey Method*.

ISO 11820:1996, *Measurements on Silencers In Situ*.

ISO 11821:1997, *Measurement of the In Situ Sound Attenuation of a Removable Screen*.

ASTM C522-87(1997), *Standard Test Method for Airflow Resistance of Acoustical Materials*. The measurement of airflow resistance, specific airflow resistance, and airflow resistivity of porous materials. Materials may be thick boards or blankets to thin mats, fabrics, papers, and screens.

ISO 9053:1991, *Materials for Acoustical Applications—Determination of Airflow Resistance*.

ASTM E756-98, *Standard Test Method for Measuring Vibration-Damping Properties of Materials*. Measures the vibration-damping properties—loss factor η, Young's modulus E, and shear modulus G—of materials over a frequency range of 50 Hz to 5 kHz and over the useful temperature range of the material. This method tests materials that have application in structural vibration, building acoustics, and the control of audible noise. Test materials include metal, enamel, ceramics, rubber, plastic, reinforced epoxy matrix, and wood that can be formed to the test specimen bar configuration.

ASTM E795-00, *Standard Practices for Mounting Test Specimens during Sound Absorption Tests*. Standard specimen mountings for tests performed in accordance with C423.

ASTM E1042, *Classification for Acoustically Absorptive Materials Applied by Trowel or Spray*.

ASTM E1050-98, *Standard Test Method for Impedance and Absorption of Acoustical Materials Using a Tube, Two Microphones, and a Digital Frequency Analysis System*. The two-microphone impedance tube method, including a digital frequency analysis system, to measure the normal-incidence sound absorption coefficients and normal specific acoustical impedance ratios of materials.

ISO 354. 2003, *Acoustics—Measurement of Sound Absorption in a Reverberation Room*. Similar to ASTM C423.

ISO 10534-1:1996, *Determination of Sound Absorption Coefficient and Impedance in Impedance Tubes*. Part 1: *Method Using Standing Wave Ratio*. Similar to ASTM C384.

ISO 11654:1997, *Sound Absorbers for Use in Buildings—Rating of Sound Absorption*.

ISO 10844:1994, *Specification of Test Tracks for the Purpose of Measuring Noise Emitted by Road Vehicles.*

ISO 13472-1:2002, *Measurement of Sound Absorption Properties of Road Surfaces In Situ.* Part 1: *Extended Surface Method.* A vertical impedance tube test method for measuring In Situ the sound absorption coefficient of road surfaces as a function of frequency in the range from 250 Hz to 4 kHz.

Architectural Acoustics, Reverberation, and Noise Control Design

ANSI S12.2-1995 (R1999), *Criteria for Evaluating Room Noise.* Defines NC, NCB, RC, and perceptible acoustically induced low-frequency vibration criterion curves for the octave-band SPL spectrum of noise and gives rules for using them to evaluate room background noise.

ANSI S12.60-2002, *Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools.* Acoustical performance criteria, design requirements, and design guidelines for new school classrooms and other learning spaces to achieve a high degree of speech intelligibility in learning spaces. Conformance test procedures are provided.

ASTM E1041, *Guide for Measurement of Masking Sound in Open Offices.*

ASTM E1110-01, *Standard Classification for Determination of Articulation Class.* Provides a single figure rating that can be used for comparing building systems and subsystems for speech privacy purposes. The rating is designed to correlate with transmitted speech intelligence between office spaces.

ASTM E1111-02, *Standard Test Method for Measuring the Interzone Attenuation of Ceiling Systems.* Measures the sound reflective characteristics of ceiling systems with partial-height space dividers, used in offices and sometimes in schools to achieve speech privacy between work zones in the absence of full-height partitions. Restricted to a fixed space divider height of 5 ft, a ceiling height of nominally 9 ft, a source height of 4 ft, and microphone positions at 4 ft height.

ASTM E1130-02, *Standard Test Method for Objective Measurement of Speech Privacy in Open Offices Using Articulation Index (AI).* Measuring speech privacy objectively between existing locations in open offices. Uses acoustical measurements, published information on speech levels, and speech intelligibility to compute the Articulation Index (AI).

ASTM E1179-87 (1998), *Standard Specification for Sound Sources Used for Testing Open Office Components and Systems.* Specifies the sound source used for measuring the speech privacy between open offices or for measuring the laboratory performance of acoustical components (see E1111 and E1130).

ASTM E1375-90 (2002), *Standard Test Method for Measuring the Interzone Attenuation of Furniture Panels Used as Acoustical Barriers.* Measurement of the interzone attenuation of furniture panels used as acoustical barriers in open-plan spaces to provide speech privacy or sound isolation between working positions.

ASTM E1376-90 (2002), *Standard Test Method for Measuring the Interzone Attenuation of Sound Reflected by Wall Finishes and Furniture Panels.* Measures the degree to which reflected sound is attenuated by vertical surfaces in open-plan spaces.

ASTM E1573-02, *Standard Test Method for Evaluating Masking Sound in Open Offices Using A-Weighted and One-Third Octave Band Sound Pressure Levels.* Procedures to evaluate the spatial and temporal uniformity of masking sound in open offices using A-weighted or one-third-octave-band SPLs.

ASTM E1574-98, *Standard Test Method for Measurement of Sound in Residential Spaces.* Practical measurement of residual building interior noise SPLs.

ASTM E2235, *Standard Test Method for the Measurement of Decay Rates for Use in Sound Insulation Test Methods.* Measurement of sound decay rate ($60/T$) in any room, where T is the reverberation time, seconds.

ISO 3382:1997, *Measurement of the Reverberation Time of Rooms with Reference to Other Acoustical Parameters.* Measurement of reverberation time T in performance spaces. Specifies additional measures of auditorium gain (G), early decay (EDT), clarity (C80), Deutlichkeit (D50), central time (CT) lateral energy fraction (LF) and interaural cross correlation (IACC) and of T in any room.

ISO 10053-1991, *Measurement of Office Screen Sound Attenuation under Specific Laboratory Conditions.* Similar to ASTM E1375.

APPENDIX B

American System of Units

The American system of units [which used to be referred to as the English system of units until England converted to the meter-kilogram-second (mks) system] is inherently confusing. In everyday American life, the *pound* (abbreviated lb) is used either as a force or as a weight, both having the units of force. To further complicate matters, some technical writers seek to provide a system parallel to the metric system by using either of two quantities for force and either of two corresponding quantities for mass. Thus, some adopt the pound as the unit of force and define a *slug* as the unit of mass. Others define a *poundal* as the unit of force and adopt the pound as the unit of mass. Neither the slug nor the poundal has found general acceptance in the literature, although we use the former in this text.

As one well-traveled acoustician said, "I have determined that 1 kg of butter bought in Zurich is exactly the same amount as 2.2 lb bought in New York. Whenever I wish to solve a technical problem in America without confusion, I immediately divide the number of pounds by 2.2 to obtain the equivalent number of kilograms. Then I work in the mks system, where force and mass are clearly distinguished." Let us take a moment to distinguish further between mass and force.

The mass of a body is defined as $m = F/\ddot{x}$, where F is the vector sum of all forces acting on the center of gravity of the unrestrained body and $\ddot{x}$ is the acceleration produced in the direction of the force F.

The weight of a body is defined as $w = mg$, where g is the acceleration of gravity (9.81 m/s^2 on earth) and w is the force that must act on the otherwise unrestrained body to keep it stationary when exposed to the gravitational field. Consequently, a body has the same mass but different weight on the moon than on earth. On earth the weight of a 1-kg mass, which is designated as one kilopond (1 kp), is 1 kp weight $=$ 1 kg mass $\times$ 9.81 m/s^2 $=$ 9.81 newtons.

CONSISTENT SYSTEMS OF UNITS USED IN THIS TEXT

Two consistent systems of units are used in this text, the *mks* and the *fss* systems. To describe them, let us start with Newton's second law:

$$\text{Force} = \text{mass} \times \text{acceleration} \tag{B.1}$$

In the *meter-kilogram-second* system

$$\text{No. of newtons} = \text{no. of kg} \times \text{no. of m/s}^2 \tag{B.2}$$

In the *foot-slug-second* system

$$\text{No. of pounds force (lb)} = \text{no. of slugs} \times \text{no. of ft/s}^2 \tag{B.3}$$

The relations among the magnitudes of the units are

$$\begin{aligned} 1\text{kp} &= 2.205\text{lb weight} \\ 1\text{ kg} &= 0.0685\text{slug} \\ 1\text{slug} &= 14.59\text{ kg} \\ 1\text{ newton} &= 0.225\text{lb force} \\ 1\text{lb force} &= 4.448\text{ newtons} \\ 1\text{slug} &= 32.17\text{lb weight} \\ 1\text{lb weight} &= 0.03108\text{slug} = 0.454\text{ kg} \end{aligned}$$

Example. If 1 kg mass is to be accelerated 1 m/s^2, we see, by Eq. (B.2), that a force of 1 newton is required. How many pounds (force) is required for the same result?

Solution 1 kg equals (2.205/32.17) slug and 1 m/s^2 = 3.28 ft/s^2. Thus, by Eq. (B.3), 0.225 lb (force) is required.

INCONSISTENT SYSTEMS OF AMERICAN UNITS USED IN THE LITERATURE

Two inconsistent systems of American units are commonly encountered, the *fps* and the *ips* systems.

In the *foot-pound-second* system (inconsistent system)

$$\text{No. of pounds force (lb)} = \frac{\text{no. of pounds weight (lb)}}{g} \times \text{no. of ft/s}^2 \tag{B.4}$$

where g is the acceleration due to gravity in units of ft/s^2, that is, 32.17 ft/s^2.

In the *inch-pound-second system* (inconsistent system)

$$\text{No. of pounds force (lb)} = \frac{\text{no. of pounds weight (lb)}}{g} \times \text{no. of in./s}^2 \tag{B.5}$$

where g is the acceleration due to gravity in units of in./s^2, that is, 3.86 in./s^2. Mechanical engineers often use the *in.-lb-s* system in the field of shock and vibration.

Example. A 1-kg mass is accelerated 5 m/s^2. Find the force necessary to do this in newtons and pounds (force).

Solution

$$\begin{aligned} 1\text{ kg} &= 2.2\text{ lb weight} = 0.0685\text{ slug} \\ 5\text{ m/s}^2 &= 16.4\text{ ft/s}^2 \\ F\text{ (newtons)} &= 1 \times 5 = 5\text{ newtons} \\ F\text{ (lb)} &= 0.0685 \times 16.4 = 1.124\text{ lb (force)} \end{aligned}$$

APPENDIX C

Conversion Factors

The following values for the fundamental constants were used in the preparation of the factors:

$$1 \text{ m} = 39.37 \text{ in.} = 3.281 \text{ ft}$$

$$1 \text{ lb (weight)} = 0.4536 \text{ kp} = 0.03108 \text{ slug}$$

$$1 \text{ slug} = 14.594 \text{ kg}$$

$$1 \text{ lb (force)} = 4.448 \text{ newtons}$$

$$\text{Acceleration due to gravity} = 9.807 \text{ m/s}^2$$

$$= 32.174 \text{ ft/s}^2$$

$$\text{Density of } H_2O \text{ at } 4°C = 10^3 \text{ kg/m}^3$$

$$\text{Density of Hg at } 0°C = 1.3595 \times 10^4 \text{ kg/m}^3$$

$$1 \text{ U.S. lb} = 1 \text{ British lb}$$

$$1 \text{ U.S. gallon} = 0.83267 \text{ British gallon}$$

$$°F = (\tfrac{9}{5})°C + 32$$

$$°C = (\tfrac{5}{9})(°F - 32)$$

(Received 26 March 2015; revised 8 December 2015; accepted 8 December 2015; published online 31 March 2016)

The current study was the first to assess stress reactions associated with wind turbine noise (WTN) exposure using self-reported and objective measures. Randomly selected participants, aged 18–79 yr (606 males; 632 females), living between 0.25 and 11.22 km from wind turbines, were exposed to outdoor calculated WTN levels up to 46 dBA (response rate 78.9%). Multiple regression modeling left the great majority (77%–89%) of the variance in perceived stress scale (PSS) scores, hair cortisol concentrations, resting blood pressure, and heart rate unaccounted for, and WTN exposure had no apparent influence on any of these endpoints. PSS scores were positively, but weakly, related to cortisol concentrations and resting heart rate (Pearson $r = 0.13$ and $r = 0.08$, respectively). Across WTN categories, modeled mean PSS scores ranged from 13.15 to 13.84 ($p = 0.8614$). Modeled geometric means for hair cortisol concentrations, resting mean systolic, diastolic blood pressure, and heart rate were 150.54–191.12 ng/g ($p = 0.5416$), 113.38–116.82 mmHg ($p = 0.4990$), 67.98–70.34 mmHg ($p = 0.5006$), and 68.24–70.71 bpm ($p = 0.5223$), respectively. Irrespective of WTN levels, diastolic blood pressure appeared to be slightly (2.90 mmHg 95% CI: 0.75,5.05) higher among participants highly annoyed by blinking lights on turbines ($p = 0.0081$). Collectively, the findings do not support an association between exposure to WTN up to 46 dBA and elevated self-reported and objectively defined measures of stress.

I. INTRODUCTION

Noise exposure has the potential to act as a stressor and can directly or indirectly impact one's health [World Health Organization (WHO), 1999, 2011; Guski, 2001; Vallet, 2001]. Susceptibility or resistance to indirect stressor-induced health effects depends on a complex interaction between a stressor and coping strategies developed through previous experience, psychological, biological, and social factors, in addition to competing stressors and personality type (Job, 1988, 1996; Institute of Medicine, 2001; Stansfeld and Marmot, 2002). At the dwelling, wind turbine noise

[a]Electronic mail: david.michaud@canada.ca

(WTN) levels are well below levels expected to cause direct health effects (McCunney *et al.*, 2014). Potential effects are more likely to be mediated through a complex interaction as described above, wherein the perception of wind turbines becomes the acting stressor. Other factors such as noise sensitivity and the magnitude of annoyance or perceived stress engendered by a noise exposure could very likely contribute to the overall response. A theoretical representation for such an indirect pathway is presented in the Appendix.

Social surveys, which have been relied on to measure annoyance, perceptions of stress, and/or health effects, provide only partial support for potential WTN-mediated health effects because they are based on unverified self-reporting. An additional level of insight is provided from the current study, which includes objective measures of stress to characterize the associations between WTN exposure and stress.

Stress-induced cortisol changes have traditionally been measured using blood and saliva samples, which can be difficult to interpret (Legler *et al.*, 1982; Hennig *et al.*, 2000; Edwards *et al.*, 2001; Broderick *et al.*, 2004). Many of the limits associated with short-term sampling can be eliminated by using a measure of cortisol that is integrated over time (Russell *et al.*, 2012; Stalder and Kirschbaum, 2012). Cortisol integrates and remains in hair over time as it grows further from the scalp. As human scalp hair have a predictable average growth rate of ∼1 cm/month (Wennig, 2000), cortisol in hair can be measured and used to retrospectively characterize cortisol levels over several months. For this reason, hair cortisol analysis has become an increasingly utilized methodology for examining chronic stress and its effects on human health (Van Uum *et al.*, 2008; Pereg *et al.*, 2011; Gerber *et al.*, 2013; Grunau *et al.*, 2013; Hinkelmann *et al.*, 2013; Manenschijn *et al.*, 2013; Pereg *et al.*, 2013; Stalder *et al.*, 2013; Walton *et al.*, 2013; Veldhorst *et al.*, 2014; Wells *et al.*, 2014; Wester *et al.*, 2014) making hair cortisol analysis a particularly useful methodology in evaluating the impact that long-term exposure to WTN may have on the human stress response. Hair cortisol analysis, when considered together with validated questionnaires such as the perceived stress scale (PSS) (Cohen *et al.*, 1983; Al kalaldeh and Shosha, 2012), as well as blood pressure measures, provides a more comprehensive assessment of WTN exposure and stress reactions.

The purpose of the current study was to investigate the possibility that living in the vicinity of wind turbines increases stress. To this end, multiple measures of stress reported by and objectively measured in participants exposed to WTN were assessed. In addition, multiple regression analysis was used to identify the variables that best predicted the modeled stress-related endpoints.

II. METHODS

A. Sample design

1. Target population, sample size, and sampling frame strategy

Michaud *et al.* (2013) and Michaud *et al.* (2016a) have described the study design, target population, final sample size, allocation of participants, as well as the sampling strategy. Briefly, the study locations were drawn from areas in southwestern Ontario (ON) and Prince Edward Island (PEI) where there were a sufficient number of dwellings within the vicinity of wind turbine installations. There were 2004 potential dwellings identified from the ON and PEI sampling regions, which included 315 and 84 wind turbines, respectively. All turbines had three pitch controlled rotor blades (∼80 m diameter) upwind of the tower. The wind turbine electrical power outputs ranged between 660 kW and 3 MW [average 2.0, standard deviation (SD) 0.4 MW]. Turbine hub heights were predominantly 80 m. All identified dwellings within ∼600 m from a wind turbine and a random selection of dwellings between 600 m and 11.22 km were selected from which one person per household between the ages of 18 and 79 years was randomly chosen to participate.

This study was approved by the Health Canada and Public Health Agency of Canada Review Ethics Board (Protocol Nos. 2012-0065 and 2012-0072).

B. Wind turbine sound pressure levels

Keith *et al.* (2016a) have provided a detailed description of the approach applied to sound pressure level modeling. Briefly, sound pressure levels were estimated at each dwelling using both ISO 9613-1 (ISO, 1993) and ISO 9613-2 (ISO, 1996) as incorporated in the commercial software CadnaA version 4.4 (Datakustik®, 2014). The calculations included all wind turbines within a radius of 10 km, and were based on manufacturers' octave band sound power spectra at 10 m height, 8 m/s wind speed for favourable propagation conditions. The few dwellings beyond this distance were assigned the same calculated WTN value as dwellings at 10 km. The manufacturers' data were verified for consistency using on-site measurements of wind turbine sound power (Keith *et al.*, 2016b). Unless otherwise indicated, all references to decibels (dB) are A-weighted values.

In the current study, low-frequency noise was estimated by calculating C-weighted sound pressure levels. The correlation between C-weighted and A-weighted levels ranged from r 0.81 to 0.97 (Keith *et al.*, 2016b) and, therefore, no additional benefit would be gained by assessing outcomes in relation to dBC.

C. Data collection

1. Questionnaire content and administration

A detailed description of the questionnaire content has been presented by Michaud *et al.* (2013), Michaud *et al.* (2016a), and Feder *et al.* (2015). Briefly, the questionnaire instrument includes modules on basic demographic variables, annoyance, health effects, quality of life, sleep quality, perceived stress, lifestyle behaviours, and prevalent chronic diseases, including diagnosed high blood pressure. Long-term high annoyance toward several wind turbine features was assessed with separate questions that targeted specific wind turbine features (i.e., noise, blinking lights, vibrations, visual, and shadow flicker). As per ISO (2003), high annoyance was defined by combining the top two response categories of the following five-point adjectival scale: *not at all*, *slightly*, *moderately*, *very*, and *extremely*. The time reference period for annoyance was intended to capture the participants' integrated annoyance toward wind turbine features over the previous year while at home (see Michaud *et al.*, 2016b, for more details). Self-reported stress was assessed using the PSS (Cohen *et al.*, 1983), which is a widely used questionnaire with established, acceptable psychometric properties, designed to measure an individual's perception of stress. The questionnaire evaluates the degree to which respondents believe their life is unpredictable, uncontrollable, and overloaded during the previous month. In addition, the scale includes a number of direct questions about current levels of experienced stress. According to Cohen *et al.* (1983), this instrument was designed for use in community samples that have at least a junior high school education, and contains questions that are of a general nature and free of content specific to any subpopulation. Body mass index (BMI) was calculated based on self-reported height and weight, whereby weight in kilograms was divided by height in meters squared.

Consistent with many epidemiological studies that aim to reduce possible survey bias, an attempt was made to mask the primary subject of interest in this study, which was to investigate the community response to wind turbines. To this end, the study was introduced to participants as the *Community Noise and Health Study* and the questionnaire included several items unrelated to wind turbines. A total of 16 trained interviewers collected data through in-person interviews between May, 2013, and September, 2013, in southwestern ON and PEI. Once a roster of adults living in the dwelling was compiled, a computerized method of random selection was used with no substitution permitted.

D. Blood pressure and heart rate evaluation

Measures of blood pressure and heart rate followed the standardized procedures used by the Canadian Health Measures Survey (Bryan *et al.*, 2010) with the following two exceptions: (1) the interviewer remained in the room, seated behind the respondent during testing as it was neither practical nor appropriate for the interviewer to leave the room during in-home testing; and (2) there was no imposed 5 min rest period prior to testing. This was considered to be unnecessary because the participant had already been seated for the previous 40–45 min while completing the questionnaire.

Systolic and diastolic blood pressure and resting heart rate were measured electronically in a quiet room with a firm chair and table using an automated oscillometric device (BpTRU^{TM}BPM-100, Medical Devices Ltd., Coquitlam, British Columbia). A series of six consecutive measurements were taken at one minute intervals. Interviewers ensured proper functioning of the BpTRU^{TM} and the respondent did not talk or move during the test. The last five measurements of the series were used to determine the average resting heart rate and blood pressure.

E. Hair cortisol analysis

1. Hair sample collection

Hair samples were obtained from the vertex posterior of the head using scissors and cutting as close to the scalp as possible. The diameter of the grouping of hair strands removed was 5–10 mm. The hair sample was then taped to a section of bar-coded paper that identified the scalp end of the hair. The sample was stored in an envelope at room temperature for later analysis. The average time lapse between storage and analysis was ~60 days, which would not degrade cortisol concentrations (Webb *et al.*, 2010).

2. Hair treatment and enzyme-linked immunosorbent assay (ELISA)

In subjects from whom a length of 3 cm or more of hair was collected, the 3 cm portion most proximal to the scalp was analyzed. Hair sample collection and cortisol analysis were conducted in accordance with a previously established protocol described by Pereg *et al.* (2013). A hair mass of 10–15 mg was required for each analysis. Each hair sample was washed twice in isopropanol for 3 min to remove contaminants coating the hair. Following washing, hair samples were allowed to dry for a minimum of 5 h in a fume hood. A methanol extraction was then used to remove the cortisol from the hair. Hair samples were immersed in 1 ml of methanol, minced finely with surgical scissors and then incubated for 16 h at 50 °C while shaking at 100 rpm. The methanol solution was then removed and evaporated under nitrogen gas. The remaining residue was reconstituted with 250 μl of phosphate buffered saline and analyzed using a salivary cortisol immunoassay (Alpco Diagnostics, Salem, NH). The value determined was subsequently corrected to the hair mass used to yield a hair cortisol concentration in nanograms of cortisol per gram (ng/g) of hair. The lower quantification limit was 25 ng/g for hair mass of 10 mg and 16.67 ng/g for hair mass of 15 mg. The upper limit of detection was 20 000 ng/g and 13 333 ng/g, respectively. The assay detection limit was 0.063 ng/g and 0.042 ng/g for 10 mg and 15 mg hair mass samples, respectively. The intra- and inter-assay variations were 5.87% and 7.05%, respectively.

F. Statistical methods

The main objective of the analysis was to assess the exposure-response relationship between WTN levels and hair cortisol concentrations, scores on the PSS, blood pressure/heart rate, and to evaluate the sample characteristics that may influence these relationships. All of these health outcomes were measured on a continuous scale. The analysis for continuous outcomes closely follows the description outlined in Michaud *et al.* (2013), which gives a summary of the planned study design and objectives, as well as proposed data analysis. A-weighted WTN categories were defined based on final data collection and are as follows: {<25 dB; [25–30) dB; [30–35) dB; [35–40) dB; [40–46] dB}. Identification of variables that best explain the variability in self-reported and objectively measured stress-related endpoints was done using multiple linear regression. As a first step to develop the best predictive model for each outcome, univariate regression models only adjusting for WTN exposure groups and province were fitted. Explanatory variables significant at the 20% level for univariate analysis were considered in the multiple linear regression models. It should be emphasized that variables considered in the univariate analysis have been previously demonstrated to be related to the modeled endpoint and/or considered by the authors to conceptually have a potential association with the modeled endpoint. Province was initially assessed as an effect modifier. Since the interaction was never statistically significant, province was treated as a confounder in all of the regression models.

Multiple linear regression models describing the relationship between a stress endpoint (PSS, hair cortisol concentrations, blood pressure, and resting heart rate measurements) and predictors were developed using stepwise regression with a 20% significance entry criterion for predictors and a 10% significance criterion to remain in the model. The stepwise regression was carried out in three different ways wherein the base model included exposure to (1) WTN category and province; (2) WTN category, province, and an adjustment for individuals who reported receiving personal benefit from wind turbines in the area; and (3) WTN category and province, stratified for those who received no personal benefit. When developing the model for PSS, hair cortisol was not used as an explanatory variable as this would reduce the sample size substantially from 1231 observations to 675. When developing the model for hair cortisol, PSS was used as a potential explanatory variable in the model. Since time of day was shown to significantly influence heart rate, it was included in the multiple regression model to adjust for it.

Hair cortisol, blood pressure, and resting heart rate endpoints were log-normally distributed (by the Anderson-Darling test for normality), therefore, the geometric mean and corresponding 95% confidence interval (CI) were reported for these endpoints. When the assumptions for the various models for these endpoints were still not satisfied for the logged data, non-parametric approaches were used, in which case the geometric mean and CI were still reported, but the test results were based on non-parametric methods.

Statistical analysis was performed using SAS (Statistical Analysis System) version 9.2 (2014). A 5% statistical significance level was implemented throughout unless otherwise stated. In addition, Tukey corrections were made to account for all pairwise comparisons to ensure that the overall Type I (false positive) error rate was <0.05.

III. RESULTS

A. Wind turbine sound pressure levels at dwellings

Modeled sound pressure levels and the measurements used to support the calculations are presented in detail by Keith *et al.* (2016a,b). Calculated immission levels as determined by the ISO 9613-1 (ISO, 1993) and ISO 9613-2 (ISO, 1996) reached levels as high as 46 dB under conditions of 8 m/s wind speeds at 10 m heights for favourable propagation conditions. Calculations are representative of typical worst case long-term (1 yr) average WTN levels.

B. Response rates and sample characteristics

A detailed breakdown of the response rates, along with sample characteristics variables by WTN category is presented by Michaud *et al.* (2016a). Of the 2004 potential dwellings, 1570 were valid and 1238 agreed to participate in the study. This yielded a final response rate of 78.9%. For blood pressure measurements, a total of 1077 respondents participated providing a response rate of 87.0%. A total of 195 respondents were not able to participate in the hair cortisol portion of the physical measures, therefore, a potential 1043 respondents remained. A subsample of 917 of these 1043 respondents consented to the hair sampling for cortisol analysis (response rate, 87.9%).

Factors that could potentially exert an influence on stress responses, including self-reported prevalence of diagnosed chronic diseases and health conditions, quality of life, satisfaction with health, noise sensitivity, and self-reported high sleep disturbance (in general) were all found to be equally distributed across WTN categories (Michaud *et al.*, 2016a).

C. Hair cortisol, perceived stress, blood pressure, and heart rate

Table I presents the summary statistics for hair cortisol, PSS, blood pressure, and resting heart rate endpoints along with Cronbach's alpha (α) for the PSS. Cronbach's α is a measure of the internal consistency or reliability of test scores. Cronbach's α was substantially over the recommended acceptable range of 70% for PSS (Cronbach's α 0.86).

Of the 917 participants who consented to take part in the hair cortisol sampling, 214 samples were found to be of insufficient mass (i.e., <10 mg). Of the remaining 703 samples, 9 exceeded the ELISA upper limit of quantification for which no value was given, and the computed results from 19 observations were found to be above the assay detection limit but below the lower limit of quantification. These were removed because 14 of the 19 participants in this subgroup reported using a chemical hair treatment within the previous 3 months, indicating that the results were not reliable. A total of 675 observations remained for hair cortisol analysis. The majority of the hair samples collected were from females (n 431, 63.9%), and individuals aged between 45 and 64 years

TABLE I. Descriptive statistics for stress-related outcomes.

	n	GM (95% CI)[a]	(Min, Max)	Cronbach's α
Hair cortisol (ng/g)	675	146.09 (135.46,157.56)	(18.12,7139.34)	
Perceived stress scale	1231	11.87 (11.49,12.24)[b]	(0,37)	0.86
Systolic blood pressure (mmHg)	1077	119.23 (118.27,120.19)	(83,186)	
Diastolic blood pressure (mmHg)	1077	75.15 (74.55,75.75)	(50,114)	
Heart rate (bpm)	1077	72.50 (71.79,73.21)	(41,125)	

[a]GM is the geometric mean and corresponding 95% confidence interval (CI) unless otherwise indicated.
[b]Arithmetic mean and corresponding 95% CI.

(n 311, 46.1%). The age group least represented were individuals in the ≤25 yr age group (n 35, 5.2%). Hair cortisol levels ranged from 18.12 to 7139.34 ng/g with a geometric mean of 146.09 ng/g and 95% CI: (135.46,157.56).

Blood pressure measurements were fairly equally distributed between men and women (males 527, 48.9%), although the majority of the measures were from individuals aged between 45 and 64 years (n 467, 43.4%). Similar to hair sampling, those least represented were individuals in the ≤25 yr age-group (n 62, 5.8%). The time of day that blood pressure and heart rate measures were taken had no impact on blood pressure, but did significantly influence resting heart rate (p 0.0008). Average resting heart rate was lower during the morning hours (06:00–11:59 h; 69.19, 95%CI: 67.50,70.92) compared to afternoon (12:00–17:59 h; 72.66, 95% CI: 71.47,73.87) and evening (18:00–22:00 h; 72.65, 95% CI: 71.01,74.32) (data not shown).

1. Association between self-reported and measured blood pressure

The consistency between self-reported diagnosed high blood pressure and measured blood pressure was assessed by the two-sample t-test. In the self-reported high blood pressure group, the geometric mean for systolic blood pressure was 127.51 (95% CI: 125.78,129.27) compared to 115.83 (95% CI: 114.77,116.90) for those who did not report high blood pressure ($p < 0.0001$). Similarly, the corresponding geometric means for diastolic blood pressure were 76.62 (95% CI: 75.51,77.75) and 74.54 (95% CI: 73.83,75.25) (p 0.0019).

D. Effects of personal and situational variables on hair cortisol concentrations, blood pressure, resting heart rate, and scores on the PSS

An exploratory univariate analysis of self-reported personal and situational variables in relation to hair cortisol concentrations, measured blood pressure, resting heart rate, and scores on the PSS only adjusting for WTN levels and province is presented in the supplementary material attached to the online version of this article.[1] The list of variables considered was extensive and includes, but is not limited to, demographics, illnesses/chronic diseases, quality of life, sleep disturbance, caffeine consumption, and variables related to the perception of wind turbines.

E. Association between PSS scores, hair cortisol concentrations, blood pressure and resting heart rate

The consistency between self-reported stress and an objective measure of stress was assessed by examining the association between PSS scores and hair cortisol concentrations. Hair cortisol was positively correlated with the PSS scores (Pearson r 0.13, p 0.0007) regardless of WTN exposure. When examining each of the WTN categories, a positive correlation between PSS and hair cortisol is significant only in the following WTN categories: [25–30) dB (r 0.35, p 0.0137) and [40–46] dB (r 0.20, p 0.0270). Nevertheless, in fitting a regression line relating hair cortisol to PSS and accounting for WTN exposure and province, the slope is positive and significant [slope 0.02, standard error (SE) 0.01, p 0.0008]. This indicates that higher levels of PSS are correlated with higher levels of hair cortisol.

The association between measured blood pressure and resting heart rate with hair cortisol and PSS was also investigated. Hair cortisol levels were not correlated with blood pressure values (regardless of WTN exposure levels; $r < 0.04$, $p > 0.30$, in all cases). Furthermore, it was observed that none of the blood pressure measures were associated with hair cortisol levels even after adjusting for WTN exposure levels in the regression models. PSS was positively associated only with resting heart rate (r 0.08, p 0.0076), but not with blood pressure. After accounting for WTN in a regression model the association remained (i.e., increased PSS scores were related to increased resting heart rate).

F. Multiple regression modeling for PSS scores, hair cortisol concentrations, blood pressure, and resting heart rate

The final models for the three approaches to stepwise regression listed in the statistical methods section produced nearly identical results. Therefore, only the regression model whereby the variables WTN, province, and personal benefit were forced into the model is presented. Table II provides a summary of the variables retained in the final multiple linear regression models for the self-reported and objectively measured stress-related outcomes.

1. PSS scores and hair cortisol concentrations

Tables III(a) and III(b) present the detailed results for the multiple linear regression models for PSS and hair cortisol, respectively. Exposure to WTN was not found to be significantly associated with these endpoints. Some of the variables that increased PSS scores at the 5% level of significance included age (i.e., being <65 years of age), income (i.e., making <$60000 per year), smoking status (i.e., being a smoker), and the presence of self-reported health conditions including migraines/headaches, dizziness, chronic pain, and a diagnosed sleep disorder. PSS scores were not related to receiving personal benefit from having wind turbines in the area (p 0.1579). The final multiple linear regression model explained 21% of the variability in PSS scores.

Being male, having high school or trade/certificate/college education, being obese, and having tinnitus significantly increased the hair cortisol concentrations at the 10% level. Cortisol was reduced among those who cosmetically treated their hair and among those who washed their hair more than eight times per week compared to those who washed it less than once per week. Hair cortisol concentrations were not associated with receiving personal benefit (p 0.1084). Finally, as PSS scores increased so did hair cortisol concentrations (p 0.0037). The final multiple linear regression model accounted for 14% of the variability observed in hair cortisol concentrations.

2. Blood pressure and resting heart rate

Tables IV(a)–IV(c) present the multiple linear regression models for systolic and diastolic blood pressure, as well as resting heart rate. In all three models exposure to WTN

TABLE II. A summary of significant variables retained in multiple linear regression models for self-reported and measured stress endpoints. The specific direction of change, level of statistical significance, and pairwise comparisons between variable groups are provided in Tables III(a), III(b), and IV(a)–IV(c).

was not found to be a significant factor in explaining the variability in these measures. Overall, the ON sample had higher systolic and diastolic blood pressures and heart rate (regardless of WTN exposure).

a. Resting systolic and diastolic blood pressure. Increased systolic blood pressure was associated with being male, 45 years of age or more, and having a BMI $\geq$25. The participants who self-identified as having high blood pressure or a history of high blood pressure in the family did, in fact, have significantly higher measured systolic blood pressure. In the multiple linear regression model, diastolic blood pressure was not only affected by the same factors as systolic blood pressure, but was also elevated among smokers, those who consumed caffeinated beverages within 2 h of measurements being taken and 2.90 mmHg (95% CI: 0.75,5.05) higher among those who were annoyed by the blinking lights atop wind turbines. The multiple linear regression models for systolic and diastolic blood pressures explained, respectively, ~23% and 19% of the variability in the outcomes.

b. Resting heart rate. Being a current smoker, being obese, and having diabetes were significantly associated with increased resting heart rate. Those who self-identified as having heart disease ($p < 0.0001$) and those who received personal benefit (p 0.0254) had significantly lower heart rates. Similarly, time of day was found to have a significant effect on resting heart rate, with lower values in the morning compared to the afternoon or evening. The multiple linear regression model for resting heart rate explained ~11% of the variability in the endpoint.

IV. DISCUSSION

Taken together, the study results do not support an association between WTN exposure and increased stress either

TABLE III. (a) Multiple linear regression model for perceived stress. (b) Multiple linear regression model for hair cortisol concentrations.

reported by, or objectively measured among participants exposed to WTN levels up to 46 dB. In the final multiple linear regression models, the level of WTN was not found to be related to any of the stress-related endpoints. Furthermore, the finding that the WTN annoyance variable was absent in any of these models is notable because potential health effects associated with WTN would presumably be indirect and mediated, at least in part, through noise annoyance (Niemann *et al.*, 2006; Bakker *et al.*, 2012). The audibility of wind turbines, and reported annoyance with WTN, were only related to some of the stress outcomes when the analysis did not adjust for other contributing variables (e.g., age, BMI, smoking status, sex, and education) (supplementary material[1]).

After adjusting for other variables, the only wind turbine-related variable that was found to have an influence on any of the stress endpoints was high annoyance with the blinking aircraft warning lights atop wind turbines. Irrespective of WTN levels, annoyance with blinking lights appeared to be statistically associated with a slight elevation in diastolic blood pressure. Although this finding could be a statistical anomaly, the association may be related to the apparent impact that annoyance with the blinking lights was found to have on sleep. Indeed, reported and measured sleep quality has been associated with elevated blood pressure (Fiorentini *et al.*, 2007; Knutson *et al.*, 2009) and in the current study sample high annoyance with the blinking lights on wind turbines was found to be related to objectively measured sleep disturbance (Michaud *et al.*, 2016c). Until this finding is replicated in future research, the increase in diastolic blood pressure should be interpreted cautiously.

Michaud *et al.* (2016a) reported that the prevalence of hypertension and the use of blood pressure medication in the *Community Noise and Health Study* were unrelated to WTN levels. The later finding indicates that the absent association between blood pressure and WTN exposure reported in the current analysis was not related to a disproportionate use of blood pressure medication among the most exposed participants.

Multiple regression modeling left the great majority (77%–89%) of the variance in hair cortisol, systolic blood pressure, diastolic blood pressure, heart rate, and perceived stress unaccounted for. These study results may be complemented or strengthened by additional research that considers factors known to influence the response to community noise in general beyond exposure to wind turbines themselves (see Fig. 1 in the Appendix). Some of these factors include perceived control over the exposure, which could relate to the level of consultation between a developer and the community; maintaining the belief that action could have been taken to reduce WTN exposure, but was not; attitude toward wind turbines as an alternate source of renewable energy; and personality type (Borsky, 1979; Stansfeld and Matheson, 2003). Exposure to multiple stressors or other sources of annoyance, such as transportation noise, may influence the response to WTN exposure.

Transportation noise levels at participants' dwellings were not quantified, which may be a limitation considering the evidence linking exposure to transportation noise with stress-related health effects. However, it is important to keep in mind that this evidence pertains to sound pressure levels that are typically associated with higher levels of annoyance than reported in the current study (Babisch, 1998; Miedema and Vos, 1998; Babisch *et al.*, 2001; Haralabidis *et al.*, 2008). The percentage highly annoyed by aircraft, rail, and road traffic noise across all WTN categories never exceeded 5%. In our view, it is therefore unlikely that exposure to transportation noise had any significant influence on the reported stress reactions.

Another limitation in the current study is the difficulty in providing a precise timeframe for WTN exposure for each participant. Even a wind farm's operational date may not represent the true time of WTN exposure onset as wind farms are often installed over time so that exposure to WTN may vary from person to person. Future research could include specific questions to more precisely identify the individual's history of exposure. The proxy for exposure history included in the current study was derived from asking participants how long they have been hearing noise coming from wind turbines. Michaud *et al.* (2016b) reported that the odds of reporting to be highly annoyed by WTN were almost four times higher among participants who heard the wind turbines for one year or more, compared to those who heard it for less than one year. However, in the final multiple regression

models, self-reported history of hearing WTN was not related to any of the stress outcomes assessed in this study.

V. CONCLUDING REMARKS

The results provide no evidence that self-reported or objectively measured stress reactions are significantly influenced by exposure to increasing levels of WTN up to 46 dB. There is an added level of confidence in the findings as this is the first study to date to investigate the potential stress impacts associated with WTN exposure using a combination of self-reported and objectively measured endpoints. Specifically, cortisol concentrations in hair, blood pressure, resting heart rate, and perceived stress using the PSS were measured in relation to WTN exposure. Although the positive correlation found between PSS scores and hair cortisol concentrations was statistically weak, the fact that they move in the same direction provides confidence regarding the validity of the study results and selected endpoints. The weak correlation could be owing to the fact that each endpoint has a different time reference period associated with its outcome. Hair cortisol concentrations and perceived stress scores reflect the previous 90 and 30 days, respectively.

The association between perceived stress and hair cortisol concentrations was similarly found between reported high blood pressure and measured blood pressure. Specifically, participants that indicated they had been diagnosed with high blood pressure from a health care professional had higher resting systolic and diastolic blood pressure.

The observation that the WTN annoyance variable was not retained in the final multiple linear regressions should not be interpreted to mean that this variable has no influence on the modeled endpoints. Rather, in the presence of the other variables in the model, WTN annoyance was not found to contribute further to the overall variance in the measured endpoint(s). In theory, one could arrive at different conclusions if the variables considered in the modeling are not universally incorporated across different study designs.

ACKNOWLEDGMENTS

The authors acknowledge the support they received throughout the study from Serge Legault and Suki Abeysekera at Statistics Canada, and are especially grateful to the volunteers who participated in this study. The authors also thank Dr. Stan Van Uum for his insight in planning the hair analysis. This research was funded by Health Canada. The authors have declared that no competing interests exist.

APPENDIX

Figure 1 presents a theoretical model of the complex processes that may be involved in the development of indirect stress-related health effects from exposure to wind turbines. The model assumes the origin of an indirect pathway

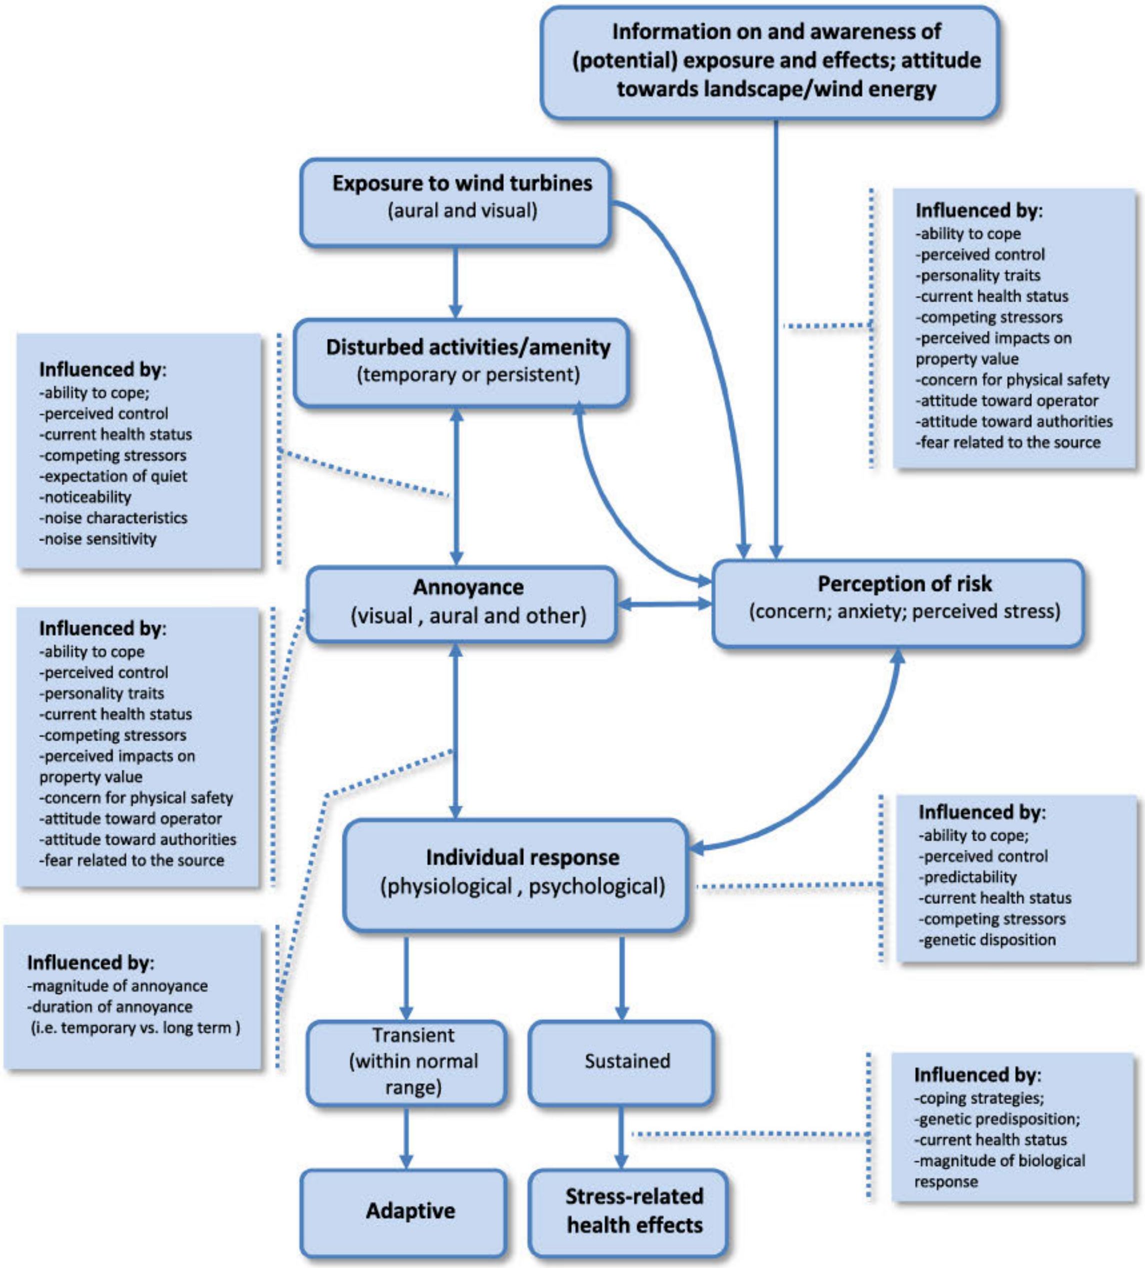

FIG. 1. (Color online) A theoretical model demonstrating the complex processes that may be involved in the potential progression towards indirect health effects from community noise exposure.

beginning with exposure, which can lead to an individualized perception of risk, which itself may be based on information about and attitude toward wind turbines. Perceived risk, and/or other factors that increase annoyance, may then lead to the development of stress-related health effects. Solid arrows represent the proposed direction of interaction. Broken lines represent some of the factors that would be expected to exert an influence at each level in the pathway, or the progression from one level to the next. The proposed model is not limited to WTN and could be applicable for other environmental exposures that are associated with annoyance.

(Received 19 March 2015; revised 7 July 2015; accepted 20 November 2015; published online 31 March 2016)

Health Canada, in collaboration with Statistics Canada, and other external experts, conducted the Community Noise and Health Study to better understand the impacts of wind turbine noise (WTN) on health and well-being. A cross-sectional epidemiological study was carried out between May and September 2013 in southwestern Ontario and Prince Edward Island on 1238 randomly selected participants (606 males, 632 females) aged 18–79 years, living between 0.25 and 11.22 km from operational wind turbines. Calculated outdoor WTN levels at the dwelling reached 46 dBA. Response rate was 78.9% and did not significantly differ across sample strata. Self-reported health effects (e.g., migraines, tinnitus, dizziness, etc.), sleep disturbance, sleep disorders, quality of life, and perceived stress were not related to WTN levels. Visual and auditory perception of wind turbines as reported by respondents increased significantly with increasing WTN levels as did high annoyance toward several wind turbine features, including the following: noise, blinking lights, shadow flicker, visual impacts, and vibrations. Concern for physical safety and closing bedroom windows to reduce WTN during sleep also increased with increasing WTN levels. Other sample characteristics are discussed in relation to WTN levels. Beyond annoyance, results do not support an association between exposure to WTN up to 46 dBA and the evaluated health-related endpoints.

[SF] Pages: 1443–1454

I. INTRODUCTION

Jurisdiction for the regulation of noise is shared across many levels of government in Canada. As the federal department of health, Health Canada's mandate with respect to wind power includes providing science-based advice, upon request, to federal departments, provinces, territories and other stakeholders regarding the potential impacts of wind turbine noise (WTN) on community health and well-being. Provinces and territories, through the legislation they have enacted, make decisions in relation to areas including installation, placement, sound levels, and mitigation measures for wind turbines. In July 2012, Health Canada announced its

[a]Electronic mail: david.michaud@canada.ca

intention to undertake a large scale epidemiological study in collaboration with Statistics Canada entitled Community Noise and Health Study (CNHS). Statistics Canada is the federal government department responsible for producing statistics relevant to Canadians.

In comparison to the scientific literature that exists for other sources of environmental noise, there are few original peer-reviewed field studies that have investigated the community response to modern wind turbines. The studies that have been conducted to date differ substantially in terms of their design and evaluated endpoints (Krogh *et al.*, 2011; Mroczek *et al.*, 2012; Mroczek *et al.*, 2015; Nissenbaum *et al.*, 2012; Pawlaczyk-Łuszczyńska *et al.*, 2014; Pedersen and Persson Waye, 2004, 2007; Pedersen *et al.*, 2009; Shepherd *et al.*, 2011; Tachibana *et al.*, 2012; Tachibana *et al.*, 2014; Kuwano *et al.*, 2014). Common features among these studies include reliance upon self-reported endpoints, modeled WTN exposure and/or proximity to wind turbines as the explanatory variable for the observed community response.

There are numerous health symptoms attributed to WTN exposure including, but not limited to, cardiovascular effects, vertigo, tinnitus, anxiety, depression, migraines, sleep disturbance, and annoyance. Health effects and exposure to WTN have been subjected to several reviews and the general consensus to emerge to date is that the most robust evidence is for an association between exposure to WTN and community annoyance with inconsistent support observed for subjective sleep disturbance (Bakker *et al.*, 2012; Council of Canadian Academies, 2015; Knopper *et al.*, 2014; MassDEP MDPH, 2012; McCunney *et al.*, 2014; Merlin *et al.*, 2014; Pedersen, 2011).

The current analysis provides an account of the sample demographics, response rates, and observed prevalence rates for the various self-reported measures as a function of the outdoor WTN levels calculated in the CNHS.

II. METHOD

A. Sample design

Factors considered in the determination of the study sample size, including statistical power, have been described by Michaud *et al.* (2013), Michaud *et al.* (2016b), and Feder *et al.* (2015). The target population consisted of adults, aged 18 to 79 years, living in communities within approximately 10 km of a wind turbine in southwestern Ontario (ON) and Prince Edward Island (PEI). Selected areas in both provinces were characterized by flat lands with rural/semi-rural type environments. Prior to field work, a list of addresses (i.e., potential dwellings) was developed by Statistics Canada. The list consists mostly of dwellings, but it can include industrial facilities, churches, demolished/vacant dwellings, etc. (i.e., non-dwellings), that would be classified as out-of-scope for the purposes of the CNHS. The ON and PEI sampling areas included 315 and 84 wind turbines, respectively. Wind turbine electrical power output ranged between 660 kW to 3 MW (average 2.0 ± 0.4 MW). All turbines were modern design with 3 pitch controlled rotor blades (~80 m diameter) upwind of the tower, and predominantly 80 m hub heights. This study was approved by the Health Canada and Public Health Agency of Canada Research Ethics Board (Protocols #2012–0065 and #2012–0072).

B. Wind turbine sound pressure levels at dwellings

A detailed description of the approach applied to sound pressure level modeling [including background nighttime sound pressure (BNTS) levels] is presented separately (Keith *et al.*, 2016b). Briefly, sound pressure levels were estimated at each dwelling using both ISO (1993) and ISO (1996) as incorporated in the commercial software CadnaA version 4.4 (Datakustik, 2014). The calculations were based on manufacturers' octave band sound power spectra at 10 m height, 8 m/s wind speed for favorable propagation conditions (Keith *et al.*, 2016a). As described in detail by Keith *et al.* (2016b), BNTS levels were calculated following provincial noise regulations for Alberta, Canada (Alberta Utilities Commission, 2013). With this approach BNTS levels can range between 35 dBA to 51 dBA. The possibility that BNTS levels due to highway road traffic noise exposure may exceed the level estimated by Alberta regulations was considered. Where the upper limits of this approach were exceeded (i.e., 51 dB), nighttime levels were derived using the US Traffic Noise Model (United States Department of Transportation, 1998) module in the CadnaA software.

Low frequency noise was estimated in the CNHS by calculating outdoor C-weighted sound pressure levels at all dwellings. There was no additional gain by analysing the data using C-weighted levels because the statistical correlation between C-weighted and A-weighted levels was very high (i.e., r 0.81–0.97) (Keith *et al.*, 2016a).

C. Data collection

1. Questionnaire content and collection

The final questionnaire, available on the Statistics Canada website (Statistics Canada, 2014) and in the supplementary materials,[1] consisted of basic socio-demographics, modules on community noise and annoyance, health effects, lifestyle behaviors and prevalent chronic illnesses. In addition to these modules, validated psychometric scales were incorporated, without modification, to assess perceived stress (Cohen *et al.*, 1983), quality of life (WHOQOL Group, 1998; Skevington *et al.*, 2004) and sleep disturbance (Buysse *et al.*, 1989).

Questionnaire data were collected through in-person home interviews by 16 Statistics Canada trained interviewers between May and September 2013. The study was introduced as the "Community Noise and Health Study" as a means of masking the true intent of the study, which was to investigate the association between health and WTN exposure. All identified dwellings within ~600 m from a wind turbine were selected. Between 600 m and 11.22 km, dwellings were randomly selected. Once a roster of adults (between the ages of 18 and 79 years) living in the dwelling was compiled, one individual from each household was randomly invited to participate. No substitutions were permitted under any circumstances. Participants were not compensated for their participation.

2. Long-term high annoyance

To evaluate the prevalence of annoyance, participants were initially asked to spontaneously identify sources of noise they hear originating from outdoors while they are either inside or outside their home. The interviewer grouped the responses as road traffic, aircraft, railway/trains, wind turbine, and "*other*." Follow-up questions were designed to confirm the initial response where the participant may not have spontaneously identified wind turbines, rail, road and aircraft as one of the audible sources. For each audible noise source participants were asked to respond to the following question from ISO/TS (2003a): "*Thinking about the last year or so, when you are at home, how much does noise from [SOURCE] bother, disturb or annoy you?*" Response categories included the following: "*not at all*," "*slightly*," "*moderately*," "*very*," or "*extremely*." Participants who reported they did not hear a particular source of noise, were classified into a "*do not hear*" group and retained in analysis (to ensure that the correct sample size was accounted for in the modeling). The analysis of annoyance was performed after collapsing the response categories into two groups (i.e., "*highly annoyed*" and "*not highly annoyed*"). As per ISO/TS (2003a), participants reporting to be either "*very*" or "*extremely*" annoyed were treated as "*highly annoyed*" in the analysis. The "*not highly annoyed*" group was composed of participants from the remaining response categories in addition to those who did not hear wind turbines. Similarly, an analysis of the percentage highly subjectively sleep disturbed, highly noise sensitive, and highly concerned about physical safety from having wind turbines in the area was carried out applying the same classification approach used for annoyance.

The use of filter questions and an assessment of annoyance using only an adjectival scale are approaches not recommended by ISO/TS (2003a). The procedures followed in the current study were chosen to minimize the possibility of participant confusion (i.e., by asking how annoyed they are toward the noise from a source that may not be audible). Although there is value in confirming the response on the adjectival scale with a numerical scale, this approach would have added length to the questionnaire, or led to the removal of other questions. Collectively, the deviations from ISO/TS (2003a) conformed to the recommendations by Statistics Canada and to the approach adopted in a large-scale study conducted by Pedersen *et al.* (2009).

D. Statistical methodology

The analysis for categorical outcomes closely follows the description outlined in Michaud *et al.* (2013), which provides a summary of the pre-data collection study design and objectives, as well as the proposed data analysis. Final wind turbine distance and WTN categories were defined as follows: distance categories in km {$\leq$0.550; (0.550–1]; (1–2]; (2–5]; and >5}, WTN exposure categories in dBA {<25; [25–30); [30–35); [35–40); and [40–46]}. The top category included 46 dB as only six cases were observed at $\geq$45 dBA. All models were adjusted for provincial differences. Province was initially assessed as an effect modifier. When the interaction between WTN and province was significant, separate models were reported for each province. This included reporting separate chi-square tests of independence or logistic regression models for each province. When the interaction was not statistically significant, province was treated as a confounder in the model. This included using the Cochran-Mantel-Haenszel (CMH) chi-square tests for contingency tables (which adjusts for confounders), as well as adjusting the logistic regression models for the confounder of province.

The questionnaire assessed participant's long-term ($\sim$1 year) annoyance to WTN in general (i.e., location not specified), and specifically with respect to location (outdoors, indoors), time of day (morning, afternoon, evening, nighttime) and season (spring, summer, fall, winter). In addition, participants' long-term annoyance in general, to road, aircraft and rail noise was assessed. These evaluations of annoyance are considered to be clustered because they are derived from the same individuals (i.e., they are repeated measures). Therefore, in order to compare the prevalence of annoyance as a function of location, time of day, season, or noise source, generalized estimating equations for repeated measures were used to account for the clustered responses (Liang and Zeger, 1986; Stokes *et al.*, 2000).

Statistical analysis was performed using SAS version 9.2 (SAS Institute Inc., 2014). A 5% statistical significance level is implemented throughout unless otherwise stated. In addition, Bonferroni corrections are made to account for all pairwise comparisons to ensure that the overall type I (false positive) error rate is less than 0.05. In cases where cell frequencies were small (i.e., <5) in the contingency tables or logistic regression models, exact tests were used as described in Agresti (2002) and Stokes *et al.* (2000).

III. RESULTS

A. Wind turbine sound pressure levels at dwellings

Modeled sound pressure levels, and the field measurements used to support the models are presented in detail by Keith *et al.* (2016a,b). Calculated outdoor sound pressure levels at the dwellings reached levels as high as 46 dB. Unless otherwise stated, all decibel references are A-weighted. Calculations are likely to yield typical worst case long-term (1 years) average WTN levels (Keith *et al.*, 2016b).

B. Response rate

Of the 2004 addresses (i.e., potential dwellings) on the sample roster, 434 dwellings were coded as out-of-scope by Statistics Canada during data collection (Table I). This was consistent with previous surveys conducted in rural areas in Canada (Statistics Canada, 2008). In the current study, 26.7% and 20.4% of addresses were deemed out-of-scope in PEI and ON, respectively. No significant difference in the distribution of out-of-scope locations by distance to the nearest wind turbine was observed in PEI (χ^2 3.19, p 0.5263). In ON, a higher proportion of out-of-scope addresses was observed in the closest distance group ($\leq$0.55 km) compared to other distance groups ($p < 0.05$, in all cases). After adjusting for province, there was a

TABLE I. Locations coded out-of-scope.

Code C	2 (1.4)	36 (4.1)	61 (7.8)	7 (7.4)	1 (1.0)	107 (5.3)	
Code D	4 (2.8)	35 (3.9)	50 (6.4)	2 (2.1)	5 (5.1)	96 (4.8)	
Code E	0 (0.0)	7 (0.8)	4 (0.5)	0 (0.0)	0 (0.0)	11 (0.6)	
Code F	2(1.4)	3(0.3)	1(0.1)	0(0.0)	0(0.0)	6(0.3)	

[a]The Cochran Mantel-Haenszel chi-square test is used to adjust for province, p-values <0.05 are considered to be statistically significant.
[b]Total number of potential dwellings out of scope (given as a percentage of total potential dwellings) is broken down by province, as well it is equal to the sum of Code A-F. The percentages of dwellings that are coded as out-of-scope are based on the total number of potential dwellings in the area. Code A—address was a business/duplicate/other (17%), address listed in error (83%). Code B—an inhabitable dwelling unoccupied at the time of the survey, newly constructed dwelling not yet inhabited, a vacant trailer in a commercial trailer park. Code C—summer cottage, ski chalet, or hunting camps. Code D—all participants in the dwelling were >79 years of age. Code E—under construction, institution, or unavailable to participate. Code F—demolished for unknown reasons.
[c]Chi-square test of independence.

significant association between distance groups and the proportion of locations assigned a *Code A* (p 0.0068) (Table I). A post-collection screening of interviewer notes by Statistics Canada has confirmed that of the total number of *Code A* locations, the vast majority (i.e., 83%) were locations listed in error. In rural areas, there is more uncertainty in developing the address list frame and this can contribute to a higher prevalence of addresses listed in error within 0.55 km of a wind turbine where the population density is lower compared to areas at greater setbacks.[2]

The remaining 1570 addresses were considered to be valid dwellings, from which 1238 residents agreed to participate in the study (606 males, 632 females). This resulted in a final response rate of 78.9%, which was not statistically different between ON and PEI or by proximity to wind turbines (Table II).

C. Sample characteristics

Table III outlines demographic information for study populations in each 5 dB WTN category. The prevalence of employment was the only variable that appeared to consistently increase within increasing WTN levels. Household income and education were unrelated to WTN levels. There was no obvious pattern to the changes observed in the other variables that were found to be statistically related to WTN level categories (i.e., age, type of dwelling, property ownership and facade type).

D. Perception of community noise and related variables as a function of WTN level

The prevalence of reporting to be very or extremely (i.e., highly) noise sensitive was statistically similar across all WTN categories (p 0.8175). As expected and as shown in Fig. 1, visibility and audibility of wind turbines increased with increasing WTN levels.

The overall audibility of other noise sources is shown in Table IV. Not shown in Table IV is how often the noise source was spontaneously reported as opposed to being identified following a prompt by the interviewer (see Sec. II).

TABLE II. Sample response rate.

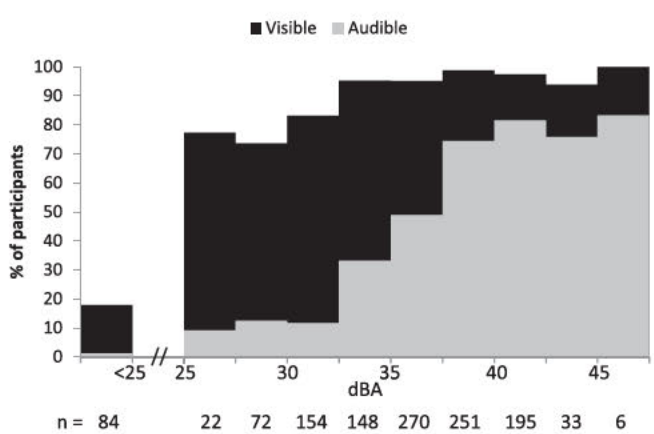

FIG. 1. Proportion of participants as a function of calculated outdoor A-weighted WTN levels. The figure plots the proportion of participants that reported wind turbines were visible from anywhere on their property or audible from inside or outside their homes from the total number of participants with valid responses living in each WTN level category.

Among the participants who reported hearing each specific noise source, the prevalence of spontaneously reporting road traffic, wind turbines, rail and aircraft was 84%, 71%, 66%, and 30%, respectively. A total of 102 participants (8.2%) indicated that there were no audible noise sources around their home. These participants lived in areas where the average WTN levels were 32.4 dB [standard deviation (SD) 8.3] and the mean distance to the nearest turbine was 1.7 km (SD 2.0) (data not shown).

Table IV also provides the observed prevalence rates for high (i.e., very or extreme) annoyance toward wind turbine features. The results suggest that there was a tendency for the prevalence of annoyance to increase with increasing WTN levels, with the rise in annoyance becoming evident when WTN levels exceeded 35 dB. The pattern was slightly different for visual annoyance among participants drawn from the ON sample, where there was a noticeable rise in annoyance among participants living in areas where WTN

[a]The Cochran Mantel-Haenszel chi-square test is used to adjust for provinces unless otherwise indicated, p-values <0.05 are considered to be statistically significant.
[b]Columns may not add to total due to missing data.
[c]Sensitivity to noise reflects the prevalence of participants that reported to be either very or extremely (i.e., highly) noise sensitive in general.
[d]Chi-square test of independence.
[e]Nobody reported hearing rail noise in PEI as there is no rail activity in PEI, therefore the percent is given as a percentage of ON participants only.
[f]Refers to anyone in the participant's household ever lodging a formal complaint (including signing a petition) regarding noise from wind turbines.
[g]Reasons for closing bedroom windows due to aircraft noise was suppressed due to low cell counts (i.e., n <5 overall).

levels were between [25 and 30) dB. The prevalence of *household* complaints concerning wind turbines, which could include signing a petition regarding noise from wind turbines, was 2.8% overall and unrelated to WTN levels (p 0.2578). However, complaints were found to be greater among the PEI sample (13/224   5.8%), compared to ON (22/1010   2.2%) (p 0.0050).

Other notable observations from Table IV include the finding that the number of participants who self-reported to personally benefit in any way (e.g., rent, payments or indirect benefits such as community improvements) from having turbines in their area, was not equally distributed among provinces. In ON, reporting such benefits was significantly related to WTN categories ($p < 0.0001$) and there was a gradual increase from the lowest WTN category (<25 dB: 0.0%) to the loudest WTN category ([40–46] dB: 21.4%), whereas in PEI benefits were statistically evenly distributed across the sample (p 0.1700).

Closing bedroom windows to block outside noise during sleep was equally prevalent across all WTN categories (p 0.8106); however, identifying WTs as the reason for closing the window was found to be related to WTN levels ($p < 0.0001$). In the two loudest categories, [35–40) dB and [40–46] dB, 15.2% and 21.6% of participants identified WTN as the reason for closing bedroom windows, respectively, compared to ≤2.1% in the other WTN categories (Table IV).

Figure 2 plots the fitted percentage highly annoyed by WTN category overall and for ON and PEI separately. WTN annoyance was observed to significantly increase when WTN levels exceeded ≥35 dB compared with lower exposure categories ($p < 0.009$, in all cases). Overall, observed prevalences of noise annoyance increased from less than 2.1% in the three lowest WTN level categories to 10% in areas where WTN levels were between [35 and 40) dB and 13.7% between [40 and 46] dB. Additionally, annoyance was observed to be significantly higher in the ON sample compared to the PEI sample. Across all WTN categories, the odds of being highly annoyed by WTN were 3.29 times greater in ON compared to PEI [95% confidence interval (CI), 1.47–8.68, p 0.0015]; however, the difference was most pronounced above 35 dB.

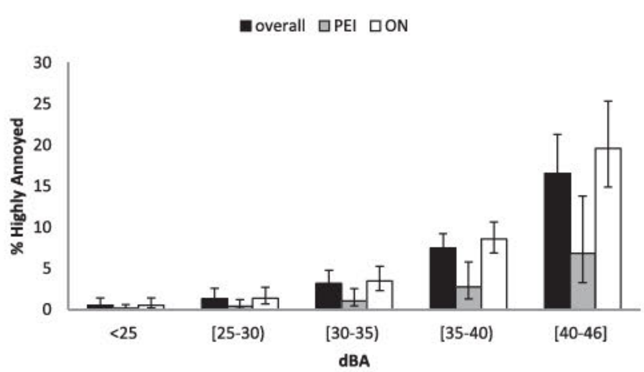

FIG. 2. Prevalence of high annoyance with wind turbine noise overall and by province as a function of calculated outdoor wind turbine noise levels. This illustrates the percentage of participants that reported to be either very or extremely (i.e., highly) bothered, disturbed or annoyed by WTN while at home over the last year. At home refers to either inside or outside the dwelling. Results are shown for participants from southwestern ON, PEI, and as an overall average. Fitted data are plotted along with their 95% confidence intervals. Results are shown as a function of calculated outdoor A-weighted WTN levels at the dwelling (dBA). WTN annoyance was observed to significantly increase when WTN levels exceeded ≥35 dB compared with lower exposure categories ($p < 0.009$, in all cases). Additionally, annoyance was observed to be significantly higher in the southwestern ON sample compared to the PEI sample ($p = 0.0015$), regardless of WTN level.

In addition to asking participants how annoyed they were toward WTN in general (i.e., without reference to their particular location), other questions were designed to assess annoyance as a function of location (i.e., indoors, outdoors). As shown in Fig. 3, the prevalence of high annoyance was significantly higher outdoors.

The prevalence of annoyance by time of day and season is provided in Table IV. For WTN levels below 30 dB, the prevalence of high annoyance was very low (<1.2%) and similar for all times of day. Starting at 30 dB, the percentage highly annoyed during the evening and nighttime were significantly higher than the morning and afternoon; however this difference was most pronounced at WTN levels ≥35 dB. For WTN levels below 30 dB, the prevalence of high annoyance was very low (<2.2%) and similar for all seasons. At WTN levels ≥35 dB, the prevalence of high annoyance during the summer was higher compared to all other seasons.

Noise annoyance toward road, aircraft and rail noise was also assessed in the questionnaire. It was of interest to determine how annoyance to these sources compared to WTN annoyance. In areas where WTN levels were <35 dB the greatest source of noise annoyance was road traffic. In WTN categories ≥35 dB, annoyance toward WTN exceeded all other sources (p <0.0003, in all cases) (see Fig. 4).

E. Self-reported health conditions and use of medication

Table V shows that subjectively reported sleep disturbance from any source while sleeping at home over the last year, in addition to a multitude of health effects, were found

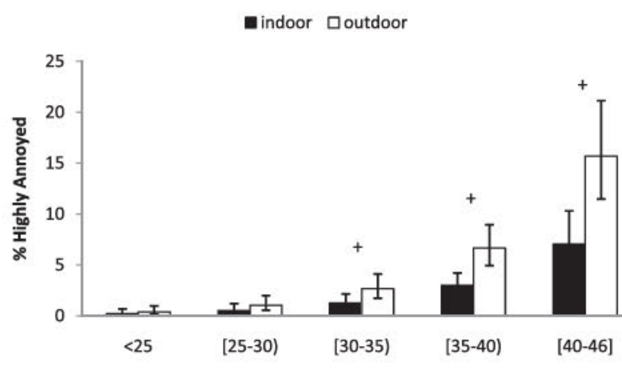

FIG. 3. Prevalence of high annoyance with wind turbine noise by location as a function of calculated outdoor wind turbine noise levels. Participants were asked to think about the last year or so and indicate how bothered, disturbed or annoyed they were by WTN while at home. The percentage of participants reporting to be either very or extremely (i.e., highly) bothered, disturbed or annoyed is shown as a function of calculated outdoor A-weighted WTN levels at the dwelling (dBA). Figure 3 presents the fitted results by location (i.e., indoors and outdoors) along with their 95% confidence intervals. + Indoor significantly different from outdoor ($p < 0.001$).

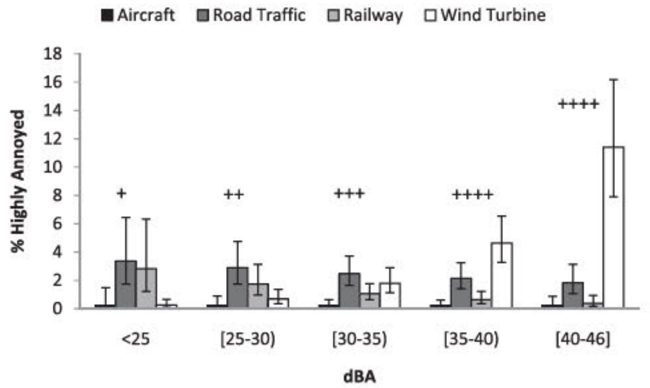

FIG. 4. Prevalence of high annoyance toward different noise sources as a function of calculated outdoor wind turbine noise levels. Illustrates the percentage of participants that reported to be either very or extremely (i.e., highly) bothered, disturbed or annoyed by road traffic, aircraft, rail and wind turbine noise (WTN) while at home over the last year. At home refers to either inside or outside the dwelling. Results represent fitted data along with their 95% confidence intervals and are shown as a function of calculated outdoor A-weighted WTN levels at the dwelling (dBA). $^{+}$WTN significantly different from road traffic and rail noise ($p < 0.001$); $^{++}$WTN significantly different from road traffic ($p < 0.001$); $^{+++}$WTN significantly different from aircraft noise ($p < 0.001$), $^{++++}$WTN significantly different from road traffic, rail, and aircraft noise ($p < 0.0003$).

to be unrelated to WTN levels. Similarly, medication use for high blood pressure, anxiety or depression was also found to be unrelated to WTN levels. Although sleep medication use was significantly related to WTN levels (p 0.0083), the prevalence was *higher* among the two lowest WTN categories {<25 dB and [25–30) dB} (see Table V).

IV. DISCUSSION

The prevalence of self-reporting to be either "*very*" or "*extremely*" (i.e., highly) annoyed with several wind turbine features increased significantly with increasing A-weighted WTN levels. When classified by the prevalence of reported annoyance overall, and in areas where WTN levels exceeded 35 dB, annoyance was highest for visual aspects of wind turbines, followed by blinking lights, shadow flicker, noise and vibrations. Consistent with Pedersen *et al.* (2009), the increase in WTN annoyance was clearly evident when moving from [30–35) dB to [35–40) dB, where the prevalence of WTN annoyance increased from 1% to 10%. This continued to increase to 13.7% for areas where WTN levels were [40–46] dB. The prevalence of WTN annoyance was higher outdoors, during the summer, and during evening and nighttime hours. Pedersen *et al.* (2009) also found that annoyance with WTN was greater outdoors compared to indoors.

Despite a similar pattern of response between the ON and PEI samples, the self-reported WTN annoyance was 3.29 times greater in ON, a difference that was most pronounced at the two highest WTN categories. This difference is in contrast to the prevalence of *household* complaints related to wind turbines. Even though the overall prevalence of such complaints was low (i.e., 2.8%), complaints were more likely in PEI (5.8%) compared to ON (2.2%). The reasons for this difference despite greater reported annoyance in ON are unclear. Research has shown that there are several contingencies that must be met before someone that is highly annoyed will complain (Michaud *et al.*, 2008). Such contingencies include knowing who to complain to, how to file a complaint and holding the belief that the complaint will result in positive change. The fact that the prevalence of complaints regarding wind turbines was unrelated to WTN levels is another indication that complaints do not always correlate well with changes in noise exposure (Fidell *et al.*, 1991). The motives underlying household complaints were not assessed in the present study, but the disparity found with annoyance could also be related to the wording used in the questionnaire. The prevalence of complaints was the one question where the respondent answered on behalf of the entire household.

More participants reported that they were highly annoyed by the visual aspects of wind turbines than by any other feature, even at higher WTN levels. Similar to WTN annoyance, the overall prevalence of annoyance with the visual impact of wind turbines was more than twice as high in the ON sample, and more prevalent across the exposure categories when compared to PEI. In the PEI sample, no participants reported visual annoyance in areas where WTN levels were below 35 dB. This is in contrast to a clear intensification in visual annoyance among the ON sample in areas where WTN levels were [25–30) dB. Exploring the variables that may underscore provincial differences was not within the scope of the current study. The questionnaire was not designed to probe underlying factors that may explain observed provincial differences; however, reported personal benefit from having wind turbines in the area was found to be different between the ON and PEI samples (Table IV).

Shepherd *et al.* (2011) assessed annoyance in response to WTN, but not in a manner that would permit comparisons with the Swedish (Pedersen and Persson Waye, 2004, 2007), Dutch (Janssen *et al.*, 2011; Pedersen *et al.*, 2009) or the current study. Shepherd *et al.* (2011) reported that 59% of participants living within 2 km of a wind turbine installation spontaneously identified wind turbines as an annoying noise source, with a mean annoyance rating of 4.59 (SD, 0.65) when the 5 category adjectival scale was analyzed as a numerical scale from 0 to 5. No exposure-response relationship could be assessed because the authors did not provide an analysis based on precise distance or as a function of WTN levels, which they reported to be between 20 and 50 dB among participants living within 2 km of a wind turbine. This encompasses the entire WTN level range in the CNHS. As such, the only tentative comparison that can be made between the current study and the Shepherd *et al.* (2011) study would be that the observed prevalence of highly annoyed (i.e., "*very*" or "*extremely*") within 2 km of the nearest wind turbine was 7.0%. These data are not shown because the focus of the current study was on WTN levels and an analysis based solely on distance to the nearest turbine does not adequately account for WTN levels at any given dwelling. WTN is a more sensitive measure of exposure level because, in addition to the distance to the turbine, it accounts for topography, presence of large bodies of water, wind turbine characteristics, the layout of the wind farm and the number of wind turbines at any given distance.

[a]The Cochran Mantel-Haenszel chi-square test is used to adjust for provinces unless otherwise indicated, p-values <0.05 are considered to be statistically significant.
[b]Columns may not add to total due to missing data.
[c]Worse consists of the two ratings: "*Somewhat worse now*" and "*Much worse now*."
[d]High sleep disturbance consists of the two ratings: "*very*" and "*extremely*" sleep disturbed.
[e]Chi-square test of independence.
[f]Quality of Life (QoL) and Satisfaction with Health were assessed with the two stand-alone questions on the WHOQOL-BREF. Reporting "*poor*" overall QoL reflects a response of "*poor*" or "*very poor*," and "*good*" reflects a response of "*neither poor nor good*," "*good*," or "*very good*." Reporting "*dissatisfied*" overall Satisfaction with Health reflects a response of "*very dissatisfied*" or "*dissatisfied*," and "*satisfied*" reflects a response of "*neither satisfied nor dissatisfied*," "*satisfied*," or "*very satisfied*." A detailed presentation of the results related to QoL is presented by Feder *et al*. (2015).

It was important to assess the extent to which the sample was homogenously distributed, with respect to demographics and community noise exposure. The reason for this is that the validity of the exposure-response relationship is strengthened when the primary distinction across the sample is the exposure of interest; in this case, WTN levels. Demographically, some minor differences were found with respect to age, employment, type of dwelling and dwelling ownership; however, with the possible exception of employment, these factors showed no obvious pattern with WTN levels and none were strong enough to exert an influence on the overall results. At the design stage, there was some concern that selecting participants up to 10 km might result in an unequal exposure to community noise sources other than WTN. This may have an influence on the underlying response to WTN. Limited data availability did not permit the modeling of sound pressure levels from other noise sources as originally intended, however it was possible to model BNTS levels. Although Fields (1993) concluded that background sound levels generally do not influence community annoyance, his review did not include wind turbines as a noise source and in the current study BNTS levels were calculated to be lower in areas where WTN levels were higher. Lower BNTS could contribute to a greater expectation of peace and quiet. Therefore, a limitation in the CNHS may be that the expectation of peace and quiet was not explicitly evaluated. This factor may influence the association between long-term sound levels and annoyance by an equivalent of up to 10 dB (ANSI, 1996; ISO, 2003b). The influence this factor may have had on the exposure-response relationship found specifically between WTN levels and the prevalence of reporting high annoyance with WTN in the CHNS is discussed in Michaud *et al*. (2016a).

In the absence of modeling, the audibility of road traffic, aircraft and rail noise provided a crude indication of exposure to these sources. In general, road traffic noise exposure was heard by the vast majority of the sample (82.1%).

Aircraft noise was uniformly audible in ON by about half the sample; in PEI however, hearing aircraft was more common in the higher WTN exposure categories (i.e., above 35 dB) where between 61% and 66% of the respondents indicated that they could hear aircraft. Future research may benefit from assessing the extent to which audible aircraft noise may have influenced the annoyance with WTN in PEI. Only when WTN levels were [40–46] dB was the audibility of wind turbines comparable to road traffic (i.e., both sources were audible by approximately 81% of participants). For these community noise sources, participants were asked how bothered, disturbed, or annoyed they were while at home over the last year or so. The findings are of interest in light of the source comparisons made by Pedersen *et al.* (2009) and Janssen *et al.* (2011), which placed WTN annoyance above all transportation noise sources when comparing them at equal sound levels. In the current study, the overall annoyance toward WTN (7.2%) was found to be higher in comparison to road (3.8%), aircraft (0.4%), and rail in ON (1.9%). Source comparisons need to be made with caution because the observed source differences in annoyance may result from an *actual* difference in sound pressure levels at the dwellings in this study. Modeling the sound levels from transportation noise sources in the current study would allow a more direct comparison between these sources and WTN annoyance at equivalent sound exposures. Another approach is to assess the relative community tolerance level of WTN with that reported for road and aircraft noise studies. This analysis indicates that there is a lower community tolerance level for WTN when compared to both road and aircraft noise at equivalent sound levels (Michaud *et al.*, 2016a).

The list of symptoms that are claimed to be caused by exposure to WTN is considerable (Chapman, 2013), but there is a lack of robust evidence from epidemiological studies to support these associations (Council of Canadian Academies, 2015; Knopper *et al.*, 2014; MassDEP MDPH, 2012; McCunney *et al.*, 2014; Merlin *et al.*, 2014). The results from the current study did not show any statistically significant increase in the self-reported prevalence of chronic pain, asthma, arthritis, high blood pressure, bronchitis, emphysema, chronic obstructive pulmonary disease (COPD), diabetes, heart disease, migraines/headaches, dizziness, or tinnitus in relation to WTN exposure up to 46 dB. In other words, individuals with these conditions were equally distributed among WTN exposure categories. Similarly, the prevalence of reporting to be highly sleep disturbed (for any reason) and being diagnosed with a sleep disorder were unrelated to WTN exposure. These self-reported findings are consistent with the conclusions reached following an analysis of objectively measured sleep among a subsample of the current study participants (Michaud *et al.*, 2016b). Medication use (for anxiety, depression, or high blood pressure) was unrelated to WTN levels. It is notable that the observed prevalence for many of the aforementioned health effects are remarkably consistent with large-scale national population-based studies (Innes *et al.*, 2011; Kroenke and Price, 1993; Morin *et al.*, 2011; O'Brien *et al.*, 1994; Shargorodsky *et al.*, 2010).

V. CONCLUDING REMARKS

Study findings indicate that annoyance toward all features related to wind turbines, including noise, vibrations, shadow flicker, aircraft warning lights and the visual impact, increased as WTN levels increased. The observed increase in annoyance tended to occur when WTN levels exceeded 35 dB and were undiminished between 40 and 46 dB. Beyond annoyance, the current study does not support an association between exposures to WTN up to 46 dB and the evaluated health-related endpoints. In some cases, there were clear differences between the southwestern ON and PEI participants; however, exploring the basis behind these differences fell outside the study scope and objectives. The CNHS supported the development of a model for community annoyance toward WTN, which identifies some of the factors that may influence this response (Michaud *et al.*, 2016a). At the very least, the observed differences reported between ON and PEI in the current study demonstrates that even at comparable WTN levels, the community response to wind turbines is not necessarily uniform across Canada. Future studies designed to intentionally explore the factors that underscore such differences may be beneficial.

ACKNOWLEDGMENTS

The authors acknowledge the support they received throughout the study from Serge Legault and Suki Abeysekera at Statistics Canada, and are especially grateful to the volunteers who participated in this study. The authors have declared that no competing interests exist.

[1]See supplementary material at http://dx.doi.org/10.1121/1.4942391 for the univariate analysis results.

[2]Locations coded as out-of-scope were originally assigned the following categories: *Demolished for unknown reasons*, *vacant for unknown reasons*, *unoccupied*, *seasonal*, *>79 years of age*, and *other* (Michaud, 2015b; Health Canada, 2014). In an effort to address feedback and provide further clarification, the categories used to define out-of-scope locations were further defined elsewhere (Michaud, 2015a) with additional details provided in the current paper. Specifically, locations that were determined to be "demolished for unknown reasons" are presented separately in Table I as Code F. Locations that were originally defined as "unoccupied for unknown reasons" are now more precisely defined under Code B (i.e., inhabitable dwelling not occupied at time of survey, newly constructed dwelling, or unoccupied trailer in vacant trailer park). Furthermore, it was confirmed that 6 dwellings originally listed under Code B (Michaud, 2015a) were in fact GPS coordinates listed in error and have therefore been reassigned to Code A.

Study Objectives: To investigate the association between self-reported and objective measures of sleep and wind turbine noise (WTN) exposure.
Methods: The Community Noise and Health Study, a cross-sectional epidemiological study, included an in-house computer-assisted interview and sleep pattern monitoring over a 7 d period. Outdoor WTN levels were calculated following international standards for conditions that typically approximate the highest long-term average levels at each dwelling. Study data were collected between May and September 2013 from adults, aged 18–79 y (606 males, 632 females) randomly selected from each household and living between 0.25 and 11.22 kilometers from operational wind turbines in two Canadian provinces. Self-reported sleep quality over the past 30 d was assessed using the Pittsburgh Sleep Quality Index. Additional questions assessed the prevalence of diagnosed sleep disorders and the magnitude of sleep disturbance over the previous year. Objective measures for sleep latency, sleep efficiency, total sleep time, rate of awakening bouts, and wake duration after sleep onset were recorded using the wrist worn Actiwatch2® from a subsample of 654 participants (289 males, 365 females) for a total of 3,772 sleep nights.
Results: Participant response rate for the interview was 78.9%. Outdoor WTN levels reached 46 dB(A) with an arithmetic mean of 35.6 and a standard deviation of 7.4. Self-reported and objectively measured sleep outcomes consistently revealed no apparent pattern or statistically significant relationship to WTN levels. However, sleep was significantly influenced by other factors, including, but not limited to, the use of sleep medication, other health conditions (including sleep disorders), caffeine consumption, and annoyance with blinking lights on wind turbines.
Conclusions: Study results do not support an association between exposure to outdoor WTN up to 46 dB(A) and an increase in the prevalence of disturbed sleep. Conclusions are based on WTN levels averaged over 1 y and, in some cases, may be strengthened with an analysis that examines sleep quality in relation to WTN levels calculated during the precise sleep period time.

Citation: Michaud DS, Feder K, Keith SE, Voicescu SA, Marro L, Than J, Guay M, Denning A, Murray BJ, Weiss SK, Villeneuve PJ, van den Berg F, Bower T. Effects of wind turbine noise on self-reported and objective measures of sleep. *SLEEP* 2016;39(1):97–109.

Significance
This study provides the most comprehensive assessment to date of the potential association between exposure to wind turbine noise (WTN) and sleep. As the only study to include both subjective and objective measures of sleep, the results provide a level of insight that was previously unavailable. The absence of an effect of WTN on sleep is based on an analysis of self-reported and objectively measured outcomes in relation to long term outdoor average sound levels. Knowledge in this area may be strengthened by future research to consider the potential transient changes in WTN levels throughout the night, which may influence subtle measures of sleep not assessed in the current study.

INTRODUCTION

Sleep loss has been implicated in a variety of negative health outcomes[1] including cardiovascular abnormalities,[2] immunological problems,[3] psychological health concerns,[4] and neurobehavioral impairment that can lead to accidents.[5] Sleep loss may be related to total sleep time restriction and/or reduced sleep quality in the sleep time obtained. Sleep disorders such as insomnia and obstructive sleep apnea are associated with an increased incidence of hypertension, heart failure, and stroke.[6,7]

Sleep can clearly be disrupted with noise.[8] It has long been recognized that electroencephalography (EEG) arousals can be induced with external environmental stimuli, but are modulated by sleep state.[9] The World Health Organization (WHO) Guidelines for Community Noise recommend that, for continuous noise, an indoor sound level of 30 dB(A) should not be exceeded during the sleep period time to avoid sleep disturbance.[10] More recently, the WHO's Night Noise Guidelines for Europe [11] suggest an annual average outdoor level of 40dB(A) to reduce negative health outcomes from sleep disturbance even among the most vulnerable groups.

Sleep can be measured by subjective and objective means[12] although due to the fundamental nature of unconsciousness in this state, people are unable to introspect on their sleep state. As such, an individual may surmise the quality of his or her sleep, with descriptions of what his or her presumed sleep was like, periods of awakening, and consequences of the state. However, sleep state misperception is a common clinical phenomenon, whereby patients with some degree of insomnia may report much worse quality of sleep than what actually occurred.[13] Subjective interpretation of sleep state is thus subject to biased reporting from the individual and therefore subjective and objective measures of sleep are frequently discordant. Therefore, objective physiological measures of sleep can provide a more accurate reflection of what actually happened during an individual's sleep and form the basis of an unprejudiced understanding of the actual biological effect of factors such as noise on sleep.

Although the current study is the first to include objective measures in the assessment of sleep quality in the context of wind turbine noise (WTN) exposure, the psychological experience of the individual must be considered, though this factor may be more prone to subjective interpretation. Numerous subjective scales of sleep have been devised. The Pittsburgh Sleep Quality Index (PSQI)[14] is a measure of the subjective experience of sleep that has had detailed psychometric assessment,[15] validation in numerous populations,[16–18] and is one of the most common subjective methodologies used in sleep research.

The PSQI has been administered in a study to compare subjective sleep quality among 79 subjects living near two different wind farms wherein it was reported that sleep quality was worse among the group living closer to the wind turbines.[19] Pedersen[20] found that self-reported sleep disturbance for any reason from any source was inconsistently related to the level of WTN. Bakker et al.[21] showed that self-reported sleep disturbance was correlated to WTN level, but when noise annoyance from wind turbines was brought into a multiple regression, sleep disturbance appeared to be highly correlated to the annoyance, but not to WTN level and only annoyance was statistically correlated to WTN level. This is consistent with the study by van den Berg et al.[22] wherein noise annoyance was reported as a better predictor of self-reported sleep disturbance than noise level for transportation, industrial, and neighbor noise.

Several studies have provided objectively measured assessments of transportation noise-induced sleep disturbance.[23–26] Although it is clear that noise is among the many factors that contribute to sleep disturbance [23,24,27,28] there has been no study to date that has provided an assessment of sleep disturbance in the context of WTN exposures using objective measures such as actigraphy.

The current study was designed to objectively measure sleep in relation to WTN exposure using actigraphy, which has emerged as a widely accepted tool for tracking sleep and wake behavior.[29,30] The objective measures of sleep, when considered together with self-report, provide a more comprehensive evaluation of the potential effect that WTN may have on sleep.

This study was approved by the Health Canada and Public Health Agency of Canada Review Ethics Board (Protocol #2012-0065 and #2012-0072).

METHOD

Sample Design

Target population, sample size, and sampling frame strategy

Several factors influenced the determination of the final sample size, including having adequate statistical power to assess the study objectives, and adequate time allocation for collection of data, influenced by the length of the personal in-dwelling interview and the time needed to collect the physical measures. Overall statistical power for the study was based on the study's primary objective to assess WTN-associated effects on sleep quality. Based on an initial sample size of 2,000 potential dwellings, it was estimated that there would be 1,120 completed survey responses. For 1,120 survey responses there should be sufficient statistical power to detect at least a 7% difference in the prevalence of sleep disturbances with 80% power and a 5% false positive rate (Type I error). There was uncertainty in the power assessment because the current *Community Noise and Health Study*, was the first to implement objectively measured endpoints to study the possible effects of WTN on sleep. How these power calculations applied to actigraphy-measured sleep was also unknown. In the absence of comparative studies, a conservative baseline prevalence for reported sleep disturbance of 10% was used.[31,32] Sample size calculation also incorporated the following assumptions: (1) approximately 20% to 25% of the targeted dwellings would not be valid dwellings (i.e., demolished, unoccupied seasonal, vacant for unknown reasons, under construction, institutions, etc.); and (2) of the remaining dwellings, there would be a 70% participation rate. These assumptions were validated (see response rates and sample characteristics related to sleep).

Study locations were drawn from areas in southwestern Ontario (ON) and Prince Edward Island (PEI) where there were a sufficient number of dwellings within the vicinity of wind turbine installations. The ON and PEI sampling regions included 315 and 84 wind turbines, respectively. The wind turbine electrical power outputs ranged between 660 kW to 3 MW (average 2.0 ± 0.4 MW). All turbines were modern monopole tower design with three pitch-controlled rotor blades (~80 m diameter) upwind of the tower and most had 80 m hub heights. All identified dwellings within approximately 600 m from a wind turbine and a random selection of dwellings between 600 m and 11.22 km were selected from which one person per household between the ages of 18 and 79 y was randomly selected to participate. The final sample size in ON and PEI was 1,011 and 227, respectively. Participants were not compensated in any way for their participation.

Wind turbine sound pressure levels at dwellings

Outdoor sound pressure levels were estimated at each dwelling using both ISO 9613-1[33] and ISO 9613-2[34] as incorporated in the commercial software CadnaA version 4.4.[35] The resulting calculations represent long-term (1 y) A-weighted equivalent continuous outdoor sound pressure levels (LAeq). Therefore, calculated sound pressure levels can only approximate with a certain degree of uncertainty the sound pressure level at the dwelling during the reference time periods that are captured by each measure of sleep. The time reference period ranges from 1–7 d (actigraphy), to 30 d for the PSQI and the previous year for the assessment of the percentage highly sleep disturbed. Van den Berg[36] has shown that, in the Dutch temperate climate, the long-term average WTN level for outdoor conditions is 1.7 ± 1.5 dB(A) below the sound pressure level at 8 m/sec wind speed. Accordingly, a best estimate for the average nighttime WTN level is approximately 2 dB(A) below the calculated levels reported in this study.

Calculations included all wind turbines within a radius of 10 km, and were based on manufacturers' octave band sound power spectra at a standardized wind speed of 8 m/sec and favorable sound propagation conditions. Favorable conditions assume the dwelling is located downwind of the noise source, a stable atmosphere, and a moderate ground-based temperature inversion. Although variations in wind speeds and temperature as a function of height could not be considered in the model calculations due to a lack of relevant data, 8 m/sec was considered a reasonable estimate of the highest noise exposure conditions. The manufacturers' data were verified for consistency using on-site measurements of wind turbine sound power. The standard deviation in sound levels was estimated to be 4 dB(A) up to 1 km, and at 10 km the uncertainty was estimated to be between 10 dB(A) and 26 dB(A). Although calculations based on predictions of WTN levels reduces the risk of misclassification compared to direct measurements, the risk remains to some extent. The calculated levels in the current study represent reasonable worst-case estimates expected to yield outdoor WTN levels that typically approximate the highest long-term average levels at each dwelling and thereby optimize the chances of detecting WTN-induced sleep disturbance. The few dwellings beyond 10 km were assigned the same calculated WTN value as dwellings at 10 km. Unless otherwise stated, all decibel references are A-weighted. A-weighting filters out low frequencies in a sound that the human auditory system is less sensitive to at low sound pressure levels.

In the current study, low-frequency noise was estimated by calculating C-weighted sound pressure levels. No additional benefit was observed in assessing low frequency noise because C- and A-weighted levels were so highly correlated. Depending on how dB(C) was calculated and what range of data was assessed, the correlation between dB(C) and dB(A) ranged from r = 0.84 to r = 0.97.[37]

Background nighttime sound levels at dwellings

As a result of certain meteorological phenomena (atmospheric stability and wind gradient) coupled with a tendency for background sound levels to drop throughout the day in rural/semi-rural environments, WTN can be more perceptible at the dwelling during nighttime.[38–41] In Canada, it is possible to estimate background nighttime sound pressure levels according to the provincial noise regulations for Alberta, Canada,[42] which estimates ambient noise levels in rural and suburban environments. Estimates are based on dwelling density per quarter section, which represents an area with a 451 m radius and distance to heavily travelled roads or rail lines. When modeled in accordance with these regulations, estimated levels can range from 35 dB(A) to 51 dB(A). The possibility that exposure to high levels of road traffic noise may create a background sound pressure level higher than that estimated using the Alberta regulations was considered. In ON, road noise for the six-lane concrete Highway 401 was calculated using the United States Federal Highway Administration (FHWA) Traffic Noise Model[43] module in the CadnaA software.[35] This value was used when it exceeded the Alberta noise estimate, making it possible to have levels above 51 dB(A).

Data Collection

Questionnaire administration and refusal conversion strategies

The questionnaire instrument included modules on basic demographics, noise annoyance, health effects, quality of life, sleep quality, sleep disorders, perceived stress, lifestyle behaviors, and prevalence of chronic disease. To avoid bias, the true intent of the study, which was to assess the community response to wind turbines, was masked. Throughout the data collection, the study's official title was: *Community Noise and Health Study*. This approach is commonly used to avoid a disproportionate contribution from any group that may have distinct views toward wind turbines. Data collection took place through in-person interviews between May and September 2013 in southwestern ON and PEI. After a roster of all adults aged 18 to 79 y living in the dwelling was compiled, a computerized method was used to randomly select one adult from each household. No substitution was permitted; therefore, if the targeted individual was not at home or unavailable, alternate arrangements were made to invite them to participate at a later time.

All 16 interviewers were instructed to make every reasonable attempt to obtain interviews, which included visiting the dwelling at various times of the day on multiple occasions and making contact by telephone when necessary. If the individual refused to participate, they were then contacted a second time by either the senior interviewer or another interviewer. If, after a second contact, respondents refused to participate, the case was coded as a final refusal.

Self-reported sleep assessment

Long-term self-reported sleep disturbance included an assessment of the magnitude of sleep disturbance experienced at home (of any type for any reason) over the past year. Participants were requested to describe their level of sleep disturbance at home over the past year using one of the following categories: "not at all," "slightly," "moderately," "very" or "extremely," where the top two categories were collapsed and considered to reflect "highly sleep disturbed." For the purposes of this analysis the bottom three categories reflect "low sleep disturbance." These categories and the classification of "highly sleep disturbed" is consistent with the approach adopted for annoyance[44] and facilitates comparisons to self-reported sleep disturbance functions developed for transportation noise sources.[45] Data were collected on prevalence of diagnosed sleep disorders. In addition, participants completed the PSQI, which provided an assessment of sleep quality over the previous 30 d. The seven components of the PSQI are scored on a scale from 0 (better) to 3 (worse); therefore the global PSQI is a score ranging between 0–21, where a value of greater than 5 is thought to represent poor sleep quality.[14,16–18]

Objectively measured sleep

An Actiwatch2® (Philips Healthcare, Andover, MA, USA) sleep watch was given to all consenting and eligible participants aged 18 to 79 y who were expected to sleep at their current address for a minimum of 3 of the 7 nights following the interview. There were 450 devices at hand that were cycled throughout the study. In order to receive the device, respondents also needed to have full mobility in the arm on which the watch was to be worn. Respondents were asked to wear the device on their wrist during all hours of the day and night for the 7 d following their interview. The Actiwatch2® provides key information on sleep patterns (based on movement), including timing and duration of sleep as well as awakenings, and has been compared with polysomnography in some patient samples,[46] but does not replace polysomnography due to imperfect sensitivity and specificity for detecting wake periods. However, this tool can provide reasonable estimates for assessing subjects objectively for more prolonged periods of time than conventional assessment tools, with minimal participant burden.[47] The devices were configured to continuously record a data point every 60 sec for the entire 7 d period. Data analysis was conducted using Actiware® Version 5.1[48] with the software set to default settings (i.e., sensitivity setting of medium and a minimum minor rest interval size of 40 min). With these settings an epoch of 40 counts (i.e., accelerometer activity above threshold) or less is considered sleep and epochs above 40 counts are considered wake. However, any given epoch is scored using a 5-epoch weighting scheme. This procedure weighs the 2 epochs adjacent to the epoch in question. The 5-epoch weighting is achieved by multiplying the number of counts in each respective epoch by the following: 1/25, 1/5, 1, 1/5, 1/25, whereby an average above 40 indicates "awake" for the central epoch. The sleep start parameter was automatically calculated by the Actiware® software determined by the first 10 min period in which no more than one 60 sec epoch was scored as mobile. An epoch is scored as mobile if the number of activity counts recorded in the epoch is greater than or equal to the epoch length in 15 sec intervals (i.e., in a 60 sec epoch an activity value of 4 or higher). Endpoints of interest from wrist actigraphy included sleep efficiency (total sleep time divided by measured time in bed), sleep latency (how long it took to fall asleep), wake after sleep onset (WASO) (the total duration of awakenings), total sleep time, and the number of awakening bouts (WABT) (during a sleep period). The WABT data was analysed as the rate of awakening bouts per 60 min in bed.

To help interpret the measured data, respondents were asked to complete a basic sleep log each night of the study. The log contained information about whether the respondent slept at home or not, presence of windows in the room where they slept, and whether or not the windows were open. After the 7 d collection period, respondents were asked to return the completed sleep log with the actigraph in a prepaid package.

Statistical Methodology

The analysis follows the description in Michaud et al.,[49] which provides a summary of the study design and objectives, as well as a proposed data analysis. Briefly, the Cochran Mantel-Haenszel chi-square test was used to detect associations between self-reported magnitude or contributing sources of sleep disturbance and WTN exposure groups while controlling for province. Because a cut-off value of 5 for the global PSQI score provided a sensitive and specific measure distinguishing good and poor sleep, the PSQI score was dichotomized with the objective to model the proportion of individuals with poor sleep quality (i.e., PSQI > 5).[14] As a first step to develop the best model to predict the dichotomized PSQI score, univariate logistic regression models only adjusting for WTN exposure groups and province were carried out. It should be emphasized that variables considered in the univariate analysis have been previously demonstrated to be related to the modeled endpoint and/or considered by the authors to conceptually have a potential association with the modeled endpoint. The analysis of each variable only adjusts for WTN category and province; therefore, interpretation of any individual relationship must be made with caution.

The primary objective in the current analysis was to use multiple regression models to identify the best predictors for (1) reporting a PSQI score greater than 5; and (2) the actigraphy endpoints. All explanatory variables that were statistically significant at the 20% level in the univariate analysis for each respective endpoint were considered in the multiple regression models. To develop the best model to predict each endpoint of interest, the stepwise method, which guards against issues of multicollinearity, was used for multiple regression models.

The stepwise regression was carried out in three different ways wherein the base model included: (1) WTN exposure category and province; (2) WTN exposure category, province, and an adjustment for individuals who reported receiving personal benefit from having wind turbines in the area; and (3) WTN category and province, stratified for those who received no personal benefit.

For the analysis of PSQI, multiple logistic regression models were developed using the stepwise method with a 20% significance entry criterion and a 10% significance criterion to remain in the model. The WTN groups were treated as a continuous variable, giving an odds ratio (OR) for each unit increase in WTN level, where a unit reflects a 5 dB(A) WTN category. The Nagelkerke pseudo R^2 is reported for logistic regression models.

Repeated-measures data from all wrist actigraphy measurements were modeled using the generalized estimating equations (GEE) method, as available in SAS (Statistical Analysis System) version 9.2 PROC GENMOD.[50–52] Univariate GEE regression models only adjusting for WTN exposure groups, province, day of the week, and the interaction between WTN groups and day of the week were carried out. The interaction between WTN and province was significant for the total sleep time outcome in the univariate models, but was no longer significant in the multiple GEE regression model. Therefore, the base model for the multiple GEE regression models included only WTN category, province, and day of the week. The same stepwise methodology that was applied to build the PSQI models was used to develop multiple GEE regression models for each actigraphy endpoint. The within-subjects correlations were examined with different working correlation matrix structures (unstructured, compound symmetry, and autoregressive of first order). An unstructured variance-covariance structure between sleep nights was applied to all endpoints with the exception of sleep latency, where compound symmetry was used. The advantage of the GEE method is that it uses all available data to estimate individual subject variability (i.e., if 1 or more nights of data is missing for an individual, the individual is still included in the analysis).

The wrist actigraphy endpoints of sleep efficiency and rate of awakening bouts do not follow a normal distribution, because one is a proportion ranging between 0 and 1 (sleep efficiency) and the other is a count (awakening bouts). Therefore, to analyze awakening bouts a Poisson distribution was assumed. The

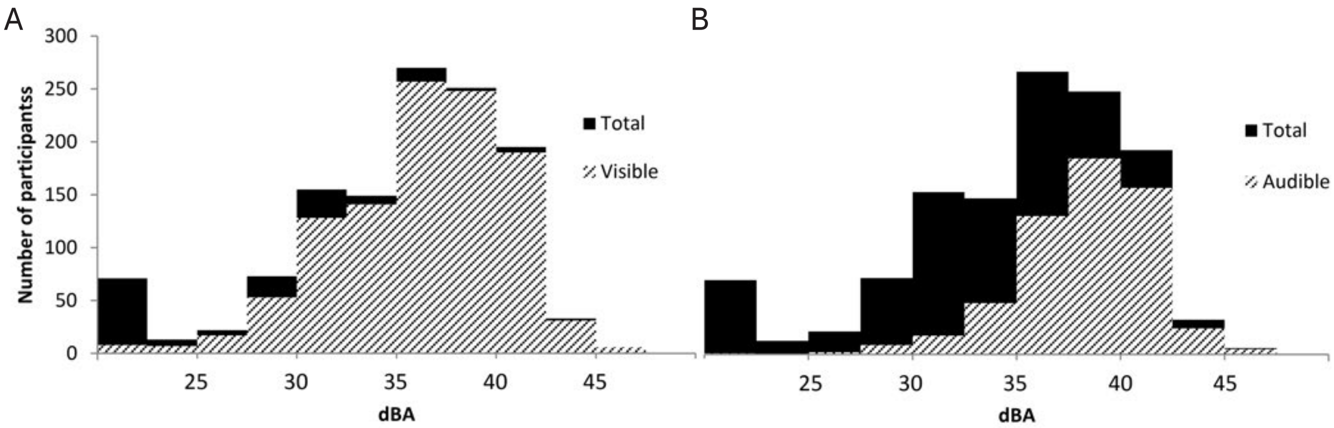

Figure 1—Histogram showing the distribution of participants as a function of calculated outdoor A-weighted wind turbine noise levels. (A) The number of participants who self-reported on the questionnaire that wind turbines were visible from anywhere on their property. (B) The number of participants who self-reported that wind turbines were audible from inside or outside their home.

number of awakening bouts was analyzed with respect to the total time spent in bed and is reported as a rate of awakening bouts per 60 min in bed. Sleep efficiency, sleep latency, and WASO were transformed in order to normalize the data and stabilize the variance.[53–55] In the GEE models, statistical tests were based on transformed data in order to satisfy the normality and constant variance assumptions. Because back-transformation was not possible for some endpoints, the arithmetic mean (least squares mean [LSM]) is presented for all endpoints.

All regression models for PSQI and actigraphy endpoints were adjusted for provincial differences. Province was initially assessed as an effect modifier. Because the interaction was not statistically significant for any of the multiple regression models, province was treated as a confounder in the models with associated adjustments, as required. Statistical analysis was performed using SAS version 9.2. A 5% statistical significance level was implemented throughout unless otherwise stated and Tukey corrections were applied to account for all pairwise comparisons to ensure that the overall Type I (false positive) error rate was less than 0.05.

Actigraphy Data Screening

The sleep actigraphy file consisted of 4,742 nights of actigraphy measured sleep (i.e., sleep nights) data from 781 participants. The following adjustments to the file were made to account for data that could not be processed: removal of sleep nights with no data (n = 15), data where the dates from the sleep watch and sleep log diary did not match (n = 61), recordings beyond 7 d (representing data collected off wrist or during return shipment) (n = 56), nights with shift work (n = 630), and data related to sleep nights away from home (n = 132). Removal of these data supported the objective to relate sleep behavior to noise exposure from wind turbines at the participants' dwelling. Sleep starting after 05:00 with awakening on the same day before 18:00 was considered day sleep and removed from the analysis (n = 70). One participant was removed where there appeared to be a watch malfunction (i.e., indicated nearly constant sleep). The final sample size consisted of 3,772 sleep nights and 654 participants. Any sleep that started after midnight, but before 05:00 was re-coded and considered as sleep for the previous night to avoid having two sleep observations for the same night. For the remaining data, all available data was used whether the person wore the watch for 1 d or for the maximum 7 d.

RESULTS

Wind Turbine Sound Pressure Levels at Dwellings

Calculated outdoor sound pressure levels at the dwellings determined by ISO 9613-1[33] and ISO 9613-2[34] reached levels as high as 46 dB(A). Results are considered to have an uncertainty of ± 4 dB(A) within distances that would have the strongest effect on sleep (i.e., ~600 m). Figure 1 illustrates the distribution of participants as a function of WTN levels and identifies the number of participants who reported wind turbines were visible from anywhere on their property (panel A) and audible (panel B) while they were either outside or inside their dwelling.

Background Nighttime Sound Pressure Levels

Modeled background nighttime sound (BNTS) levels ranged between 35 and 61 dB(A) in the sample. Average BNTS was highest in the WTN group 30–35 dB(A) and lowest in areas where modeled WTN levels were between 40–46 dB(A).[37] In the univariate analysis of global PSQI, the proportion of people with poor sleep (i.e., global scores above 5) was statistically similar among the BNTS levels (P = 0.9727). For actigraphy, BNTS levels were only statistically significant for the endpoint WASO (P = 0.0059), where it was found that individuals in areas with louder BNTS levels tended to have longer durations of awakenings. WASO increased from 50.7 min (95% confidence interval [CI]: 46.9, 54.4) in areas with < 40 dB(A) BNTS to 67.2 min (95% CI: 57.0, 77.5) in areas with ≥ 55 dB(A) BNTS levels (see supplemental material).

Response Rates and Sample Characteristics Related to Sleep

A detailed breakdown of the response rates, along with personal and situational variables by WTN category, is presented by Michaud.[37] Of the 2,004 potential dwellings, 1,570 were valid and 1,238 agreed to participate in the survey (606 males,

Participants were asked to report their magnitude of sleep disturbance over the last year while at home by selecting one of the following five categories: not at all, slightly, moderately, very, or extremely. Participants that indicated at least a slight magnitude of sleep disturbance were asked to identify all sources perceived to be contributing to sleep disturbance. [a]The Cochran Mantel-Haenszel chi-square test was used to adjust for provinces. [b]At least slightly sleep disturbed includes participants indicating the slightly, moderately, very or extremely categories. [c]Highly sleep disturbed includes participants who reported the very or extremely categories. The prevalence of reported sleep disturbance was unrelated to wind turbine noise levels. [d]Of the 757 participants who reported at least a slight amount of sleep disturbance, 31 did not know what contributed to their sleep disturbance. Of the remaining 726, at least one source was identified. Columns may not add to sample size totals as some participants did not answer questions and/or identified more than one source as the cause of their sleep disturbance.

Table 2—Summary of Pittsburgh Sleep Quality Index scores.

	Wind Turbine Noise, dB(A) < 25	25–30	30–35	35–40	40–46	Overall
Mean (95% CI)	6.22 (5.32, 7.11)	5.91 (5.05, 6.77)	6.00 (5.51, 6.50)	5.74 (5.33, 6.16)	6.09 (5.55, 6.64)	5.94 (5.72, 6.17)
n (%) score > 5[a]	40 (49.4)	45 (48.9)	138 (46.5)	227 (44.4)	106 (46.7)	556 (46.0)

[a]Pittsburgh Sleep Quality Index score above 5 is considered to represent poor sleep. CI, confidence interval.

632 females), resulting in a final overall response rate of 78.9%. Of the 1,238 participants, 1,208 completed the PSQI in its entirety (97.6%) and 781 participated in the sleep actigraphy portion of the study (63%). Sleep actigraphy participation rates were in line with projections based on an unpublished pilot study designed to assess different sleep watch devices and participant compliance. Participation rate was equally distributed across WTN categories.

The prevalence of reporting a diagnosed sleep disorder was unrelated to WTN levels (P = 0.3102).[27] In addition, the use of sleep medication at least once a week was significantly related to WTN levels (P = 0.0083). The prevalence was *higher* among the two lowest WTN categories (< 25 dB(A) and 25–30 dB(A)).[37] Factors that may affect sleep quality, such as self-reported prevalence of health conditions, chronic illnesses, quality of life, and noise sensitivity were all found to be equally distributed across WTN categories.[37,56] In response to the general question on magnitude of sleep disturbance for any reason over the past year while at home, a total of 757 participants (61.3%) reported at least a "slight" magnitude of sleep disturbance (includes ratings of "slightly," "moderately," "very" and "extremely"), with a total of 164 (13.3%) classified as "highly" sleep disturbed (i.e., either very or extremely). The levels of WTN were not found to have a statistically significant effect on the prevalence of sleep disturbance whether the analysis was restricted to only participants highly sleep disturbed (P = 0.4300), or if it included all participants with even a slight disturbance (P = 0.7535) (Table 1). When assessing the sources reported to contribute to sleep disturbance among all participants with even slight disturbance, reporting wind turbines was significantly associated with WTN categories (P < 0.0001). The prevalence was ≥ 15.1% among the participants living in areas where WTN levels were ≥ 35 dB(A) compared to ≤ 3.9% in areas where WTN levels were below 35 dB(A). However, wind turbines were not the only, nor the most prevalent, contributing source at these sound levels (see Table 1).

PSQI Scores

For the 1,208 participants who completed the PSQI in its entirety, the average PSQI score across the entire sample was

5.94 with 95% confidence interval (CI) (5.72, 6.17). The Cronbach alpha for the global PSQI was 0.76 (i.e., greater than the minimum value of 0.70 in order to validate the score). Table 2 presents the summary statistics for PSQI as both a continuous scale and a binary scale (the proportion of respondents with poor sleep; i.e., PSQI above 5) by WTN exposure categories. Analysis of variance was used to compare the average PSQI score across WTN exposure groups (after adjusting for provinces). There was no statistical difference observed in the mean PSQI scores between groups ($P = 0.7497$) as well as no significant difference between provinces ($P = 0.7871$) (data not shown). Similarly, when modeling the proportion of respondents with poor sleep (PSQI > 5) in the logistic regression model, no statistical differences between WTN exposure groups ($P = 0.4740$) or provinces ($P = 0.6997$) were observed (see supplemental material).

Effects of Personal and Situational Variables on PSQI Scores and Actigraphy

A univariate analysis of the personal and situational variables in relation to the PSQI scores (logistic regression) and actigraphy (GEE) was conducted. The list of variables considered was extensive and included, but was not limited to, age, sex, income, education, body mass index, caffeine consumption, housing features, diagnosed sleep disorders, health conditions, annoyance, household complaints, and personal benefit (i.e., rent, payments or other indirect benefits through community improvements) from having wind turbines in the area. The analysis of these and several other variables in relation to the endpoints has been made available in the supplemental material.

Multiple Logistic Regression Models for PSQI

Table 3 provides a summary of the variables retained in the multiple regressions for the PSQI and actigraphy endpoints. A detailed description of the statistical results, including the direction of change and the pairwise comparisons made among the groups within each variable is available in the supplemental material.

Table 4 presents the results from stepwise multiple logistic regression modeling of the proportion of respondents with "poor sleep" (i.e., scores above 5 on the PSQI). The final models for the three approaches to stepwise regression as listed in the Statistical Methods section produced nearly identical results to one another. Therefore, results are only presented for the regression method where the variables WTN category, province, and personal benefit were forced into the model that fit the data well (Hosmer-Lemeshow test, $P > 0.05$). Using stepwise regression, the predictive strength of the final model was 37%. There was no observed relationship between the proportion of respondents with poor sleep and WTN levels ($P = 0.3165$).

Participants who had improved sleep quality after closing their bedroom window were found to have the same odds of poor sleep when compared to those who did not need to close their window ($P = 0.0565$). Participants who stated that closing their window did not improve sleep quality had higher odds of poor sleep in comparison with both those who had improved sleep quality after closing windows and those who did not need to close windows ($P \leq 0.0006$, in both cases). Unemployed individuals had higher odds of poor sleep compared with those who were employed (OR [95% CI]: 1.55 [1.12, 2.15]).

Long-term sleep disturbance (of any type by any source) was included in the study because dose-response relationships have been published for this measure in relation to other community noise sources[45] and this endpoint provides a longer time reference period than the previous 30 d assessed using the PSQI. Those who reported a very or extremely high level of sleep disturbance (i.e., percentage highly sleep disturbed) by any source while at home had 6 times higher odds of poor sleep assessed with the PSQI (OR [95%CI]: 6.28 [3.46, 11.40]) when compared to those with no, slight, or moderate reported sleep disturbance. Finally, participants suffering from migraines/headaches, asthma, arthritis and a diagnosed sleep disorder (e.g., sleep apnea or insomnia) had higher odds of poor sleep when compared to those not suffering from these health and chronic conditions.

Sleep Actigraphy

The majority of participants (56%) wore the watch for the full 7 nights (mean number of days 5.77, SD = 1.85). The frequency across the days of the week was equally distributed (data not shown). Response rates for the actigraph were equally distributed across WTN exposure groups ($P = 0.5585$), although a higher proportion of participants were noted in PEI, in comparison to ON ($P = 0.0008$).

Table 5 presents the summary data for each sleep actigraphy endpoint analyzed. Although mean values appear stable between one sleep night to the next within an endpoint, the standard deviation is observed to fluctuate between sleep nights (data not shown). The observed correlations between the PSQI and the actigraphy endpoints are presented as supplemental material.

Multiple GEE Regression Models for Actigraphy

Multiple regression models for the five sleep actigraphy endpoints were developed. Variables that were associated with each endpoint (i.e., significant at the 10% level) are summarized in Table 3. Specific information on these variables, including the direction of change, P values, and pairwise comparisons has been made available in the supplemental material. Table 6 presents the LSM and the P values for the exposure of interest, the WTN exposure categories, obtained from the GEE regression models for the sleep actigraphy endpoints. Unadjusted results reflect the base model (including WTN, province, day of the week, and the interaction between WTN and day of the week) whereas adjusted results come from the multiple regression models obtained through the stepwise method and take into account factors beyond the base model. The level of exposure to WTN was not found to be related to sleep efficiency ($P = 0.3932$), sleep latency ($P = 0.6491$), total sleep time ($P = 0.8002$), or the number of awakening bouts ($P = 0.3726$). There was an inconsistent association found between WASO and WTN exposure where there was a statistically significant reduction in WASO time observed in areas where WTN levels were 25–30 dB(A), in comparison with < 25 dB(A) and 40–46

Table 3—Variables retained in multiple generalized estimating equations and multiple logistic regression models.

Arthritis	Yes/No	0.0497	1.45 (1.00, 2.10)
Diagnosed sleep disorder	Yes/No	0.0001	2.99 (1.71, 5.23)

[a]The logistic regression is modeling the probability of having a PSQI score above 5. [b]Where a reference group is not specified it is taken to be the last group. [c]P value significance is relative to the reference group. [d]OR (CI) odds ratio and 95% confidence interval based on logistic regression model. [e]The exposure variable, WTN level, is treated as a continuous scale in the logistic regression model. [f]The source identified by participants as the cause of closing bedroom windows to reduce noise levels was not road traffic, aircraft, rail or wind turbines. [g]Evaluates the magnitude of reported sleep disturbance at home from not at all to extremely for any reason over the previous year. [h]H-L P > 0.05 indicates a good fit. CI, confidence interval; H-L, Hosmer-Lemeshow test; ON, Ontario; OR, odds ratio; PEI, Prince Edward Island; PSQI, Pittsburgh Sleep Quality Index; WTN, wind turbine noise.

dB(A) WTN categories. This was because of a higher mean WASO time among participants from PEI living in areas where WTN levels were less than 25 dB(A) (data not shown).

DISCUSSION

The effects on health and well-being associated with accumulated sleep debt have been well documented.[1–5,57] The sound pressure levels from wind turbines can exceed the WHO recommended annual average nighttime limit of 40 dB(A) for preventing health effects from noise-induced sleep disturbance.[11] The calculated outdoor A-weighted WTN levels in this study reached a maximum of 46 dB(A), with 19% of dwellings found to exceed 40 dB(A). Within an uncertainty of approximately 4 dB(A), the calculated A-weighted levels in the current study can be compared to the WHO outdoor nighttime annual average threshold of 40 dB(A).[11,58] With the average façade attenuation with windows completely opened of 14 ± 2 dB(A),[58] the average bedroom level at the highest façade level, 46 dB(A), will be 32 ± 2 dB(A), which is close to the 30 dB(A) indoor threshold in the WHO's Guidelines for Community Noise.[10] Considering the uncertainty in the calculation model and input data, only dwellings in the highest WTN category are expected to have indoor levels above 30 dB(A) and thus sensitivity to sleep disturbance. However, with windows closed, indoor outdoor level difference is approximately 26 dB, which should result in an indoor level around 20 dB(A) in the current study.

Factors including, but not limited to, medication use, other health effects (including sleep disorders), caffeine consumption, and annoyance with blinking lights on wind turbines were found to statistically influence reported and/or actigraphically measured sleep outcomes. However, there was no evidence for any form of sleep disturbance found in relation to WTN levels. Studies published to date have been inconsistent in terms of self-reported evidence that WTN disrupts sleep,[59,60] and none of these studies assessed sleep using an objectively measured method. These inconsistent findings are

[a]The base model for the multiple generalized estimating equations (GEE) regression models for all endpoints included wind turbine noise (WTN) exposure groups, province, day of the week, and the interaction between WTN groups and day of the week. [b]A complete list of the other variables included in each multiple GEE regression model based on the stepwise methodology is presented in Table 3. [c]Sample size for the adjusted GEE regression models. [d]The base model for total sleep time includes the interaction between WTN groups and province. [e]LSM, least squares means, for each group after adjusting for all other variables in the multiple GEE regression model and corresponding 95% confidence interval (CI). P values for both the adjusted and unadjusted models are based on the transformed variable in order to satisfy model assumptions of normality and constant variance.

not entirely surprising considering that sleep disturbance reported as a result of transportation noise exposure occurs at sound pressure levels that exceed WTN levels calculated in the current study.[27,28,45] Study results concur with those of Bakker et al.,[21] with outdoor WTN levels up to 54 dB(A), wherein it was concluded that there was no association between the levels of WTN and sleep disturbance when noise annoyance was taken into account.

The current study employed a wide range of self-reported and objectively measured endpoints related to sleep to provide a comprehensive assessment of the potential effects that WTN exposure may have on sleep. Self-reported diagnosed sleep disorders[37] and self-reported highly sleep disturbed for any reason were factors found to be unrelated to WTN exposure. Furthermore, taking medication at least once per week was more commonly reported among participants living in areas where WTN levels were below 30 dB(A). Scores on the PSQI, either analyzed as a proportion above 5, or as a mean score, were also unrelated to WTN level. Actigraphy-measured sleep latency, sleep efficiency, the rate of awakening bouts, and total sleep time were all found to be unrelated to WTN exposure. The only statistically significant finding found between WTN level and actigraphy was a reduced wake time after sleep onset among participants living in areas where WTN levels were 25–30 dB(A) and this was because of a higher WASO time at the lowest WTN category among PEI participants. The results of the current study do not support conclusions that exposure to WTN up to 46 dB(A) has any statistically significant effect on self-reported or objectively measured sleep. However, annoyance with blinking lights on wind turbines (used as aircraft warning signals) may be related to a higher rate of awakening bouts and reduced total sleep time.

This study has some important limitations. Objective measures of sleep were assessed for up to 7 d, whereas the PSQI and the reported highly sleep disturbed outcomes represent time periods of 30 d and 1 y, respectively. The concern is that 7 d of actigraphy may not represent long-term average sleep patterns. However, the selected time frame for actigraphy measures is typical, and supported in the literature and considered more than adequate for evaluating sleep in a nonclinical study sample.[30,61] If there were situational factors (e.g. an ill child) that made sleep worse in the actigraphy-assessed week, it would not be expected to bias against the effect of wind turbines on sleep, and in fact, would overstate the effect of recent situational events as compared to the long-term theoretical concern about WTN-induced sleep disturbance. As previously discussed, the analysis of actigraphy results was based on nightly average sleep patterns in relation to long-term WTN levels. Although WTN calculations would be expected to produce the highest sound pressure levels at the dwelling, they do not take into consideration the influence that night-to-night variations in outdoor WTN levels may have had on actigraphy results. Similarly, an analysis based on long-term average sound level does not fully account for transient deviations in WTN levels that could potentially interfere with sleep. An analysis based on a time-matched comparison between operational turbine data and actigraphy would permit a more refined assessment of the possible effect that night-to-night variations in WTN levels may have on sleep. These limitations extend to the fact that fluctuations in indoor sound levels during sleep remain unknown.

The possibility that wind turbine operators may have intentionally altered the output of their turbines in order to reduce potential WTN effects on sleep has been one of the concerns raised during the external peer review of this paper. When the *Community Noise and Health Study* was originally announced several months preceding data collection the study locations were unknown. Although awareness of the precise study locations would have become greater as data collection commenced, the deployment of the sleep watches took place over several months among a subsample of participants across the entire study sample. Furthermore, the reference period time for self-reported sleep disturbance was over the previous year and previous 30 d (PSQI). Finally, the subsets of sound power measurements were consistent with manufacturer-supplied data. In the authors' opinion, there is no evidence to suggest that wind turbine operators intentionally altered the output of their turbines to minimize potential effects on sleep at any point in the study.

CONCLUSIONS

The potential association between WTN levels and sleep quality was assessed over the previous 30 d using the PSQI, the previous year using percentage highly sleep disturbed, together with an assessment of diagnosed sleep disorders. These self-reported measures were considered in addition to several objective measures including total sleep time, sleep onset latency, awakenings, and sleep efficiency. In all cases, in the final analysis there was no consistent pattern observed between any of the self-reported or actigraphy-measured endpoints and WTN levels up to 46 dB(A). Given the lack of an association between WTN levels and sleep, it should be considered that the study design may not have been sensitive enough to reveal effects on sleep. However, in the current study it was demonstrated that the factors that influence sleep quality (e.g. age, body mass index, caffeine, health conditions) were related to one or more self-reported and objective measures of sleep. This demonstrated sensitivity, together with the observation that there was consistency between multiple measures of self-reported sleep disturbance and among some of the self-reported and actigraphy measures, lends strength to the robustness of the conclusion that WTN levels up to 46 dB(A) had no statistically significant effect on any measure of sleep quality.

The WHO's[11] health-based limit for protecting against sleep disturbance is an annual average outdoor level of 40 dB(A). This level was exceeded in 19% of the cases, but by no more than 6 dB(A) and as such represents a limit to detecting a potential effect on sleep. It is therefore important to acknowledge that no inferences can be drawn from the current results to areas where WTN levels exceed 46 dB(A). Likewise, assuming a baseline prevalence of 10%, the study was designed so that the statistical power would be sufficient to detect at least a 7% difference in the prevalence of self-reported sleep disturbance. A larger sample size would be required to detect smaller differences. The statistical power of a study design is a limitation that applies to all epidemiological studies.

Although it may be tempting to generalize the current study findings to other areas, this would have required random selection of study locations from all communities living near wind turbines in Canada. Despite the fact that participants in the study were randomly selected, the locations were not and for this reason the level of confidence one has in generalizing the results to other areas can only be based on a certain level of scientific judgment regarding the level of exposure and the similarity between the current study sample and others. Despite limitations in generalizing the results of this analysis beyond the study sample, the current study is the largest and most comprehensive analysis of both self-reported and objectively measured sleep disturbance in relation to WTN levels published to date.

NOISE AND HEARING LOSS

What is noise?

- ✓ Any disturbing, harmful, or unwanted sound.
- ✓ The most common hazard in the workplace or during training.
- ✓ The primary cause of hearing loss in the Army.

What are the different types of noise?

- ✓ Noise can be continuous, or steady.
  Examples include power tools, vehicles and aircraft.
- ✓ Noise can also be impulsive.
  Examples include explosions, weapons fire and certain metal-forming machinery.

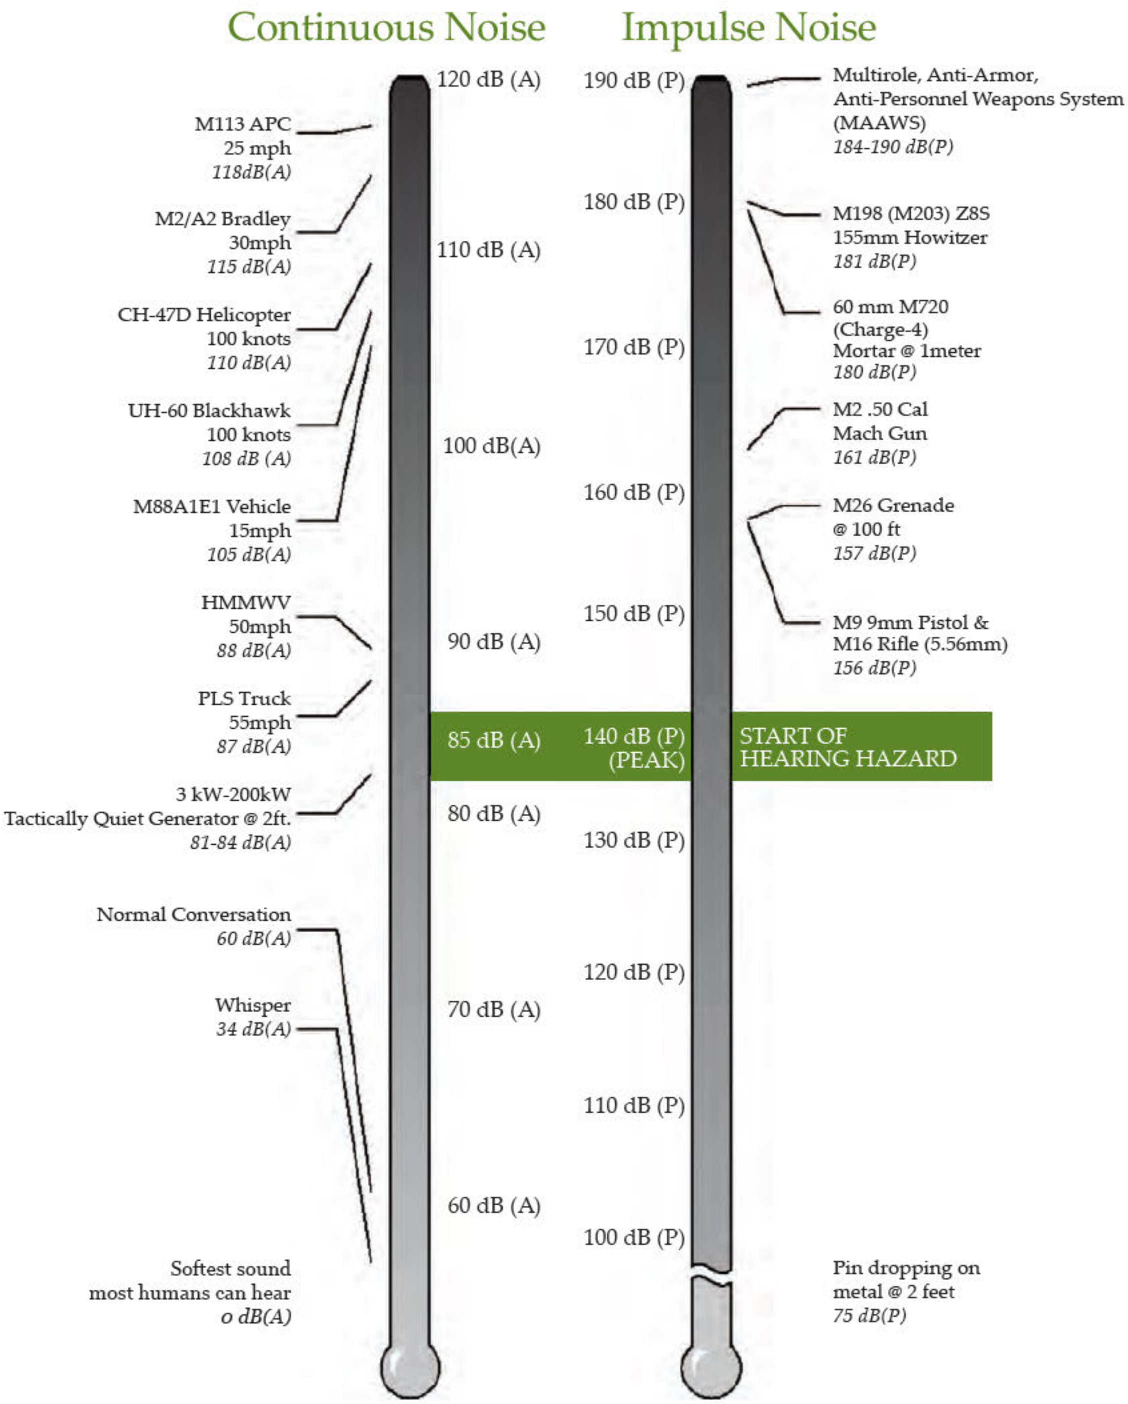
Will noise toughen your ears?

- ✓ No! Noise destroys your ability to hear and to understand speech.
- ✓ Military veterans are four times more likely to have hearing loss than non-veterans.
- ✓ Hearing loss and tinnitus (ringing in the ears) are the top two service connected disabilities for military veterans.

When and where can noise impair your hearing?

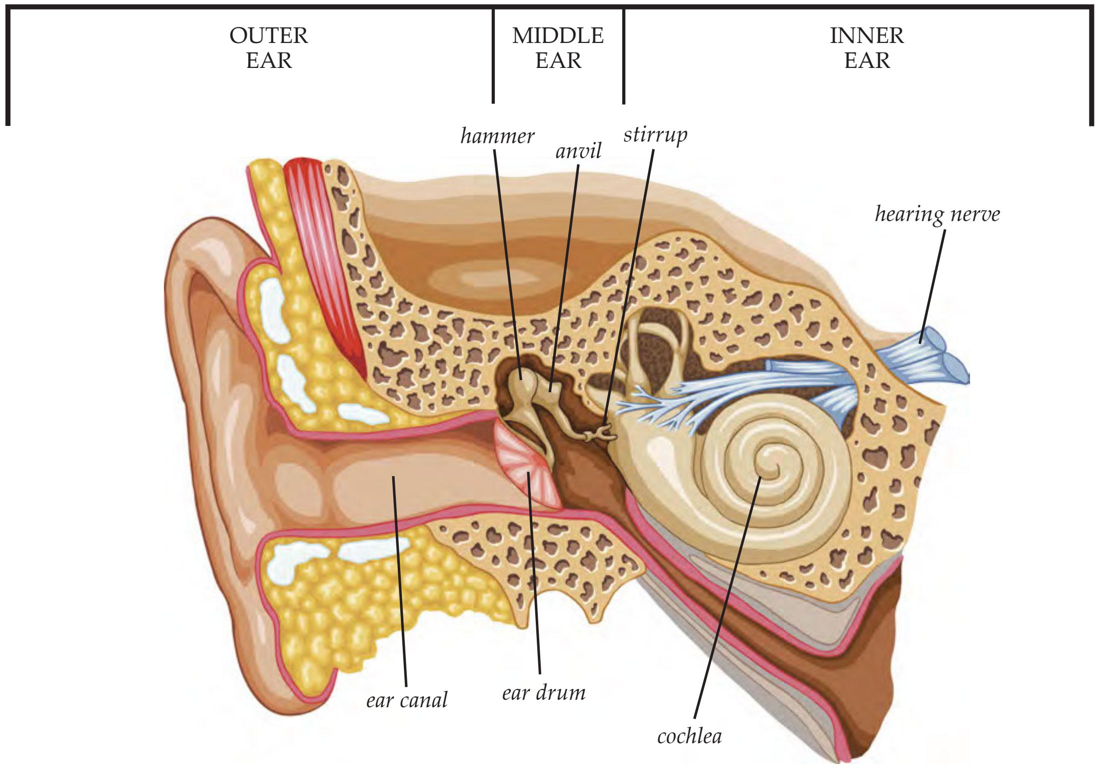
- ✓ During any weapon firing.
- ✓ Noise can damage your hearing at work, at home and during recreational activities.
- ✓ If you have to raise your voice to be heard, the noise is considered hazardous.
- ✓ Noise in combination with some chemical exposures can increase hearing damage, for example, toluene, lead, carbon monoxide, etc.

DECIBEL THERMOMETERS



HOW THE EAR WORKS

Your ear is divided into three parts.

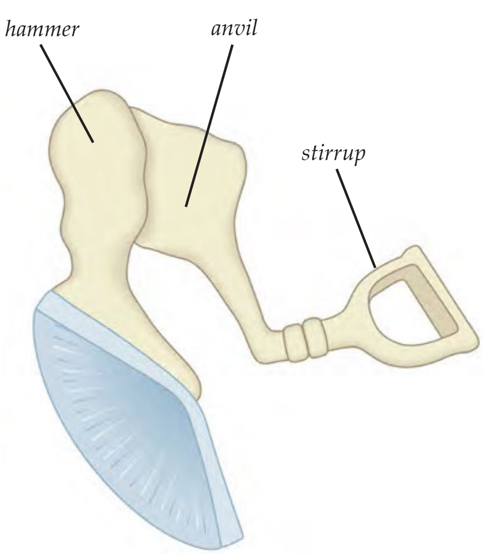


OUTER EAR

The outer ear directs sound waves into the ear canal to the eardrum. The eardrum vibrates and sets into motion part of the middle ear.

MIDDLE EAR

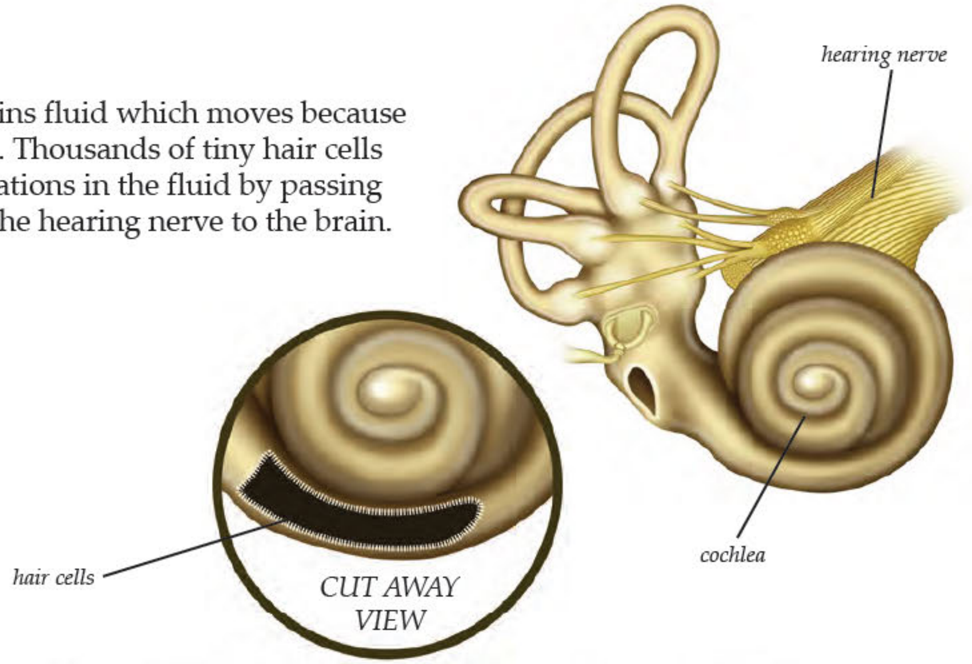
The middle ear contains the three smallest bones in your body—the hammer, anvil and stirrup. These bones vibrate and pass the sound waves into the inner ear.

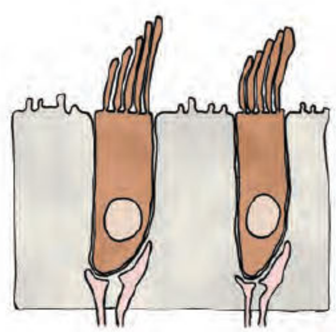


HOW THE EAR WORKS

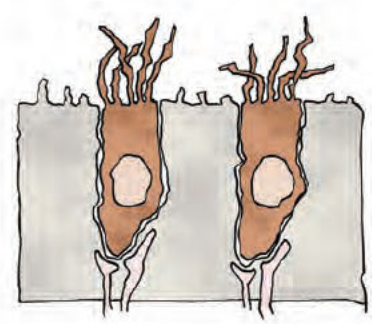
INNER EAR

The inner ear contains fluid which moves because of the sound waves. Thousands of tiny hair cells respond to the vibrations in the fluid by passing information along the hearing nerve to the brain.





HEALTHY HAIR CELLS



DAMAGED HAIR CELLS

Damage to your hair cells caused by intense noise could be seen as hearing loss on your next audiogram when your hearing is checked.

Hearing problems in the outer and middle ears are usually medically treatable. However, there is no proven cure for inner ear hearing loss caused by the noise.

Noise does not have to cause pain or bleeding to do damage.

CAUTION

*HIGH INTENSITY NOISE
HEARING PROTECTION
REQUIRED*

HEARING PROTECTORS

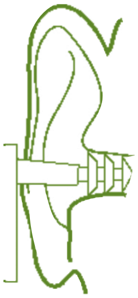
Earplugs and noise muffs are available at no charge to everyone who works in noise.

Make-shift protectors, such as cigarette filters, cotton or bullet casings do not protect you and they are not hygienic.

EARPLUGS

Preformed earplugs come in various types and sizes and need to be fitted by a medically-trained person. This type of hearing protection should be issued with a carrying case, the top lid of which serves as a inserting device for several types of earplugs.

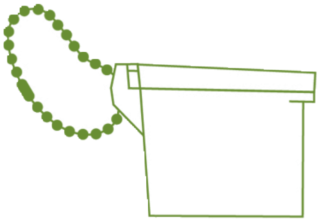
Triple-Flange earplugs are available in small, medium and large sizes.



Quad-Flange earplugs are available in one size fits many; however, its stem is too wide for use with the earplug inserting device.

Combat Arms Earplugs (CAE) are in their third generation. The current generation of CAE's come in earth tone colors and three different sizes with a toggle switch. The closed position protects from continuous and impulse noise, while the open position only protects from impulse noise but allows some softer sounds to be audible.

Earplug Inserting Device (Top) and Carrying Case



Sound-Guard foam earplug (two-color)

Foam earplugs come in small, medium and large and are semi-disposable.

For a proper fit:

✓ Roll and compress the plug into a very thin cylinder ensuring there are no wrinkles that may allow sound to get through.

✓ While compressed, quickly insert the plug well into the ear canal.

✓ Gently hold the plug in place until it expands to fill the entire ear canal.

Remember:

✓ Your voice will sound muffled or low-toned or muffled, as if in a barrel, when your earplugs are properly inserted.

✓ Adjusting to wearing earplugs may take a little time.

✓ You can be refitted with a different size and type.

✓ If using preformed earplugs such as triple or quad flanged, keep the earplugs clean with soap and water and use them only when dry.

NOISE MUFFS

When properly fitted, noise muffs form a seal around your ears. For proper maintenance, replace hardened or torn earcup seals and degraded acoustic foam padding.

REMEMBER, THE BEST HEARING PROTECTOR IS THE ONE THAT IS WORN!

HEARING TESTING

- ✓ All personnel who work in noise-hazardous areas need an annual hearing check.
- ✓ The first test serves as the reference (baseline) from which any future change or shift in your hearing is measured.
- ✓ You will be notified when your annual hearing check is due. At that time, your hearing protective devices need to be checked and, if necessary, replaced.
- ✓ An audiogram reflects the softest tones you are able to hear at low, middle and high frequencies. *(See page 9.)*
- ✓ When loud noise makes your hearing worse, damage usually occurs first in the higher frequencies. Then nearby frequencies are affected.

MODERATE LOSS
SEVERE LOSS
Poorest Hearing

READINESS AND HEARING LOSS

Why is protecting your hearing so important?

- ✓ Hearing loss caused by loud noise becomes permanent and is not medically treatable.
- ✓ Impaired hearing can cause serious or fatal mistakes at work or in training and combat situations.
- ✓ Good hearing is critical to the success of the mission, both in offensive and defensive operations.

Offensive & Defensive Operations

- ✓ Localizing snipers
- ✓ Locating patrol members
- ✓ Determining the position, number and type of friendly or enemy vehicles
- ✓ Determining types of booby traps
- ✓ Hearing the activation of perimeter alarms
- ✓ Hearing enemy movement through leaves, grass and twigs
- ✓ Determining enemy locations from the sounds of wildlife, loading of cartridges, safety locks and clipped barbed wire
- ✓ Aiding in small arms accuracy and weapons identification
- ✓ Hearing radio messages and verbal orders

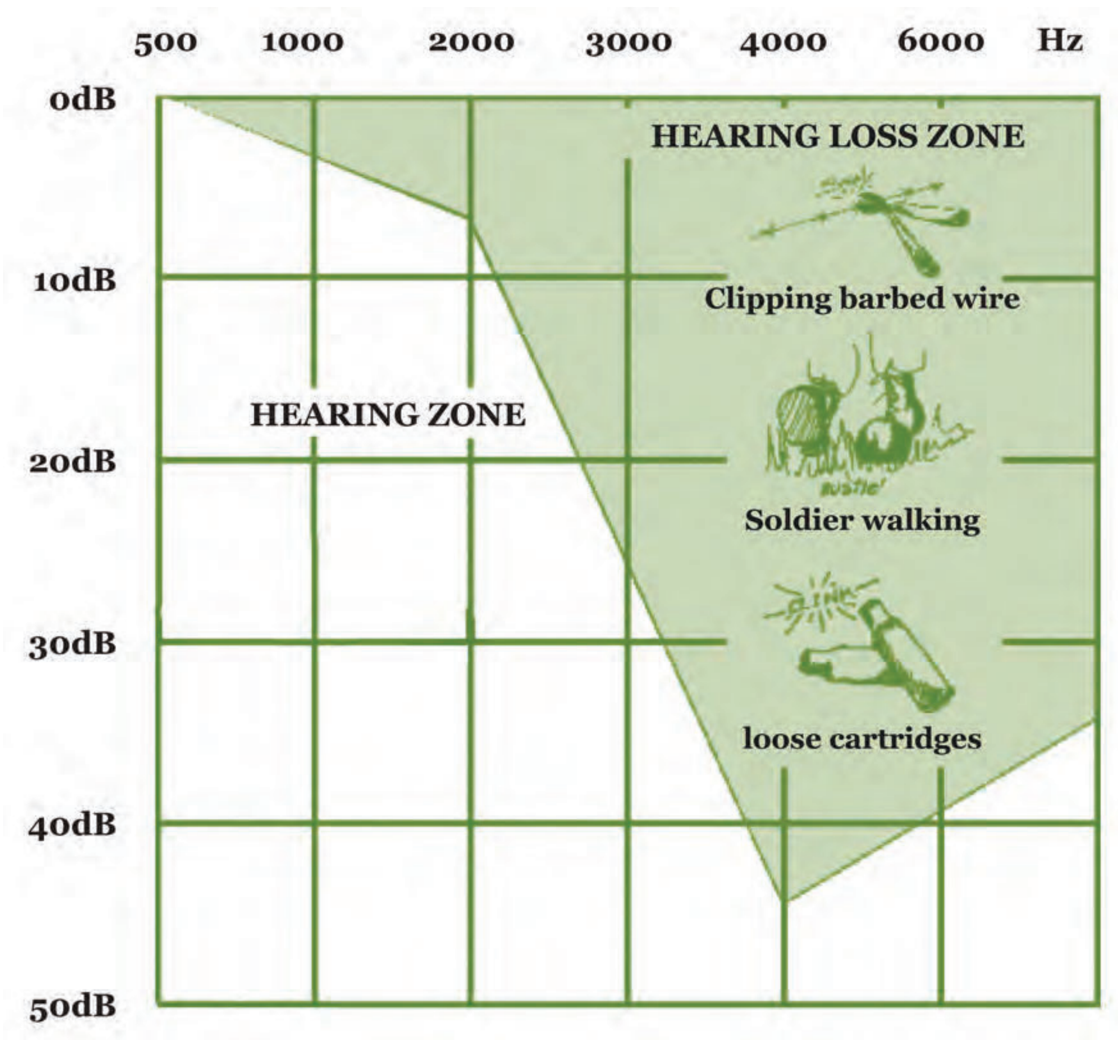
Remember:

- ✓ Early signs of hearing loss include ringing in the ears and speech sounds that are muffled.
- ✓ Speech and other sounds have to be louder to be heard or understood.

Noise Level, dBA	Permitted daily exposure time
85	8 HOURS
88	4 HOURS
91	2 HOUR
94	1 HOUR
97	30 MINUTES
100	15 MINUTES
103	7.5 MINUTES

What does a Soldier with a high frequency hearing loss miss in terms of readiness?

High-pitched combat sounds!



MOST NOISE-INDUCED HEARING LOSS OCCURS DURING TRAINING

HEALTH EDUCATION

✓ Each year you must receive additional training and information concerning your installation's hearing conservation program.

✓ You also have certain responsibilities as a participant in the hearing conservation program.

1. Wear your hearing protection when in hazardous noise.
2. Report for all scheduled hearing checks, including follow ups, if required.
3. Attend an annual health education briefing.
4. Maintain the engineering noise controls that are in place for your safety.

✓ Know your rights as a participant in the hearing conservation program.

1. You have the right to copy or access your hearing records.
2. You have the freedom to choose the type of hearing protective equipment you wish to wear, unless a medical reason limits your choice.
3. You have the right to copy or access the noise exposure data pertinent to your work site or duties.
4. You have the right to make suggestions that might lead to quieter equipment or less noise exposure for individuals you work with.

Summary

Insomnia disorder comprises symptoms during night and day that strongly affect quality of life and wellbeing. Prolonged sleep latency, difficulties to maintain sleep and early morning wakening characterize sleep complaints, whereas fatigue, reduced attention, impaired cognitive functioning, irritability, anxiety and low mood are key daytime impairments. Insomnia disorder is well acknowledged in all relevant diagnostic systems: Diagnostic and Statistical Manual of the American Psychiatric Association, 5th revision, International Classification of Sleep Disorders, 3rd version, and International Classification of Diseases, 11th revision. Insomnia disorder as a chronic condition is frequent (up to 10% of the adult population, with a preponderance of females), and signifies an important and independent risk factor for physical and, especially, mental health. Insomnia disorder diagnosis primarily rests on self-report. Objective measures like actigraphy or polysomnography are not (yet) part of the routine diagnostic canon, but play an important role in research. Disease concepts of insomnia range from cognitive-behavioural models to (epi-) genetics and psychoneurobiological approaches. The latter is derived from knowledge about basic sleep–wake regulation and encompass theories like rapid eye movement sleep instability/restless rapid eye movement sleep. Cognitive-behavioural models of insomnia led to the conceptualization of cognitive-behavioural therapy for insomnia, which is now considered as first-line treatment for insomnia worldwide. Future research strategies will include the combination of experimental paradigms with neuroimaging and may benefit from more attention to dysfunctional overnight alleviation of distress in insomnia. With respect to therapy, cognitive-behavioural therapy for insomnia merits widespread implementation, and digital cognitive-behavioural therapy may assist delivery along treatment guidelines. However, given the still considerable proportion of patients responding insufficiently to cognitive-behavioural therapy for insomnia, fundamental studies are highly necessary to better understand the brain and behavioural mechanisms underlying insomnia. Mediators and moderators of treatment response/non-response and the associated development of tailored and novel interventions also require investigation. Recent studies suggest that treatment of insomnia may prove to add significantly as a preventive strategy to combat the global burden of mental disorders.

anxiety, CBT-I, depression, insomnia, insomnia models, prevention, treatment guidelines

1 | DEFINITION AND DIAGNOSIS OF INSOMNIA DISORDER (ID)—DSM-5, ICSD-3, ICD-11

In the last 50 years all medical diagnostic classification systems have included ID. DSM (Diagnostic and Statistical Manual of the American Psychiatric Association) in its previous versions DSM-III-R/DSM-IV (American Psychiatric Association, 1987, 1998) suggested a distinction between primary and secondary insomnias, whereas DSM-5 (American Psychiatric Association, 2013) heralded a paradigmatic change by establishing ID as an overarching diagnostic category, eliminating artificial distinctions. The ICSD (International Classification of Sleep Disorders) in its third version (American Academy of Sleep Medicine, 2014) confirmed this new nosology (see Table 1; diagnostic criteria for chronic ID according to ICSD-3).

The ICD-10 (International Classification of Diseases, 10th edition; World Health Organization, 1993) distinguished between organic and non-organic sleep disorders; however, ICD-11 will follow the avenue paved by DSM-5 and ICSD-3 (World Health Organization, 2019). When analysing the "new" criteria for ID all systems list both night-time and daytime symptoms and, notably, the symptom of non-restorative sleep was dropped from the criteria due to lack of specificity.

Abandoning the distinction between primary/secondary insomnia constituted a major advance in acknowledging that insomnia frequently is not just a symptom of any other somatic or mental disorder, but constitutes an independent disorder, deserving specific consideration in clinical practice. It is important to note that insomnia probably more frequently occurs as a co-morbid condition together with somatic and mental disorders, than it does occur in its isolated form. DSM-5, ICSD-3 and ICD-11 pay respect to this by explicitly allowing co-morbidity. Furthermore, it turned out that cognitive-behavioural treatment for insomnia (CBT-I) not only has decisive effects on sleep/insomnia complaints, but also positively influences somatic/mental co-morbidities and quality of life. At present, evidence is accumulating that insomnia treatment with CBT-I may even have surplus benefits with respect to general treatment and prevention especially of mental disorders (Benz et al., 2020; Cheng et al., 2019; Hertenstein et al., 2022; Irwin et al., 2022; Leerssen et al., 2021).

Nevertheless, ID as a "one size fits all" category is seen critical by many working in the field. There is still a lively and ongoing discussion about different insomnia phenotypes, for example focussing on the main nocturnal complaint, that is, insomnia with or without "objective" short sleep (Vgontzas et al., 2013), or sleep-onset insomnia versus sleep-maintenance insomnia (Pillai et al., 2015). Indeed, the profile of dominant sleep complaints matters for the risk of developing first-onset major depressive disorder (Blanken et al., 2020). However, subtyping based on sleep characteristics may not be that robust, even across 2 nights (Johann et al., 2017), let alone across months or years (Edinger et al., 2011). Apparently, insomnia complaints change over time. More robust insomnia subtypes surfaced by multivariate profiling of personality features rather than sleep features (Blanken, Benjamins et al., 2019).

As it would be beyond the scope of this article to comprehensively describe the diagnostic and differential diagnostic procedure for insomnia, the interested reader is referred to Riemann et al. (2022) and other textbooks (Sateia & Buysse, 2010). Some important issues

TABLE 1 Diagnostic criteria for chronic ID according to ICSD-3 (AASM, 2014)

A. The patient reports, or the patient's parent or caregiver observes, one or more of the following:
   1. Difficulty initiating sleep.
   2. Difficulty maintaining sleep.
   3. Waking up earlier than desired.
   4. Resistance to going to bed on appropriate schedule.
   5. Difficulty sleeping without parent or caregiver intervention.
B. The patient reports, or the patient's parent or caregiver observes, one or more of the following related to the night-time sleep difficulty:
   1. Fatigue/malaise.
   2. Attention, concentration or memory impairment.
   3. Impaired social, family, occupational or academic performance.
   4. Mood disturbance/irritability.
   5. Daytime sleepiness.
   6. Behavioural problems (e.g. hyperactivity, impulsivity, aggression).
   7. Reduced motivation/energy/initiative.
   8. Proneness for errors/accidents.
   9. Concerns about or dissatisfaction with sleep.
C. The reported sleep/wake complaints cannot be explained purely by inadequate opportunity (i.e. enough time is allotted for sleep) or inadequate circumstances (i.e. the environment is safe, dark, quiet and comfortable) for sleep.
D. The sleep disturbance and associated daytime symptoms occur at least three times per week.
E. The sleep disturbance and associated daytime symptoms have been present for at least 3 months.
F. The sleep/wake difficulty is not better explained by another sleep disorder.

Abbreviation: ICSD-3, International Classification of Sleep Disorders, 3rd version.

concerning diagnostic procedures, however, should be highlighted here. The use of sleep diaries constitutes an integral part of insomnia assessment for both research and/or clinical purposes (e.g. consensus sleep diary by Carney et al., 2012). Sleep diaries are easy to apply and to evaluate. Sleep diaries focus on the experience of sleep and can be reviewed by the clinician as they are presented, but the inherent information can also be used to create highly informative graphical displays of sleep and bedtimes (Figure 1).

Beyond sleep diaries, other insomnia-specific questionnaires like the Insomnia Severity Index (Bastien et al., 2001) or the Sleep Condition Indicator (Espie et al., 2014) should be used.

For both clinical and fundamental research, it is favourable to take note of the recommendations for a standard research assessment of insomnia (Buysse et al., 2006). Several paradigms were developed to elucidate specific aspects of insomnia, for example, the attentional bias paradigm (Espie et al., 2006; Harris et al., 2015). This paradigm suggests that patients with chronic insomnia have developed a bias in their perception and processing of stimuli related to insomnia. Other highly promising paradigms investigate failing overnight amelioration of distress, which seems key to persistence of hyperarousal (Wassing et al., 2016; Wassing, Benjamins et al., 2019; Wassing, Lakbila-Kamal, et al., 2019; Wassing, Schalkwijk, et al., 2019). At present, not yet being ready for standard clinical practice, it is conceivable that these paradigms might be used in the future to measure responsiveness to CBT-I, also in combination with neuroimaging methods.

As the diagnosis of insomnia is solely based on subjective complaints and their measurement, it remains a matter of long-standing debate what the role of technical methods like actigraphy or polysomnography (PSG) might be. It is a highly controversial issue as to whether PSG should be part of the diagnostic process. Doubtlessly PSG helps to unravel suspected occult pathology of sleep, that is, periodic limb movements during sleep (periodic limb movement disorder) or sleep apnea (obstructive sleep apnea syndrome). US guidelines clearly deny the usefulness of PSG to diagnose insomnia (Kushida et al., 2005), whereas guidelines of the German and the European Sleep Research Society (Riemann, Baum, et al., 2017; Riemann, Baglioni, et al., 2017) suggest that PSG be used for patients with therapy-refractory insomnia who have not responded to a previous adequate "dose" of pharmaco- or psychotherapy.

The frequently described discrepancy between subjective (i.e. data from sleep diaries) and objective data (PSG) called paradoxical insomnia or sleep state misperception is seen as a major clinical and scientific challenge. PSG contrasted with subjective data does not reveal as pronounced disturbances of sleep as indicated by subjective data (Feige et al., 2008). A PSG meta-analysis revealed mean total sleep time differences between insomnia and good sleepers of about 25 min, whereas subjective estimates demonstrated an almost 2-hr difference (Baglioni, Regen, et al., 2014; Baglioni, Spiegelhalder, et al., 2014). Traditional PSG reveals only a glimpse of the brain activity during sleep. Advanced analyses have commenced to reveal electroencephalogram (EEG) correlates of subjective wakefulness during sleep, like simultaneous wake-like and sleep-like brain activity in people with insomnia (Christensen et al., 2019; Stephan et al., 2021). Furthermore, classification of individual insomnia patients based on their PSG and EEG power-spectral variables can distinguish between those with objective short sleep and those with sleep state misperception (Kao et al., 2021). Accordingly, the "misperception" may in fact be "mismeasurement": an inappropriate use or interpretation of traditional PSG features by clinicians, rather than inappropriate interpretation of subjective experiences by people with insomnia. It is important to bear in mind that these same challenges apply to mental disorders in general. There is no objective "test" for depression, anxiety or psychosis. The validation of any such tests needs to apply self-report coupled with clinical judgement as the "gold-standard."

Vgontzas and colleagues have postulated that the long-term health consequences of insomnia may be related specifically to objective short sleep duration of less than 6 hr (Vgontzas et al., 2013). However, patients with short sleep insomnia during one night do not fulfil that criteria on another night, and an increased risk of hypertension in short sleeping insomnia could not be replicated (Johann et al., 2017). Also, the hypothesis that the presence of objectively documented short sleep may be of relevance for the choice of therapy (Riemann et al., 2011), that is, pharmacotherapy for insomnia patients with objective short sleep duration versus psychotherapy for insomnia patients with objective normal sleep duration, has yet to be resolved and deserves further consideration (Vgontzas et al., 2013). More details will be provided in the aetiology/pathophysiology section. Figure 2 gives some examples of PSG determined sleep profiles of a good sleeper and two patients with ID.

2 | EPIDEMIOLOGY OF INSOMNIA AND INSOMNIA AS A RISK FACTOR FOR OTHER DISORDERS

Insomnia more frequently afflicts females than males (60% versus 40%), and its prevalence increases with age (for an overview, see Ohayon, 2002). The European Academy for CBT-I has summarized prevalence data for ID across some European countries (Baglioni et al., 2020), varying strongly from country to country. Data for Germany indicate a prevalence of 5.7%, whereas French surveys indicate figures up to 20%. On average, approximately 10% of the adult European population suffer from chronic insomnia. The heterogenous data clearly stress the need for the prospective collection of pan-European samples with state-of-the-art methods to obtain the full picture for planning of insomnia healthcare services.

The costs of insomnia for the individual and society are staggering: it was demonstrated that insomnia conveys increased risks for cardiovascular diseases (Li et al., 2014), obesity and diabetes (Anothaisintawee et al., 2016; Chan et al., 2018), depression (Baglioni et al., 2011; Hertenstein et al., 2019), anxiety (Hertenstein et al., 2019) and suicide (Pigeon et al., 2012). Wickwire (2019) reported that untreated insomnia leads to increased all-cause healthcare utilization based on a randomly selected and nationally representative sample from the USA. Data from Norway indicate that insomnia strongly predicts sick leave and disability pension (Overland

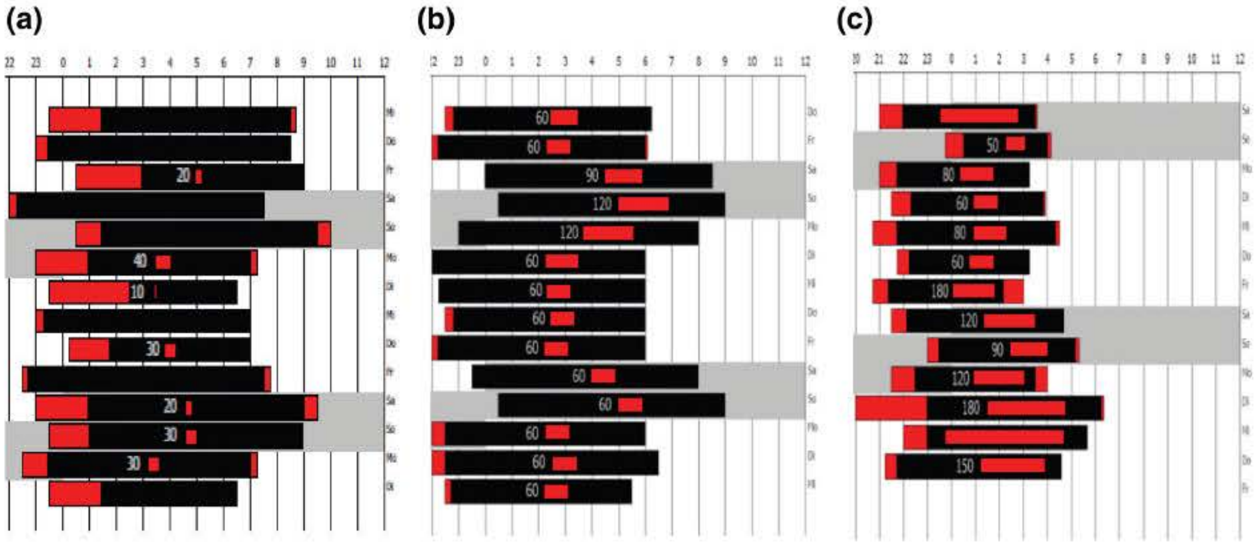

FIGURE 1 Sleep diary data from different patients with insomnia. (a) An insomnia patient who shows an increased sleep-onset latency. (b) A patient with insomnia experiencing difficulty in maintaining sleep. (c) A patient with mixed insomnia showing difficulty in both sleep onset and sleep maintenance

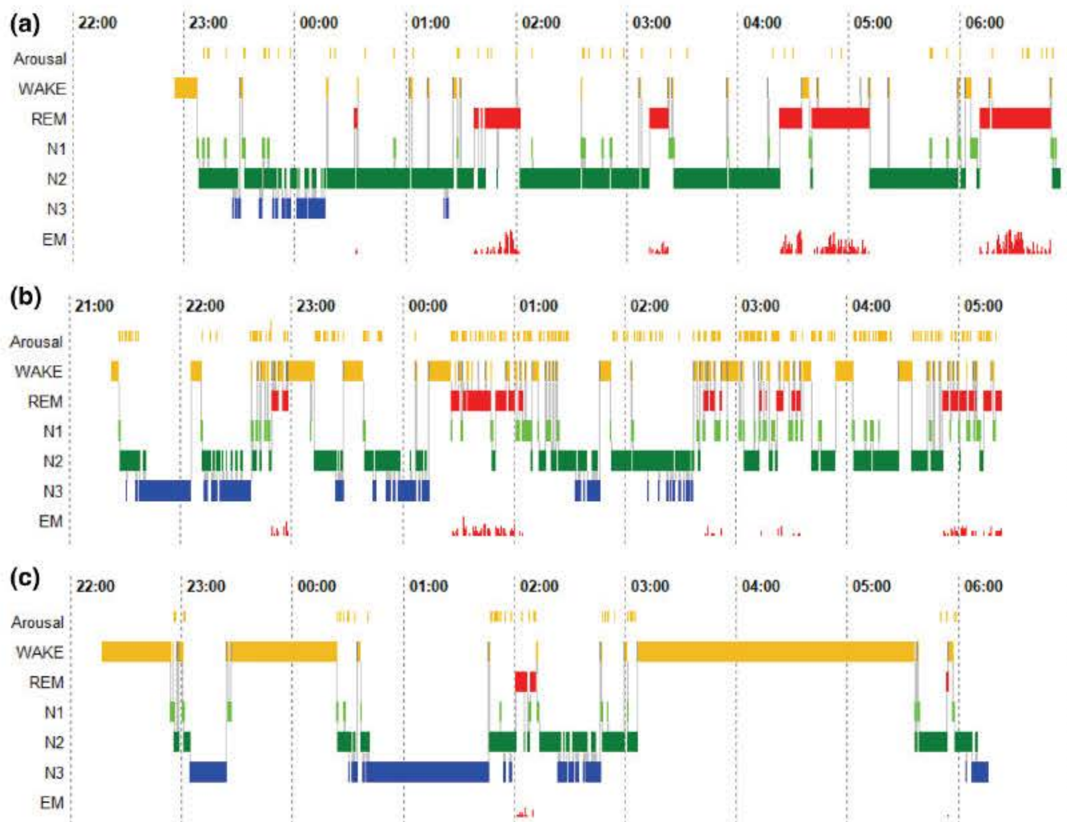

FIGURE 2 Polysomnographic (PSG) profiles of a good sleeper (upper panel; a) and patients with insomnia (lower panels; b,c). The *y*-axis displays arousal (micro-arousals), wake and sleep stages (rapid eye movement [REM], stage N1, N2 and N3) as well as eye movements. The *x*-axis is the time axis. (b) A patient with insomnia who has only a slightly reduced total sleep time, but a high number of arousals during sleep and a fragmented REM sleep. (c) A patient with insomnia who has an objectively shortened sleep duration

et al., 2008; Sivertsen et al., 2009). Data from France indicated a sum of 2 billion USD in 1995 (Leger et al., 1999). Data from the USA resulted in a sum of 150 billion US dollars for direct and indirect costs of insomnia (Reynolds & Ebben, 2017). A Canadian study (Daley et al., 2009) reported total annual costs for ID alone to be about 6.5 billion Canadian dollars. Recent data indicate that treatment using digital CBT-I reduces healthcare expenditure, and Markov health economic modelling indicates that digital CBT-I may be highly cost-effective when offered at scale (Darden et al., 2021). Further details of the costs and risks of insomnia are given in the European Academy for Cognitive Behavioural Therapy for Insomnia Report (Baglioni et al., 2020). An important clinical and research question relates to the hypothesis that adequate insomnia treatment might not only effectively target insomnia symptoms but might reduce subclinical and clinical psychopathology, and also be of general preventive value for mental disorders and physical diseases.

3 | AETIOLOGICAL AND PATHOPHYSIOLOGICAL CONSIDERATIONS

Recent reviews synthesized current neurobiological, cognitive, behavioural and emotional models for insomnia and its relationship to psychopathology (Figure 3; Espie, 2022; Riemann et al., 2020; Van Someren, 2021).

Current theoretical approaches span from cognitive-behavioural to neurobiological models, and models taking into account both levels simultaneously.

The basic structure of the model depicted in Figure 3 is taken from the so-called 3P model of insomnia (Spielman et al., 1987). The 3Ps signify: predisposing, precipitating and perpetuating factors.

"Predisposing" factors come from the areas of (epi-)genetics and early life stress that contribute to individual differences at the level of brain function and personality. Genetic and epigenetic factors have been shown to be involved in the aetiology of insomnia by family and twin studies (for an overview, see Palagini et al., 2014). Genome-wide association studies point to an involvement of a very large number of genes, each with a very small contribution, and shared genetic factors for insomnia and restless legs, cardiometabolic, and especially psychiatric traits (Jansen et al., 2019; Lane et al., 2019). Interestingly, the brain tissues and cell types expressing sets of insomnia risk genes are not primarily part of the known circuitry regulating sleep but are rather part of circuitries involved in emotion regulation (Van Someren, 2021).

Still, for completeness, a discussion on the development and maintenance of insomnia should include the neurobiological mechanisms of sleep, notably homeostatic and biological time-keeping mechanisms (Borbély, 1982). The flip-flop switch model of sleep regulation (Saper et al., 2005) suggests a bistable switch mechanism between sleep and wake promoting centres of neuronal cell groups. Wakefulness is governed by a network of cell populations in the hypothalamus (including orexinergic neurons), basal forebrain and brain stem, activating thalamus and cortical structures. These structures include and extend beyond the cell groups in the reticular formation of the brainstem (originally described as ascending reticular activating system). The main sleep-inducing centres are located in the ventrolateral-preoptic nucleus (VLPO), which becomes active during sleep and inhibits all major wake-promoting centres in the hypothalamus and brain stem, with the neurotransmitters galanin and gamma-aminobutyric acid. The VLPO receives afferent input from each of the major monoaminergic systems, and is inhibited by noradrenaline and serotonin. A mutual inhibitory circuit between both systems, the wake and the sleep system, leads to a flip-flop switch with "sharp" transitions between sleeping and waking. Thus, insomnia on this level can be conceptualized as imbalance between sleep-inducing and wake (i.e. arousal)-inducing mechanisms. A hyperactivity of the arousal system or a hypoactivity of the sleep system or both simultaneously could thus "drive" the insomnia. Circadian and homeostatic mechanisms are also involved in this switch process, and it has been speculated that a dysfunctional "key switch" (see above) could play a role in the pathogenesis of insomnia. According to the two-process model of sleep regulation (Borbély, 1982), sleep–wake behaviour is governed by circadian time-keeping mechanisms and a homeostatically controlled process S, representing the sleep drive. Being out of synchrony with the internal body clock (e.g. due to shift work) or having a decreased sleep drive would logically result in sleep complaints. Indeed, the main effective component of CBT-I, sleep restriction, is hypothesized to act on the sleep drive (Maurer et al., 2018), and long-term effectiveness of CBT-I improves with the addition of circadian interventions (Dekker et al., 2020; Leerssen et al., 2021). Notwithstanding these effects, decades of research in insomnia have failed to reveal circadian and homeostatic mechanisms as primary factors involved the origin and pathophysiology of the majority of people suffering from ID (Van Someren, 2021). One might conclude that enhancement of homeostatic sleep pressure and support of circadian rhythm amplitude alleviates insomnia, but that we may have to look beyond hourglass and clock to find underlying causes predisposing to insomnia.

A third factor involved in sleep and predisposing to insomnia is emotion (Saper et al., 2005). This factor is frequently overlooked, in spite of the ubiquitous experience that sleep initiation is difficult under threatening conditions—no matter what our hourglass and clock suggest. Indeed, from an evolutionary perspective this would be extremely disadvantageous. An increasing number of observations suggests a key role of this third factor in the origin and pathophysiology of the predisposition to insomnia (for review, see Van Someren, 2021). For example, the trait to exhibit a pronounced disturbed sleep response to stressful events has been shown to be a major risk factor for insomnia (Drake et al., 2014). Also other personality traits related to emotion regulation have been linked to insomnia, including neuroticism, perfectionism, sensitivity to anxiety symptoms, and the tendency to internalize problems (Dekker et al., 2017; van de Laar et al., 2010). The major early developmental factors predisposing to insomnia involve emotion as well: risk genes seem to have a preference for brain circuitries involved in emotion regulation, and early childhood adversity likewise affects these circuitries (Van Someren, 2021).

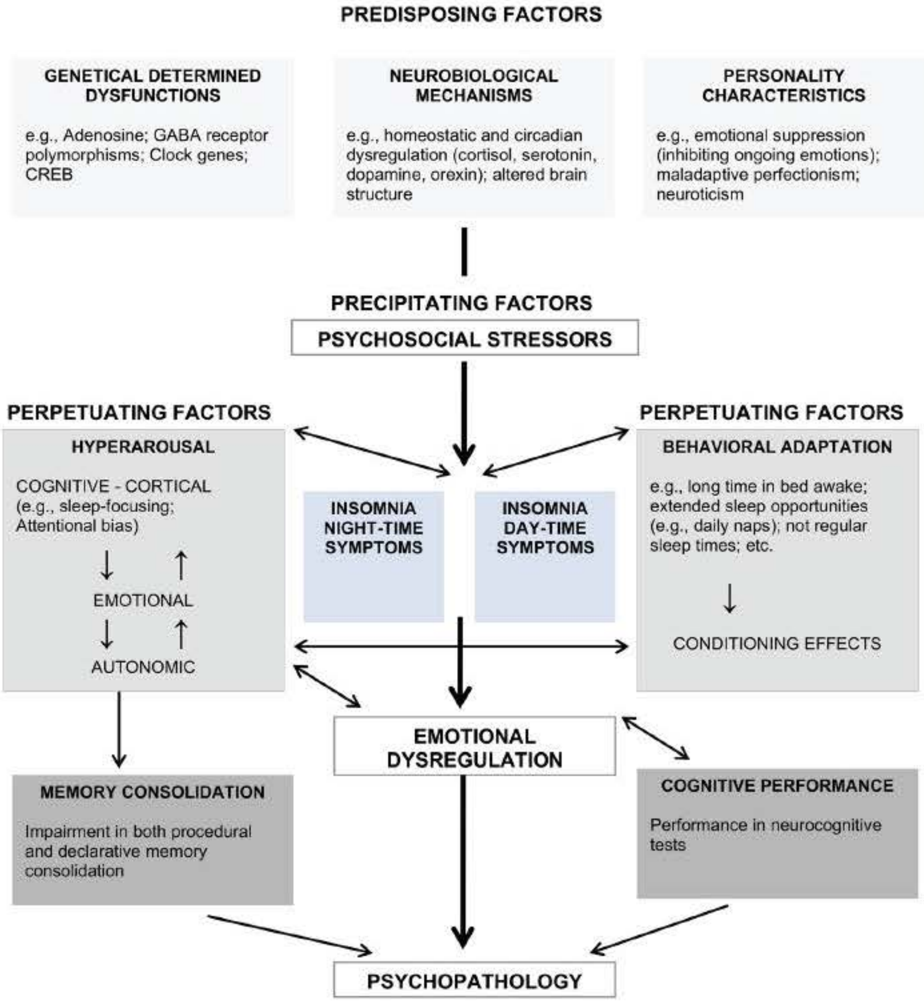

FIGURE 3 Comprehensive insomnia model (see text)

"Precipitating" factors can be readily identified in many cases. These are usually significant life events that facilitate the onset of acute episodes of insomnia. Most frequently, reported triggers of acute episodes of insomnia are stressful life events related to a threat of security to family, health and work–school living that are coupled with negative emotional valence. Fortunately, not everyone exposed to stress in adulthood develops insomnia, most likely only those that have a predisposing profile.

"Perpetuating" factors can be discussed with respect to hyperarousal, which can be conceptualized as overactivity of the arousal-promoting systems, out of balance with the activity in sleep-inducing systems. Hyperarousal includes physiological, cognitive and emotional components, and has been considered a stable characteristic of people with insomnia both during the night and during the day (Morin et al., 2015; Riemann et al., 2010, 2015). It has been demonstrated that patients with insomnia show increased levels of autonomic activity (though the issue is discussed critically with respect to heart rate variability; Dodds et al., 2017) and an overactivity of the HPA-axis, as documented by increased levels of cortisol output during day- and night-time (see meta-analysis by Dressle et al., 2022). Central nervous system (CNS) indicators of hyperarousal in people with insomnia are increased amounts of micro-arousals and increases in fast EEG frequencies (in the sigma and beta bands) during sleep (Christensen et al., 2019; Feige et al., 2013; Perlis et al., 1997, 2001; Spiegelhalder et al., 2012), and also wake EEG shows signatures of increased excitation (Colombo, Ramautar, et al., 2016; Colombo, Wei, et al., 2016) and somatic awareness and responsivity (Wei et al., 2016; Wei, Blanken, & Van Someren, 2018; Wei, Ramautar, et al., 2018). Although still too small for voxel-wise consistent findings (Tahmasian et al. 2018), the rapidly increasing number of neuroimaging studies on insomnia (Riemann et al., 2015) suggests an overactivity of cortico-limbic networks relative to sleep-promoting neuronal networks. Most interestingly, in recent years a special role of rapid eye movement (REM) sleep disturbance (REM sleep instability/restless REM sleep) has been postulated to be of utmost relevance for the experience of insomnia, and specifically their altered perception of sleep and inability to discard hyperarousal (Riemann et al., 2012; Van Someren, 2021). This lead was primarily based on the finding of increased micro-arousals during REM sleep in insomnia (Feige et al., 2008)—further studies revealed that upon awakening out of REM sleep, patients with insomnia more frequently stated having been awake compared with non-REM (NREM) sleep and good sleepers (Feige et al., 2018). Following up on these findings, Feige et al. (2021) used an event-related potentials paradigm to demonstrate that ID patients differed from good sleepers by showing reduced P2 amplitudes only in phasic REM sleep. These studies highlight a special role of REM sleep for insomnia.

The mechanisms underlying this special role of REM sleep in the predisposition, perpetuation and psychiatric consequences were addressed in a series of seminal studies (Wassing et al., 2016; Wassing, Benjamins, et al., 2019; Wassing, Lakbila-Kamal, et al., 2019; Wassing, Schalkwijk, et al., 2019). In brief, Wassing et al. showed that the restless REM sleep that is characteristic of people with insomnia interferes with overnight adaptation in limbic circuits of the brain. The consequential difficulties with dissolving of distress could be key to the development and perpetuation of hyperarousal as well to the risk of developing psychiatric disorders, as supported by other studies (Halonen et al., 2021; Pesonen et al., 2019). Restless sleep lacks the prolonged silencing of the locus coeruleus and consequential drop in cerebral noradrenaline that characterizes normal restful REM sleep (Kjearby et al., 2020). Because REM sleep is a period of pronounced limbic reactivation of emotional memory traces, it has been hypothesized that the increased level of noradrenaline during restless REM sleep interferes with the synaptic plasticity processes underlying adaptation of the neuronal engrams that represent distress, and could even result in sensitization, indicating maladaptive sleep (Van Someren, 2021). Others have proposed that the low level of noradrenaline during REM sleep is key to restore the noradrenergic tone, to enable a low tonic and high phasic locus coeruleus activity during wakefulness (Goldstein & Walker, 2014).

Restless REM sleep thus has a specific contribution to "emotional" perpetuating factors, and may explain why patients with insomnia are so prone to develop anxiety and depressive disorders in the long run. Indeed, sleep has been conceptualized as a basic psychophysiological process that is fundamental for stress, behaviour and emotion regulation (Hagger, 2010; Palmer & Alfano, 2017). Consistently, most mental disorders are associated with sleep impairment (Baglioni et al., 2016), and insomnia-related problems in children have been linked with difficulties in socio-emotional development (Sadeh et al., 2014; Vermeulen et al., 2021). In adults, insomnia has been found to be a predictor of years-long lingering of emotional distress (Wassing et al., 2016; Wassing, Lakbila-Kamal, et al., 2019), of depression, and of anxiety disorders (Baglioni et al., 2011; Hertenstein et al., 2019; Leerssen et al., 2021). Experimental studies have shown that patients with insomnia report more negative emotions than good sleepers (McCrae et al., 2008; Scott & Judge, 2006). Psychophysiological studies have also evidenced an emotional bias in people with insomnia to sleep-related stimuli with negative valence compared with good sleepers (Baglioni et al., 2010; Baglioni, Spiegelhalder, et al., 2014).

Perpetuating factors also include inadequate "behaviours", like prolonged bedtimes, irregular sleep–wake schedules, napping during the day and other maladaptive behaviours, such as using alcohol to combat insomnia. Usually, these strategies are attempted to compensate for lost sleep; however, in the end insomnia is maintained and exacerbated by decreasing sleep drive.

In addition, "cognitive perpetuating factors" have been identified, such as beliefs, worry and attentional bias (Espie, 2002; Harvey, 2002; Morin et al., 2007). These cognitions include unrealistic beliefs about sleep requirements and excessive worry for not meeting these standards. In recent years, the literature has emphasized the role of selective attention processes in people with insomnia. Specifically, it has been argued that the attentional system of patients with insomnia may be abnormally sensitive to sleep-related information (Harris et al., 2015). It has been hypothesized that such attention bias may exacerbate sleep-related rumination and lead to sleep effort (Espie et al., 2006; Harvey, 2002).

Summarizing, acute precipitating life events can "set the wheels in motion"—acute insomnia is triggered. The question of why most individuals who develop acute insomnia do not go on to develop the chronic condition has not yet been clarified (Ellis et al., 2012)—but likely involves genetic and early life stress-induced neurobiological vulnerability to keep "the train rolling." A complex network of associated symptoms including cognitive-, emotional- and cerebral hyperarousal, unstable REM sleep and maladaptive behaviours will keep the furnace burning. Sleep-preventing learned associations (conditioning effects) are strongly involved in this process as well, giving credit to Bootzin's assumption that in insomnia the original connection between the bed (stimulus) and the behaviour of sleep (response) has been lost or "unlearned" (Bootzin et al., 1991).

The CBT-I (see below) mainly targets the perpetuating factors, for example, relaxation techniques and mindfulness aim to address psychophysiological hyperarousal; sleep hygiene, stimulus control and sleep restriction try to correct maladaptive behaviours and enhance sleep drive; whereas cognitive strategies aim to alter "racing thoughts", dysfunctional beliefs and attitudes, and to reduce nocturnal worrying and ruminations.

4 | TREATMENT (S)—FOCUS ON PSYCHOLOGICAL APPROACHES: PRESENT GUIDELINES, WHAT IS CBT-I, STEPPED CARE AND DIGITAL CBT-I?

All insomnia-related guidelines published in the last 5 years agree that CBT-I should be the first-line treatment for insomnia, based on the accumulated scientific evidence from the literature. These guidelines include the American College of Physicians (Brasure et al., 2016; Kathol & Arnedt, 2016; Qaseem et al., 2016; Wilt et al., 2016), the American Academy of Sleep Medicine (AASM; Edinger et al., 2021a, b), the German and the European Sleep Society (Riemann, Baum, et al., 2017; Riemann, Baglioni, et al., 2017), and the British Association for Psychopharmacology consensus statement (Wilson et al., 2019). Overall, these guidelines make a strong case for CBT-I as first-line treatment for insomnia, and hypnotics are recommended for short-term use and only if CBT-I is either not available or ineffective. As hypnotics in this context, melatonin agonists, benzodiazepines, benzodiazepine receptor antagonists, some sedating antidepressants and orexin receptor antagonists are recommended mainly for short-term use (less than 4 weeks) only. An overview of the present state of hypnotic treatment can be found in reviews (Herring et al., 2019; Riemann & Nissen, 2012; Roehrs & Roth, 2012).

The CBT-I comprises a family of interventions and is not "one" homogenous therapeutic strategy *per se* (Table 2).

The CBT-I is in essence a multicomponent approach, comprising cognitive and behavioural parts, within each of which domain there is a wide range of treatment options. The principal behavioural therapies are sleep restriction and stimulus control. Cognitive techniques include reappraisal, cognitive control and paradoxical intention. There is also a range of relaxation therapies, and sleep hygiene education, although not effective as a standalone treatment, is commonly part of the CBT-I toolkit. A brief description of these techniques is given in the table. For further details, the interested reader is referred to a new CBT-I textbook that will be published in 2022 (Baglioni et al., 2022). A new clinician handbook on insomnia will also be available shortly (Espie, 2022).

Logically therefore CBT-I is not "a treatment" but is "a system of cognitive and behavioural therapeutics", akin to pharmacotherapy (which is not a drug treatment but a "pharmaceutical approach" to clinical care; Espie, 2022). The history of evidence-based psychotherapy (in most disorders) reveals a period of time during which there was a tendency towards "lumping" of therapeutic elements, rather than the creation of precision techniques that "may" be used in combination. This is certainly true of the non-pharmacological management of insomnia, and the term CBT-I has for the past 20 years or more been used rather generically in the literature because the majority of studies have deployed a CBT-I package.

In earlier times there was a focus upon more specific interventions. For example, comparing the effectiveness of abbreviated progressive relaxation, stimulus control therapy and paradoxical intention (Espie et al., 1989), or even investigating components of a single therapy (Woolfolk & McNulty, 1983: compared progressive relaxation, progressive relaxation without tension release, imagery with tension release, and imagery without tension release). Interestingly, of late, there has been renewed interest in single-component therapies. We now find ourselves unpicking or deconstructing CBT to evaluate its active component treatments, and even its active treatment ingredients. The best example is sleep restriction therapy (SRT), widely regarded to be the most effective element of CBT (Edinger et al., 2021a; Maurer, Schneider et al., 2021). A series of laboratory-based experiments has recently explored the homeostatic, arousal and circadian mechanisms of sleep restriction (Maurer et al., 2020, 2022; Maurer, Ftouni et al., 2021).

In support of this is the fact that CBT protocols are effective even when they vary. The AASM practice parameters task force recently grappled with the question, what are the "minimal characteristics" of effective CBT (Edinger et al., 2021a). They concluded that "all studies included SRT, stimulus control and some form of cognitive therapy"; however, the cognitive component varied widely. Whether or not relaxation strategies or sleep hygiene were included in the CBT-I regimen varied across studies as well. It was beyond the scope of this (group) to recommend a specific CBT protocol, and "these variations did not appear to systematically impact the effectiveness of the treatment" (p. 261). This evidences the versatility and robustness of what is sometimes now referred to as CBTx (cognitive and behavioural therapeutics), that is, a "therapeutic formulary", where not everyone needs the same content, or the same order of content (Espie, 2022). Analysis of how SRT is configured suggests there is gross variability between studies and protocols (Kyle et al., 2015); it would be prudent to establish what is the most effective combination of SRT parameters, including tailoring to presenting insomnia phenotype. Indeed, the widespread development of "precision medicine" (Ginsburg & Willard, 2009; Jain, 2002) has spawned interest in how "personalized behavioural sleep medicine" for insomnia may evolve in the future (Kyle et al., 2014).

Despite the impressive evidence base for CBT-I, its recognition internationally as the treatment of first choice for the management of insomnia and the fact that the CBTx formulary of treatments is quite wide ranging, in practice the majority of insomnia patients seeking medical help continue to receive medication. The issue here is not so much overprescribing of drugs as it is under-provision of CBT-I. Two innovations have been developed to address this problem. The first, at the level of the treatment itself there has been growing interest in, and a rapidly accelerating evidence base for digital CBT-I, that is CBT-I delivered by fully automated web and mobile means. The second, at the level of the service, has been the development of the "stepped care" model of insomnia service delivery.

The effectiveness of digital CBT-I has been robustly and rigorously demonstrated against psychological placebo (Espie et al., 2012), attention control (Christensen et al., 2016; Kaldo et al., 2015), sleep hygiene (Espie et al., 2019; Ritterband et al., 2017; Vedaa et al., 2020), waitlist (Zachariae et al., 2018) and usual care (Freeman et al., 2017) in a range of clinical and co-morbid populations. Several meta-analyses report large between-group effects on insomnia severity, and medium effects on sleep diary outcomes (Seyffert et al., 2016; Soh et al., 2020; Zachariae et al., 2016), and benefits to sleep are durable, being maintained up to a year and beyond (Blom et al., 2017; Luik et al., 2020; Vedaa et al., 2019). Whereas meta-analyses report effect sizes in the range of face-to-face CBT-I thereby suggesting non-inferiority, head-to-head comparisons have shown mixed findings (Blom et al., 2015; De Bruin et al., 2016; Kallestad et al., 2021; Lancee et al., 2016). It seems likely, however, that the evolution of highly engaging clinically evidenced software will address engagement and treatment implementation challenges that are apparent for all forms of CBT-I delivery. It may also be the case that differences exist between different digital CBT-I formats (Hasan et al., 2022). These outstanding questions warrant further investigation.

Beyond improved sleep, digital CBT-I, like "traditional" CBT-I, yields benefits to additional clinical and functional outcomes of relevance to insomnia. Several studies have documented reductions in symptoms of anxiety and depression, including in individuals with clinically significant depressive symptoms (Blom et al., 2015, 2017; Cheng et al., 2019; Henry et al., 2021; Pillai et al., 2015; van der Zweerde

TABLE 2 CBT-I ingredients (from Baglioni et al., 2020)

CBT-I strategy	Description
Sleep restriction	*Behavioural strategy*: A method that aims at strengthening homeostatic sleep pressure and stabilizing circadian control of sleep and wakefulness, by decreasing the opportunity to sleep over successive nights. Patients are instructed to restrict their time in bed to match their average (self-report in sleep diaries) total sleep duration. The time in bed is then gradually increased until reaching patients' optimal sleep need. An alternative method, called *sleep compression*, consists in gradual constriction of time in bed until reaching the optimal sleep need.
Stimulus control	*Behavioural strategy*: Several instructions aiming at strengthening the bed as a cue for sleep, weakening it as a cue for activities that might interfere with sleep, and helping the insomniac acquire a consistent sleep rhythm, based on operant conditioning model: (1) lie down to go to sleep only when you are sleepy; (2) do not use your bed for anything except your sleep and sexual activity; (3) if you find yourself unable to fall asleep, get up and go to another room. Stay up as long as you wish, and come back to bed when you feel sleepy; (4) If you still cannot fall asleep, repeat step (3). Do this as often as is necessary throughout the night; (5) Set your alarm and get up at the same time every morning irrespective of how much sleep you got during the night; (6) no napping during daytime.
Sleep hygiene education	Behavioural and educational strategy: General health instructions about internal and external factors that might influence sleep (e.g. sport, light, temperature, etc.).
Relaxation	Behavioural and cognitive strategy: A set of methods aiming at reducing somatic or cognitive hyperarousal (e.g. progressive muscle relaxation, autogenic training, imagery training, meditation).
Cognitive reappraisal	Cognitive strategy: Strategies directed to reduce dysfunctional beliefs, attitudes, concerns and false beliefs about the cause of insomnia and about the inability to sleep.
Cognitive control/ Worry time	Cognitive strategy: The patient is instructed to sit comfortably in an armchair, and write down a list of worries and list of what to do the next day. The rationale of this strategy is to prevent emotionally loaded intrusive thoughts during the sleep-onset period, as all worries have been "already" processed before going to bed.
Paradoxical intention	Cognitive strategy: Strategy aimed at reducing the anticipatory anxiety at the time of falling asleep. Patients are instructed to remain still in bed with the eyes closed and to try to keep awake as long as they can. This takes away the responsibility to try to fall asleep, which in turn often leads to falling asleep quicker.

Abbreviation: CBT-I, cognitive-behavioural treatment for insomnia.

et al., 2019). From a scientific perspective, digital CBT-I confers advantages such that it permits examination of potential mediators of treatment effects using a standardized therapeutic approach. Large randomized-controlled trials and secondary analyses show that insomnia symptom reduction mediates improvements in mental health symptoms (Freeman et al., 2017; Henry et al., 2021), and improvements in quality of life, health and wellbeing, and cognitive function (Espie et al., 2019; Kyle, Hurry, et al., 2020). This evidence therefore supports treating insomnia complaints whenever it presents. Emerging data also suggest that demographic variables including age, race, gender or socio-economic status do not moderate the effectiveness of digital CBT-I (Cheng et al., 2019).

Real-world evidence further underscores the value of digital CBT-I. Recent uncontrolled data evaluating digital CBT-I in existing healthcare settings in the UK show reductions in insomnia and augmentation of the effects of in-person therapy for anxiety and depression (Cliffe et al., 2020; Luik et al., 2017; Stott et al., 2021). Importantly, from a health economic perspective, analyses suggest that digital CBT-I is cost-effective, and may lead to cost savings if made available at scale (Darden et al., 2021; Sampson et al., 2021). This growing body of evidence behind digital CBT-I has led to increased recognition of it as a viable and effective treatment option. Indeed, in the USA, Somryst has been cleared by the FDA as a prescription digital therapeutic (Morin, 2020). Likewise, Sleepio (www.sleepio.com) is widely available in the USA, integrated into healthcare pathways and on the digital formulary, and is available in major parts of the UK National Health Service.

By overcoming the barriers preventing access to therapist-delivered CBT-I, digital CBT-I has the potential to provide access to clinically effective, evidenced-based and guideline-recommended insomnia treatment. These fundamental properties of effectiveness and scalability make digital CBT-I attractive as a first-line insomnia intervention, providing an accessible alternative to pharmacotherapy (Figure 4).

The stepped-care model is a population health service approach to providing people with insomnia with access to evidence-based care (Espie, 2009; Espie et al., 2013). Stepped care is often conceptualized as a pyramid consisting of different levels, with at the bottom the least specialized help applicable for those with less severe and more generic complaints and highly specialized help for those with more severe, complex and rare problems as the top. The level of intervention is naturally not arbitrary; treatment is tailored to and based on the needs of the patient and the nature of their complaints. The number of steps in any stepped care model would be determined by the levels of intervention that are proven and available, and by what within the healthcare system would be affordable. Stepped care models have been recommended for use in insomnia (Baglioni et al., 2020, 2022), and are sometimes adopted in healthcare systems (Vincent & Walsh, 2013).

With regard to insomnia, therefore, digital CBT might be particularly suitable to be one of the entry-level methods for the treatment

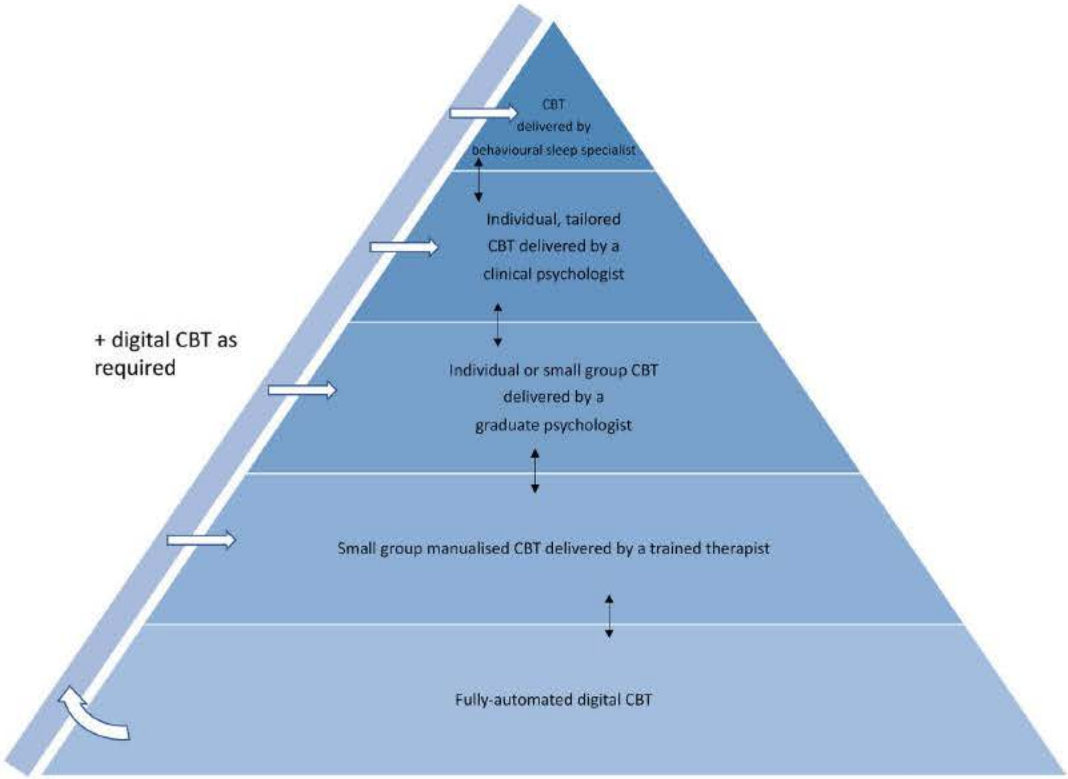

FIGURE 4 A proposed stepped care model for delivery of cognitive-behavioural therapy (CBT) as clinical guideline care. Digital CBT offers accessible treatment for all, but also may be integrated into the care pyramid supporting in-person therapy. The stepped care model conserves expert resources for more complex and treatment-resistant cases

of insomnia, as it has considerable "scalability", particularly when fully automated. Another approach at this level might be using self-help books of good standing, perhaps as part of a "books on prescription" scheme. Next in the hierarchy might be insomnia services that require some in-person support, but thought would be given to how such care could be provided with efficiency. Examples here might include telehealth rather than in a clinic, and the use of small group therapy rather than individual treatment. Other factors to be considered would be the nature of the treatment itself and the expertise of the therapist. For example, it could be possible to train healthcare workers in the provision of manualized CBT-I without them having to have a deep understanding of sleep medicine or mental health (training primary care nurses, for example). This approach is very protocol-driven and can be readily standardized (Kyle, Madigan, et al., 2020). As you then continue up the hierarchy there is greater need for insomnia-specific expertise and for the use of tailored therapy. At the peak of the pyramid the likelihood is that not only specialist expertise but also specialized facilities such as those available at a sleep centre may be required to address the needs of the most complex patients.

Stepped care systems require decision algorithms for two processes. First, to ensure that people are correctly allocated to the appropriate level of care in the first instance; and secondly, to ensure that people are able to step up to more advanced care depending on their treatment response.

5 | FUTURE PERSPECTIVES WITH RESPECT TO DIAGNOSIS, MEASUREMENT, AETIOLOGY AND PATHOPHYSIOLOGY; NEW TREATMENTS

Given the drastic changes we have been witnessing concerning insomnia and its diagnosis, pathophysiology/aetiology and treatment in the last 30 years, one might be tempted to answer the question "Can we rest yet?" (Harvey & Tang, 2003) with "Yes!." However, this would be premature and inadequate with respect to the many open questions still facing us in the insomnia field. Therefore, at this point, we would like to highlight some issues/avenues for future research and clinical practice we consider of utmost importance.

Given the fact that at present we have reached the unique situation that all major diagnostic systems (DSM-5, ICSD-3, ICD-11) have agreed upon ID (American Academy of Sleep Medicine, 2014; American Psychiatric Association, 2013; World Health Organization, 2019), the situation seems ideal that all types of studies into ID use more or less the same diagnostic criteria, which would be ideal to make data coming from all over the world easily comparable. This would also entail homogenization of our diagnostic and research instruments (questionnaires, PSG, etc.). However, as mentioned before, there definitely are different insomnia phenotypes that should not be neglected. A data-driven approach to delineate and characterize these phenotypes seems warranted (Blanken, Benjamins, et al., 2019; Kao et al., 2021), possibly further refined by adding physiological data by means of PSG to questionnaire datasets.

In this regard, pooling data from different sleep labs could be beneficial in order to address the issues of small sample sizes and poor replicability in the insomnia field. This would require the use of standard methodology and paradigms across different labs. The UK Biobank (www.ukbiobank.ac.uk; see Allen et al., 2014 for a detailed description), a large biomedical database including a sample of about 500,000 adults, has already proven to be useful for insomnia research (Jansen et al., 2019; Kyle et al., 2017; Lane et al., 2019). Although the UK Biobank is not specifically optimized for insomnia research, cross-validation showed the available phenotype to very accurately match diagnosed insomnia patients (Hammerschlag et al., 2017).

Given the costs and artificiality of the traditional sleep laboratory, home-based easy to apply measures need to be developed, allowing repetitive CNS-based measurements in the natural environments of our patients, reaching beyond actigraphy (Debener et al., 2015; Mikkelsen et al., 2019). This would allow to study the dynamics of features reflecting the sleep drive and REM sleep characteristics longitudinally and in relation to different treatments and their outcomes in much more detail.

Given the prominence of the hyperarousal concept in almost all insomnia models, one should also start to think about developing a hyperarousal test, which at best could be applied during daytime or routine office/hospital hours. One could think about a stress/challenge paradigm, measuring autonomous nervous system activity (e.g. heart rate, galvanic skin response, etc.), cortisol as main marker of the stress response and EEG during baseline, rest and different stress conditions. One of the best accepted stress paradigms now is the Trier social stress test—its usefulness has already been tested (Chen et al., 2017). Alternatively, probably just the instruction "please try to sleep now" probably might offset a marked stress response in insomniacs. Such a psychophysiological paradigm administered during the day can also easily be coupled with neuroimaging methods, that is, functional magnetic resonance imaging. Needless to say, these data should be coupled with descriptive questionnaire data. Assuming that it will be possible to develop an easy to apply and valid hyperarousal test, this instrument could be used for phenotyping, relating the data to (epi-)genetic data, general diagnostics, differential-therapeutics and therapy outcomes. Given the emerging evidence of maladaptive sleep (Van Someren, 2021), essential insights could require repeated assessment of hyperarousal from evening to morning across recorded nights. Analyses can then address which sleep features determine the overnight fate of distress—which could range from full adaptation even to maladaptive sensitization (Wassing, Benjamins, et al., 2019; Wassing, Lakbila-Kamal, et al., 2019). Nevertheless, deeper insights into the mechanisms of hyperarousal in insomnia, its causes and consequences for cognitive processes and brain health in general are needed. This will help to further increase the value of the hyperarousal concept for insomnia research and could also help to identify a valid hyperarousal test.

Interestingly, also with therapeutics at present we have reached a unique situation concerning treatment—all presently published relevant guidelines agree that CBT-I should be the first-line treatment for insomnia. A statement like this would have caused a lot of many raised eyebrows even just 10 years ago! This development is probably because on one hand, the CBT-I literature is blooming and has generated a solid and ever-increasing evidence base, but on the other hand maybe also due to a stagnation in the sector of hypnotic development and the withdrawal of many major players in psychopharmacology from CNS-oriented Research & Development. It has to be judged in the next few years whether the worldwide introduction of orexin receptor antagonists will markedly alter the hypnotic market. From a future perspective, we would like to suggest that research into the roles of histamine and noradrenaline and sleep regulation could lead to new discoveries (Thakkar, 2011; Van Someren, 2021). Maybe also approaches encompassing non-invasive brain stimulation might complement insomnia treatment strategies (Herrero Babiloni et al., 2021).

A better understanding of the psychoneurobiological mechanisms of insomnia is urgently needed to monitor and evaluate treatment effects of CBT-I beyond subjective measures, and further develop complementary treatment strategies. First, preliminary findings suggest that 1 night of experimental sleep restriction (delaying bedtime by 2 hr) may help to stabilize restless REM sleep (Kao et al., 2021). However, it remains to be seen whether this stabilization is observed in therapeutic SRT, and whether it translates into improvements in regulation of emotional distress, hyperarousal and the risk of developing mental disorders. Second, notwithstanding the established efficacy of CBT-I, it is important to acknowledge that two out of five patients do not show full remission, even after boosting CBT-I effects with subsequent pharmacological treatment (Morin et al., 2020). We still have very limited insight into who will respond and who will not. Novel graph theory-based analyses like network outcome analysis and network intervention analysis may reveal how non-responders differ in their initial symptom profiles and trajectories of change of symptoms during the intervention (Blanken, Benjamins, et al., 2019; Blanken et al., 2020; Blanken, van der Zweerde, et al., 2019). Pinpointing such differences could provide leads to novel strategies.

Also the gradual wearing off of initial benefits of CBT-I deserves attention (van der Zweerde et al., 2019). Two recent studies indicate that beneficial effects of CBT-I may be preserved longer if CBT-I is combined with interventions aimed at supporting circadian rhythms (Dekker et al., 2020; Leerssen et al., 2021).

What we consider probably the most important challenge for the future is the integration of CBT-I into the standard treatment of patients with mental disorders, especially anxiety and depression. It is known that almost all mental disorders are afflicted with disturbances of sleep continuity (Baglioni et al., 2016), and we also know that paying proper therapeutic respect to including insomnia-related components into the overall therapeutic concept will improve outcomes in general and speed up the therapeutic process (Gee et al., 2019; Hertenstein et al., 2022; Manber et al., 2008). Models how to do this have been suggested by several authors (Kraepelien et al., 2022; Schneider et al., 2020)—thus, the times seem right to postulate insomnia as a transdiagnostic mechanism for mental disorders (Harvey et al., 2011, 2021; Van Someren, 2021) and also insomnia treatment based on CBT-I as a basic mode in psychiatric/psychotherapeutic treatment.

One step further will address the primary prevention of mental disorders. There is a strong probability that adequate insomnia treatment will reduce the incidence and recurrence of depressive episodes and anxiety disorders (Benz et al., 2020; Cheng et al., 2019; Irwin et al., 2022; Leerssen et al., 2021). In a first step, one might address risk groups especially prone to mental illness and offer sleep treatment versus a control condition and compare longitudinal outcomes, as recently demonstrated by Leerssen et al. (2021). In a next step it might be tested whether educating and training of the general population to utilize the principles that underlie CBT-I could prevent insomnia. Such efforts may be especially relevant to prevent mental disorders that tend to surface during important transition periods, like in students moving from high school to university.

CONFLICT OF INTEREST

Dieter Riemann is a member of the Executive Board of FAVT (Freiburg Institute for Behavioural Therapy/non for profit), a salaried activity. He is Editor-in-Chief of the *Journal of Sleep Research*, which is owned by the European Sleep Research Society (non-profit body) and receives payments for this task. Dieter Riemann receives royalties from publishing and honoraria for lecturing (no pharmaceutical industry), and is funded by several grants from the German Federal state. Colin A. Espie reports research support from NIHR-HTA (UK), receiving payments from book publishing and lecture fees. He also reports being a cofounder and Chief Scientist of Big Health Ltd (the developer of Sleepio). He is a shareholder of and receiving salary from Big Health. Alasdair L. Henry is employed by, receives a salary from and is a shareholder of Big Health. All other authors report no conflicts of interest.

AUTHOR CONTRIBUTIONS

Dieter Riemann provided an outline of the article and did the final editing. All the other authors contributed equally.

Tinnitus

Carol A. Bauer, M.D.

This Journal *feature begins with a case vignette highlighting a common clinical problem. Evidence supporting various strategies is then presented, followed by a review of formal guidelines, when they exist. The article ends with the author's clinical recommendations.*

A 55-year-old man reports hearing a high-pitched, static sound in both ears. He does not recall when it began, but the sound has been present for several months and is bothersome. How should this case be managed?

THE CLINICAL PROBLEM

Tinnitus is the perception of a sound that has no external source. The sensation is commonly described as ringing in the ear, but the sound can be perceived inside or outside the head or predominantly in one or both ears. Qualitative descriptions include humming, tonal ringing, hissing, static, roaring, or a cicada-like sound. Tinnitus can be categorized as objective or subjective. Objective tinnitus — a sound generated within the body by blood flow, muscle contractions, or spontaneous cochlear emissions that can be detected and measured by an external observer — is uncommon. This review addresses the more common variant, subjective tinnitus.

Population surveys estimate a prevalence of tinnitus of 10 to 25% among persons older than 18 years of age across various nationalities.[1-3] In population surveys, the sensation is reported to be severely bothersome in only a small percentage of persons with tinnitus (range, 1 to 7%).[1,4-6] The prevalence of persistent tinnitus increases with age, reaching a peak among persons in the seventh decade of life,[1] but the prevalence has increased among younger age groups over the past decade, presumably because of increased exposure to damaging recreational noise.[3,7] A large cross-sectional study involving children and adults who were referred to a regional otolaryngology hospital showed that 97% of those who reported tinnitus had concomitant hearing loss detected by routine audiometry.[8] In a population-based study, hearing impairment at frequencies between 500 and 4000 Hz was noted at baseline in two thirds of persons who reported tinnitus, as compared with 44% of persons who did not have tinnitus.[5] In another study, hearing loss was the strongest risk factor for tinnitus that was at least moderate in severity or that caused difficulty in sleeping (adjusted odds ratio, 3.2; 95% confidence interval, 2.3 to 4.4)[9]; a history of occupational noise exposure was also strongly correlated with tinnitus. Clinical experience suggests that sudden hearing loss is associated with sudden onset of tinnitus, but when hearing loss is gradual, tinnitus tends to develop over the course of months or years. Tinnitus frequently resolves or decreases considerably in severity with resolution of hearing loss — for example, after treatment of conductive hearing loss from cerumen impaction or middle-ear effusion.

Tinnitus can affect daily life in multiple domains. People with bothersome tinnitus report impaired sleep, interference with concentration, decreased social enjoy-

KEY CLINICAL POINTS

TINNITUS

- Tinnitus occurs in up to one fourth of adults but is severely bothersome in less than 10%. When bothersome, tinnitus negatively affects sleep, concentration, emotions, and social enjoyment.
- Tinnitus is associated with hearing loss; audiologic testing is an important component in the evaluation of persistent tinnitus.
- Imaging is not indicated in the assessment of tinnitus except in cases in which tinnitus is localized to one ear, is pulsatile, or is associated with focal neurologic abnormalities or asymmetric hearing loss.
- Randomized, controlled trials of tinnitus treatments are limited by a lack of standardized assessments, short posttreatment follow-up, and high risk of bias.
- Treatments to reduce awareness of tinnitus and tinnitus-related distress include cognitive behavioral therapy, acoustic stimulation, and educational counseling. No medications, supplements, or herbal remedies have been shown to substantially reduce the severity of tinnitus.

ment, and difficulty hearing conversational speech.[10-12] In cross-sectional studies, tinnitus has been associated with increased odds of anxiety disorder[3] and depressive symptoms.[9] In a prospective study involving community-dwelling older adults in Japan, tinnitus was associated with an increased risk of subsequent development of depressive symptoms among men, even after adjustment for age and hearing impairment, although no significant association was observed among women.[13]

Psychophysical features of tinnitus such as loudness and pitch are not highly predictive of its psychological effect.[14,15] In one report, some patients who had a tinnitus loudness that matched a sensation level of less than 5 dB (as assessed by the patient identifying an external sound most consistent with the subjective tinnitus) were very disturbed by their condition, whereas other patients who had a tinnitus loudness that matched higher sensation levels were not.[14] This discrepancy may be explained by a person's attention to tinnitus. Whereas a majority of those with chronic tinnitus become used to it and do not pay attention to it, those who are highly disturbed by the tinnitus report constant awareness.

NATURAL HISTORY

The loudness, severity, and effect of tinnitus are dynamic and change over time. Tinnitus can progress in severity in some persons, but it can decrease in severity and even resolve in others (Table S1 in the Supplementary Appendix, available with the full text of this article at NEJM.org). For example, in one longitudinal study, approximately 40% of persons who had reported mild tinnitus and almost 20% who had reported severe tinnitus at baseline reported resolution at 5 years.[5] Familiarity with the natural changes in tinnitus that occur over time is important for counseling patients on expectations for improvement. Furthermore, the potential for a spontaneous reduction in the severity of tinnitus underscores the need for a control group in trials of interventions for this condition.

STRATEGIES AND EVIDENCE

DIAGNOSIS

Persons reporting tinnitus should be questioned about the nature of the sound (location, quality, and onset [gradual or sudden]), the duration of tinnitus, the effect of tinnitus on daily life (sleep, work, concentration, mood, and social activities), and associated symptoms, including hearing difficulties. A history of ear drainage, ear pain, or both would suggest possible infectious, inflammatory, or allergic ear disease; a history of vertigo and imbalance would suggest possible cochlear or retrocochlear disorders such as Meniere's disease, acoustic neuroma, or migraine-associated vertigo. The qualitative characteristics of tinnitus as described by patients may also suggest specific causes; for example, a roaring sound may indicate Meniere's disease, and a rhythmic clicking sound may indicate stapedial or tensor tympani muscle spasm. Acute tinnitus should be distinguished from persistent tinnitus, although there is no well-accepted definition of chronicity; in clinical trials, the definition ranges from a minimum duration of 3 months to a minimum duration of 12 months.[16,17]

Comprehensive audiologic evaluation for the presence, type, severity, and symmetry of hearing loss should be performed in patients with tinnitus who report hearing difficulties, persistent tinnitus of more than 6 months' duration, or unilateral tinnitus. Audiologic evaluation of patients with new-onset tinnitus of less than 6 months' duration is also reasonable, given its frequent association with hearing loss. The results of these evaluations will determine whether additional audiometric tests (e.g., otoacoustic emissions test, high-frequency audiometry, or auditory brainstem response test) or diagnostic imaging (e.g., magnetic resonance imaging or computed tomography of the temporal bone) are indicated. Additional audiologic investigations of the qualitative characteristics of tinnitus (e.g., pitch matching, loudness matching, or tinnitus suppression with acoustic stimulation [residual inhibition]) are not diagnostic and are not used in making management decisions.

Standardized questionnaires are available for use in clinical and research settings to assess the severity of tinnitus and its effect on specific domains of a person's daily life (communication, cognition, emotion, quality of life, and sleep).[18-20] These instruments are useful in the initial assessment of tinnitus and in monitoring changes with treatment. The Tinnitus Handicap Inventory is a widely used assessment tool that is sensitive to changes in tinnitus severity after treatment (see the Supplementary Appendix).[21]

MANAGEMENT

Population surveys show that the majority of people with tinnitus are minimally bothered by the sensation.[2,22,23] Those who seek evaluation often report concern that their tinnitus is a symptom of a much worse disease, such as progressive hearing loss and deafness.[24] An important component of management includes educating patients about the causes of tinnitus and the natural history of the condition, including possible spontaneous reduction in severity with time. The provision of educational materials, information on support groups, and other self-help materials to facilitate coping with tinnitus may be helpful for some patients (see the Supplementary Appendix).[25] Treatment discussions and management goals should emphasize modulation of the patient's attention and perceptual and emotional responses to the sensation.

MEDICATIONS AND SUPPLEMENTS

A wide range of drug classes have been tested in the treatment of tinnitus, including antidepressants, anxiolytics, antiepileptics, and anesthetics. Large systematic reviews have concluded that the strength of the evidence to support these agents is low.[16,26,27] For example, a Cochrane review of the use of antidepressants for the treatment of tinnitus identified only six trials that had sufficient quality for study, of which five were rated as "low quality," and concluded that there was no evidence of efficacy of antidepressant drug therapy in the management of tinnitus.[28] Whereas some studies have reported a reduction in subjective tinnitus loudness and an improvement in tinnitus-specific quality-of-life outcomes, these modest improvements are likely to reflect the modulation of depression and anxiety rather than direct effects on tinnitus. Current clinical practice guidelines do not recommend medication for management of the condition.[12] Nonprescription treatments such as herbal extracts, dietary supplements, and vitamins are commonly advertised as tinnitus cures, although they have no proven efficacy. Ginkgo biloba is the most commonly used supplement, and a systematic review of trials likewise did not show evidence of benefit in the alleviation of tinnitus.[29]

ACOUSTIC STIMULATION

Sound in a variety of forms and intensities has been used for centuries in the empirical treatment of tinnitus. The use of acoustic stimulation to treat tinnitus is currently based on the concept that hearing loss induces homeostatic compensatory changes within central structures (known as central auditory gain) to maintain auditory neural activity.[30] Tinnitus may be a maladaptive consequence of this process.[31] This proposed mechanism of tinnitus has been supported by findings from basic science research in animals, computational models, and functional imaging studies.[32-36] It has been hypothesized that acoustic stimulation may reverse the maladaptive changes by increasing neural activity in central auditory structures.[37]

The types of sound used for acoustic stimulation include broadband noise, amplification of speech and environmental sounds with hearing aids alone, and amplification with hearing aids in combination with broadband noise or music. Acoustic stimulation can be delivered at sound levels sufficient to make the tinnitus inaudible (masking) or at lower levels of intensity at which the tinnitus remains audible. A review of four trials of acoustic stimulation showed a benefit with respect to tinnitus-specific and global quality-of-life outcomes from interventions that used hearing aids or sound generators but did not show the superiority of any specific form of acoustic stimulation over another; however, the studies were noted to have methodologic limitations.[26] More recently, a randomized trial involving adults with chronic bothersome tinnitus and hearing loss showed a significantly greater benefit with the use of combination devices (hearing aids with sound generators) and directive counseling to reduce attention and emotional response to tinnitus than with the use of hearing aids (without sound generators) and counseling with information on strategies to cope with hearing loss and improve communication.[38] In this trial, the intention-to-treat analysis showed that the rates of clinically significant improvement (defined as ≥50% decrease in Tinnitus Handicap Inventory score from baseline to the 18-month follow-up) were greater in the group that received the combination devices and directive counseling than in the group that received hearing aids (without sound generators) and audiologic counseling (74% vs. 37%, $P<0.001$). In another trial, one that involved persons with tinnitus with minimal hearing loss, no significant difference in the rate of the same outcome (clinically significant improvement) was seen between persons who received treatment with sound generators and directive counseling and those who received audiologic counseling alone (50% and 25%, respectively; $P=0.16$), although decreases from baseline in subjective measures of tinnitus loudness were significantly greater at 12 months and 18 months in the group that received treatment with sound generators than in the group that received counseling alone ($P=0.04$).[39] Because counseling was different in the experimental and control groups in these trials, the effect of directive counseling versus the sound generator on the study outcomes is unknown.

Table 1. **Elements and Examples of Cognitive Behavioral Therapy for Tinnitus.**

Elements and Examples	Identify Distortions and Exaggerations	Address the Effect of Distortions and Exaggerations	Adopt Alternate Thoughts, Behaviors, and Strategies
Cognitive restructuring			
Example 1	*People think I am crazy because I have tinnitus.*	Recognize the inaccuracy and futility of mind reading.	*I can't assume others' thoughts without evidence.*
Example 2	*I wake up with my tinnitus and know it's going to be a bad day.*	Avoid jumping to conclusions.	*It is I, not the tinnitus, who controls what I do and determines how my day goes.*
Example 3	*My tinnitus is ruining my work and my life.*	Eliminate cognitive distortion.	Identify aspects of work and life not affected by tinnitus.
Framing the problem for developing solutions			
Example 1	*My tinnitus is making me lose my mind.*	Reframe: *I can't concentrate when there is no quiet time.*	Begin training exercises shown to improve concentration and refocus attention away from tinnitus.
Example 2	*My tinnitus is changing my personality.*	Reframe: *I get angry with people because my tinnitus keeps me from hearing conversations.*	Identify techniques and approaches that improve communication ability.
Behavioral modification			
Example	*Tinnitus has ruined my social life.*	Reframe: *Tinnitus ruins my ability to enjoy going out to dinner.*	Identify aspects of going out to dinner you can enjoy (e.g., the food, the scenery, or pleasant company) and focus on the positive.
Relaxation training		Recognize that stress and physical tension promote emotional arousal and impair coping with tinnitus.	Receive programmatic instruction on breathing exercises and progressive muscle relaxation.

PSYCHOLOGICAL THERAPY

The goal of psychological intervention is to decrease the negative effect of tinnitus on a patient's life and thereby improve well-being. Interventions typically address anxiety and depression because these are the most common psychological responses to tinnitus; such interventions include biofeedback training, hypnosis, and cognitive behavioral therapy.

Cognitive behavioral therapy is currently the most common psychological approach used and studied worldwide for the management of tinnitus. Cognitive behavioral therapy is a collaborative therapy that includes attention-refocusing techniques, relaxation training, mindfulness training, cognitive restructuring, and behavioral modification to change a person's reaction to tinnitus (Table 1); it can be delivered as individual therapy, as group therapy, or remotely (Internet-based therapy). The therapy is provided by a trained medical professional and typically includes once-weekly sessions of 1 to 2 hours in duration for 8 to 24 weeks.

Large systematic reviews of trials comparing cognitive behavioral therapy with either a no-treatment control (involving participants on a waiting list to receive treatment) or an active control with various combinations of yoga, education, biofeedback, relaxation, and distraction training have yielded mixed results.[26,40,41] Participants' subjective assessment of tinnitus loudness was not reduced from baseline in those who received cognitive behavioral therapy, those who received an active control, or those who were assigned to a waiting list to receive treatment. However, tinnitus-specific quality-of-life outcomes were significantly better with cognitive behavioral therapy than with the active or no-treatment control, with small to moderate effect sizes. Depression scores were significantly better with cognitive behavioral therapy than with the no-treatment control, but the results of comparisons between cognitive behavioral therapy and active controls (yoga or educational counseling) were inconsistent (Table S2 in the Supplementary Appendix). Overall, the strength of evidence to support cognitive behavioral therapy was considered to be low, given the high risk of bias and small sample sizes in most studies.[26]

OTHER THERAPY

Repetitive transcranial magnetic stimulation is an investigative treatment for tinnitus that involves the application of strong magnetic field impulses to the scalp to induce an electrical current that alters neural activity directly in the subjacent superficial cortex and indirectly in remote brain areas. Systematic reviews of randomized trials have found conflicting results with respect to a benefit, as well as a lack of information regarding the long-term effects; determination of effectiveness is complicated by methodologic limitations of available studies, including small sample sizes and variability in design and outcome measures.[42,43]

AREAS OF UNCERTAINTY

Research suggests that an abnormal engagement of attention may be a fundamental mechanism that perpetuates tinnitus and increases tinnitus severity.[44-47] In small, short-term trials, attention-training programs designed to modulate awareness of tinnitus through multisensory game-based play or repetitive training in identifying and localizing other sounds have resulted in reductions in tinnitus severity and improvements in quality-of-life scores.[48-50] A better understanding of the mechanisms of attention might lead to more effective treatments. Further study of the relationship between mood disorders and tinnitus and of treatment strategies for patients with coexisting medical conditions is also needed. Cognitive behavioral therapy requires active engagement and commitment; a better understanding of the factors predictive of response to this approach as well as to other interventions is needed.

The subjective nature of tinnitus, its range of causes and variable effects on patients, and the reduction in severity that may occur spontaneously over time make it a challenging condition to study. The limitations of many randomized trials of tinnitus treatments include a lack of blinding, differences among trials in the definition of bothersome tinnitus, small sample sizes, a lack of attention to many variables affecting tinnitus (e.g., associated mood disorder, hearing loss, duration and severity of the tinnitus, and stability of subjective severity scores), failure to account for placebo effects, and attention to some outcomes for which results are significant but not clinically meaningful.[17,51] A standardized instrument has been used as the primary outcome measure of the effect of tinnitus in only 20 to 36% of clinical trials.[17,51] Identifying research partici-

Recommendation*	Comment
Clinicians must:	
Distinguish patients with bothersome tinnitus from patients with nonbothersome tinnitus.	This can be facilitated by the use of standardized questionnaires and patient interviews. The importance of this distinction is to identify patients who require intervention beyond the initial evaluation, assessment, and education.
Clinicians should:	
Perform a targeted history and physical examination at the initial evaluation of a patient with presumed primary tinnitus.	The goal is to identify conditions that — if promptly identified and managed — may relieve tinnitus (e.g., tinnitus resulting from conductive hearing loss caused by cerumen occlusion of ear canal, middle-ear effusion, or ossicular chain fixation).
Obtain a prompt, comprehensive audiologic examination in patients with tinnitus that is unilateral, persistent (≥6 months), or associated with hearing difficulty.	Audiologic testing will facilitate identification of retrocochlear causes of tinnitus or tinnitus from sudden idiopathic hearing loss. Testing should always be performed when patients report difficulty hearing.
Distinguish patients with bothersome tinnitus of recent onset from those with persistent symptoms (≥6 months) to prioritize intervention and facilitate discussions about the natural history of tinnitus and follow-up care.	Patients benefit from knowing about spontaneous reduction in tinnitus severity observed in population studies. Tinnitus interventions can be prioritized on the basis of duration and severity of tinnitus.
Educate patients with persistent, bothersome tinnitus about management strategies.	Patients should not be told that nothing can be done to help them.
Recommend a hearing aid evaluation for patients with hearing loss and persistent bothersome tinnitus.	The evidence for using hearing aids as treatment shows a preponderance of benefit over harm. Quality of life is improved with improved communication and decreased awareness of tinnitus.
Recommend cognitive behavioral therapy to patients with persistent, bothersome tinnitus.	It is helpful to be knowledgeable in general about the process of cognitive behavioral therapy and to have access to trained professionals with expertise in this form of therapy.
Clinicians may:	
Obtain an initial comprehensive audiologic examination in patients who present with tinnitus (regardless of laterality, duration, or perceived hearing status)	
Recommend sound therapy to patients with persistent, bothersome tinnitus.	
Clinicians should not:	
Obtain imaging studies of the head and neck in patients with tinnitus specifically to evaluate the tinnitus, unless they have one or more of the following: tinnitus that is localized to one ear, pulsatile tinnitus, focal neurologic abnormalities, or asymmetric hearing loss.	The cost and risk associated with computed tomography and magnetic resonance imaging, combined with the low diagnostic yield, do not support their application outside the noted exceptions.
Routinely recommend antidepressants, anticonvulsants, anxiolytics, or intratympanic medications for a primary indication of treating persistent, bothersome tinnitus.	Systematic reviews have not supported the use of antidepressants in the treatment of tinnitus. Nevertheless, it is important to recognize that mood disorders can occur in association with bothersome tinnitus and to offer treatment or referral when clinically indicated.
Recommend ginkgo biloba, melatonin, zinc, or other dietary supplements for treating patients with persistent, bothersome tinnitus.	Patients should be informed about the lack of evidence for supplements as tinnitus treatments.
Recommend repetitive transcranial magnetic stimulation for the routine treatment of patients with persistent, bothersome tinnitus.	

* No recommendation is provided regarding the effect of acupuncture in patients with persistent bothersome tinnitus.

pants willing to enroll in tinnitus studies with 12 to 18 months of follow-up is challenging.[38] Long-term follow-up (at least 12 months) is often lacking; in a recent systematic literature review, the median duration of follow-up in 147 clinical trials was 3 months.[17]

GUIDELINES

The American Academy of Otolaryngology–Head and Neck Surgery (AAOHNS) published a clinical practice guideline for the evaluation and management of chronic bothersome tinnitus in adults.[16] This guideline applies to adults who have had tinnitus for at least 6 months, with no identifiable cause other than sensorineural hearing loss (Table 2). The recommendations in this article are largely consistent with those in the AAOHNS guideline; an exception is the stronger recommendation provided here for hearing aids, sound generators, and directive counseling, for which supporting data were not available at the time the AAOHNS guideline was developed.[38]

SUMMARY AND RECOMMENDATIONS

The patient described in the vignette has new-onset tinnitus in both ears, and the loudness is not asymmetric. I would obtain additional history regarding vertigo or fluctuating hearing loss and examine the patient for ear disease that might suggest an underlying disorder such as otosclerosis or Meniere's disease, although symmetric tinnitus would make these conditions unlikely. I would obtain a baseline assessment of tinnitus severity using the Tinnitus Handicap Inventory and an audiogram to determine the presence and level of hearing loss. If there is notable asymmetry in hearing, I would obtain diagnostic imaging. I would review the audiogram with the patient and discuss the relationship between hearing loss and tinnitus and what is known about the natural history of new-onset tinnitus with respect to resolution or reduction in severity over time. If hearing thresholds are outside the normal range, I would recommend hearing aids. I would discuss the potential benefit of educational counseling and acoustic stimulation with hearing aids or devices that combine hearing aids with sound generators to reduce the awareness of tinnitus and the negative effects on the patient's quality of life. If there is evidence of a coexisting mood disorder or moderate to severe distress, I would discuss the options of referral to a mental health professional and a treatment strategy of cognitive behavioral therapy.

Literature review current through: Feb 2022. | **This topic last updated:** Oct 06, 2021.

INTRODUCTION

Tinnitus is a perception of sound in proximity to the head in the absence of an external source. It can be perceived as being within one or both ears, within or around the head, or as an outside distant noise. The sound is often a buzzing, ringing, or hissing, although it can also sound like other noises.

Tinnitus can be continuous or intermittent. Although both may have a significant impact on the patient, the latter is not usually related to a serious underlying medical problem. The sound may be pulsatile or non-pulsatile. Pulsatile tinnitus raises more concern for underlying significant pathology, though non-pulsatile tinnitus may also be associated with underlying disease.

The epidemiology, pathogenesis, and diagnosis of tinnitus will be reviewed here. The treatment of tinnitus is discussed separately. (See "Treatment of tinnitus".)

EPIDEMIOLOGY

According to the American Tinnitus Association, an estimated 50 million people in the United

States have chronic tinnitus, persisting for greater than six months [1]. For 12 million, it is severe enough to interfere with daily activities. These people are effectively disabled by their tinnitus to varying degrees.

Tinnitus can occur in children [2] and increases with age [3,4]. Tinnitus is more common in men than in women and is more likely to occur among individuals who smoke [1].

CLINICAL IMPACT

The impact of tinnitus on an individual can be significant. Some individuals "experience" tinnitus, while others "suffer from it." Overall, about 25 percent of tinnitus sufferers report an increase in tinnitus severity over time [5]. Chronic tinnitus is unlikely to remit completely but often becomes less bothersome over time, especially in the setting of hearing loss.

The impact of tinnitus can be consistently measured by two outcome instruments: the Tinnitus Handicap Inventory (form 1) [6] and the Tinnitus Reaction Questionnaire [7]. Studies indicate that the degree of disability perceived by tinnitus patients, and its impact on the patient's quality of life, does not directly correlate with loudness, type of tinnitus, or length of time with tinnitus.

Concurrent mood disorders can increase the perception of disability. Increased tinnitus disability also has been demonstrated in patients with insomnia [8].

PATHOGENESIS

Tinnitus can be unilateral or bilateral and can be triggered anywhere along the auditory pathway (figure 1) [9]. It is believed to be encoded in neurons within the auditory cortex. The majority of patients have "sensorineural" tinnitus due to hearing loss at the cochlea or cochlear nerve level.

Somatic sounds may be perceived as tinnitus and originate in structures with proximity to the cochlea. These sounds are often generated in vascular structures but may also be produced by musculoskeletal structures. Somatic sounds are most often associated with pulsatile tinnitus and are typically unilateral. Continuous tonal tinnitus (single pure-tone) is usually not somatic in origin.

Pathogenetic theories postulate that the central nervous system is the source or "generator" of all tinnitus that does not have a somatic origin, even in patients whose associated hearing losses are due to cochlear injury [10]. Tinnitus generated by the central nervous system can be unilateral or bilateral, and the side of the tinnitus may not always correspond with the side of initial injury. Positron-emission tomography (PET) scanning and functional magnetic resonance imaging (MRI) studies indicate that the loss of cochlear input to neurons in the central auditory pathways (such as occurs with cochlear hair cell damage due to ototoxicity, noise trauma, or a lesion of the cochlear nerve) can result in abnormal neural activity in the auditory cortex. Such activity has been linked to the perception of tinnitus [11,12].

Another construct likens tinnitus to phantom pain perception that is thought to arise from a loss of suppression of neural activity [13-15]. Known neural feedback loops act to help tune and reinforce auditory memory in the central auditory cortex. Disruption of auditory input or the feedback loop may lead to the creation of alternative neural synapses and to loss of inhibition of normal synapses.

Tinnitus has also been likened to a type of auditory seizure [16], and antiseizure medications have had limited success in some patients [17]. Abnormal auditory-evoked magnetic field potentials associated with tinnitus can be suppressed in selected patients with intravenous lidocaine [18], confirming a central tinnitus phenomenon and potentially indicating a physiologic mechanism for lidocaine sensitive tinnitus. (See "Treatment of tinnitus", section on 'Medications'.)

Electrical stimulation, with round window electrodes or promontory stimulation, can suppress tinnitus in patients with profound hearing loss [19,20]. Electrical promontory stimulation may suppress abnormal spontaneous activity of cochlear nerve fibers; alternatively, it may provide background activity that acts to suppress abnormal central neural connections in patients with baseline sensorineural hearing loss and tinnitus. Cochlear implantation for hearing loss has had a secondary result of relieving tinnitus, with reported success for tinnitus improvement varying from 34 to 93 percent [21,22].

Many patients with tinnitus exhibit signs of anxiety and/or depression [23], and elevated serum serotonin levels have been found in some tinnitus patients [24]. Serotonin and gamma-aminobutyric acid (GABA) receptors are found throughout the auditory system, and neurotransmitter abnormalities may play a role in some patients with tinnitus [24-26].

These theories encompass disruption of normal neural firing patterns along the entire auditory pathway, from the end organ to the auditory cortex. They may explain tinnitus in patients who do not exhibit hearing loss, as well as in patients who recover from temporary hearing loss (eg, noise-induced hearing loss) but develop tinnitus that is persistent.

ETIOLOGY

Vascular disorders — Pulsatile tinnitus is most commonly, though not exclusively, vascular in etiology. Some vascular tinnitus, such as venous hums and tinnitus due to atherosclerotic plaque narrowing of vessels, can be non-pulsatile. Vascular tinnitus can be unilateral or bilateral; when bilateral, it is typically louder on the side of the pathology.

In a retrospective review of 84 patients with pulsatile tinnitus seen in a neurology department, 42 percent were found to have a significant vascular disorder (most commonly a dural arteriovenous fistula [AVF] or a carotid-cavernous sinus fistula) [27]. In 12 patients (14 percent), nonvascular disorders such as paraganglioma or intracranial hypertension (due to a variety of causes) explained the tinnitus.

Arterial bruits — Arterial vessels near the temporal bone may transmit sounds associated with turbulent blood flow, especially if the loudness of the sound exceeds the hearing threshold in that ear. The petrous carotid system is the most common source, although other arteries may also be involved [28]. An arterial bruit is not itself a serious condition, although the patient may require an evaluation for underlying atherosclerotic disease.

These patients usually do not have other otologic complaints (eg, hearing loss, vertigo, aural fullness). As with many other causes of tinnitus, their tinnitus is greatest in quiet environments (eg, at night).

Arteriovenous shunts — Congenital arteriovenous malformations (AVMs) are rarely associated with hearing loss or tinnitus. AVFs are more likely to be symptomatic, usually ipsilateral to the fistula. Dural AVFs are often associated with dural venous sinus thrombosis, which may occur spontaneously or be associated with infection, tumor, trauma, or surgery. Large dural AVFs can result in intracranial hemorrhage; early detection and treatment (surgery and/or vascular embolization) can be life-saving for high-grade lesions. (See "Nonaneurysmal subarachnoid hemorrhage", section on 'Intracranial'.)

Paraganglioma — Head and neck paragangliomas are highly vascular, typically benign neoplasms arising from cells of the paraganglia that are found around the carotid bifurcation, within the jugular bulb, or along the tympanic arteries in the middle ear. Tympanic paragangliomas, previously known as glomus tympanicum tumors, and jugular bulb paragangliomas, commonly known as glomus jugulare, both commonly cause a loud pulsing tinnitus that may interfere with hearing. The tinnitus is typically unilateral, and the lesion may be visible through the tympanic membrane as a reddish or blue mass or may be palpable in the neck. As the tumor enlarges, it may cause hearing loss because of impingement on the ossicular chain (conductive loss) or the labyrinth or cochlea (sensorineural loss). Other cranial nerves may also be affected (eg, facial nerve or lower cranial nerve palsies). Paragangliomas of the head and neck are discussed separately. (See "Paragangliomas: Epidemiology, clinical presentation, diagnosis, and histology", section on 'Definition and anatomic origin' and "Paragangliomas: Epidemiology, clinical presentation, diagnosis, and histology", section on 'Head and neck paragangliomas'.)

Venous hums — These may be heard in patients with systemic hypertension, increased intracranial pressure (often due to pseudotumor cerebri) (see "Idiopathic intracranial hypertension (pseudotumor cerebri): Clinical features and diagnosis", section on 'Pulsatile tinnitus'), or in patients with a dehiscent or dominant jugular bulb (abnormally high placement of the jugular bulb). The latter may also cause a conductive hearing loss. Tinnitus in patients with a venous hum is often described as a soft, low-pitched hum that may decrease or stop with pressure over the jugular vein, with a change in head position, or with activity [28]. When tinnitus is due to asymmetry in the venous system, the tinnitus can be unilateral, or bilateral but louder on one side.

Neurologic disorders — Pulsatile tinnitus of muscular origin can result from spasm of one or both of the muscles within the middle ear (the tensor tympani and the stapedius muscle).

These muscles are innervated by cranial nerves V and VII respectively. Such muscle spasms can occur spontaneously, because of local otologic disease, and also in the presence of neurologic disease such as multiple sclerosis. Patients may also complain of hearing loss or aural fullness associated with these muscle spasms. Tympanometry and otoscopy can be particularly useful in diagnosing middle ear spasmodic activity.

Clicking noises or irregular or rapid pulsations may also result from myoclonus of the palatal muscles that attach to the Eustachian tube orifice. Myoclonus of the palatal muscles most often is caused by an underlying neurologic abnormality, such as multiple sclerosis, microvascular disease affecting the brainstem, or neuropathy related to metabolic or toxic etiology; the history and physical examination should include a search for other neurologic disease.

Tinnitus due to myoclonus can be either unilateral or bilateral; when unilateral, symptoms are ipsilateral to the site of the muscle spasm.

Eustachian tube dysfunction — A patulous Eustachian tube can cause unilateral or bilateral tinnitus, with sounds similar to an ocean roar that may be synchronous with respiration [28]. It most commonly occurs after significant weight loss or after external beam radiation to or near the nasopharynx. The symptoms may disappear when the patient lies down. Patients can also complain of an unusual awareness of their own voice (autophony) and of ear discomfort. The cause of these symptoms is a Eustachian tube that remains abnormally patent, allowing too much and then too little aeration of the middle ear space with respiration. (See "Eustachian tube dysfunction", section on 'History'.)

Other somatic disorders — Somatic non-pulsatile tinnitus is commonly caused by temporomandibular joint (TMJ) dysfunction [29] and has also been associated with whiplash injuries [30] and other cervical-spinal disorders [31]. Tinnitus may improve when patients respond favorably to treatment for symptoms of TMJ dysfunction and craniocervical disease. The exact neurophysiologic mechanism for the generation of tinnitus from either the TMJ or the cervical spine is not known but may involve disinhibition of the dorsal cochlear nucleus [30]. In cases of somatic tinnitus, unilateral or bilateral symptoms may occur.

Tinnitus with a machine-like grinding or pulsing character is sometimes associated with intracranial lesions, such as chondrosarcoma, aberrant carotid artery, and endolymphatic sac tumors.

Tinnitus originating from the auditory system — Most tinnitus is due to a sensorineural hearing loss with resulting dysfunction within the auditory system. The auditory system includes the cochlear end organ, the cochlear nerve (with its projections to and from the cochlea), the brainstem (site of the cochlear nuclei), and the primary and secondary auditory cortical projections (figure 1).

Etiologies of tinnitus generated from within the auditory system are as varied as the types of noises that patients report (table 1). The presence of tinnitus often is an early indicator of cochlear hair cell dysfunction or loss, as in the case of prolonged noise exposure [32], Meniere disease (also characterized by aural fullness and vertigo), or ototoxicity. (See "Etiology of hearing loss in adults", section on 'Inner ear causes' and "Meniere disease: Evaluation, diagnosis, and management", section on 'Clinical presentation'.)

Ototoxic medications — Tinnitus is commonly caused by ototoxic medications (table 2); the ototoxicity typically affects both sides, causing bilateral symptoms. Ototoxicity affects the various components of the cochleovestibular end organ. When such structures are damaged, a change in neural firing between the end organ and the remainder of the auditory system can be exhibited by hearing loss, distortions in hearing, or tinnitus. (See "Etiology of hearing loss in adults", section on 'Ototoxic substances'.)

Presbycusis — Presbycusis (sensorineural hearing loss with aging) or any acquired high-frequency hearing loss is commonly associated with tinnitus (often described as a high-pitched ringing sound, crickets, or bells in the ear) along with the hearing loss. Cochlear hearing losses can be asymmetric, and even when symmetric they can result in unilateral or bilateral tinnitus. (See "Presbycusis", section on 'Tinnitus'.)

Otosclerosis — This is a condition of abnormal bone repair of the stapes footplate bone (third bone in the ossicular chain) and of the otic capsule. Tinnitus can result when otosclerosis damages cochlear structures. Progressive otosclerosis can result in fixation of the stapes footplate and worsening conductive hearing loss which can be unilateral or bilateral. (See "Etiology of hearing loss in adults", section on 'Otosclerosis'.)

Vestibular schwannoma — Tumors compressing or stretching the cochlear nerve can cause tinnitus. In addition, unilateral tinnitus can be the presenting sign of a schwannoma of the vestibular nerve within the cerebellar-pontine angle or the internal auditory canal (acoustic neuroma). (See "Vestibular schwannoma (acoustic neuroma)".)

Chiari malformations — Tinnitus, unilateral or bilateral, is one of the auditory signs associated with a symptomatic Chiari malformation and occurs when low-lying cerebellar tonsils causes tension on the auditory nerve [33]. Tinnitus from Chiari malformations can be both unilateral or bilateral.

Other etiologies — Hearing loss due to a variety of causes, including vascular ischemic events, infection, nerve compression, genetic predisposition, congenital hearing loss, or endocrine or metabolic damage to the auditory system, can produce tinnitus to a variable degree.

Tinnitus may occur with barotrauma to the middle or inner ear (often associated with vertigo and hearing loss) and with fluid in the middle ear (eg, with otitis media). (See "Etiology of hearing loss in adults" and "Acute otitis media in adults", section on 'Otitis media with effusion'.)

DIAGNOSIS

Tinnitus is frequently associated with hearing loss or other cochlear injury, and it may be the presenting complaint in a patient with a central nervous system lesion. History and physical examination are the first steps in establishing the etiology of tinnitus. Some patients may also warrant audiology examination, particularly those with unilateral tinnitus; although unilateral symptoms can direct aspects of the workup, it does not necessarily portend more worrisome diagnoses. Other tests, including imaging, are warranted in specific circumstances.

History — The history in patients with tinnitus should include a description of the tinnitus (episodic or constant, pulsatile or non-pulsatile, rhythmicity, pitch, quality of the sound), as well as inciting or alleviating factors. Patients should be asked about previous ear disease, noise exposure, hearing status, head injury, and symptoms suggesting temporomandibular joint (TMJ) syndrome. All medications and supplements should be reviewed. The history should review other medical conditions, including hypertension, atherosclerosis, neurologic illness, and prior surgery. Patients should be specifically asked about depression, anxiety, and insomnia, which can both exacerbate tinnitus and magnify its impact on quality of life. Patients complaining of tinnitus should also be asked if they have difficulty hearing or have noted a hearing loss.

Tinnitus that is distinctly pulsing or is described as rushing, flowing, or humming is usually vascular in origin. Patients often describe an increase in frequency and intensity with exercise, and some may recognize a connection with their pulse. Changes in intensity or pitch with head motion or body position (lying down versus sitting or standing) also strongly suggest a vascular tinnitus.

Clicking tinnitus almost always has a physiologic explanation. Myoclonus of the palatal muscles or middle ear structures can occur spontaneously but may also suggest significant neurologic disease. Some patients report a mechanical sounding tinnitus that is not tonal in nature. A diligent investigation searching for vascular or somatic causes is warranted for this rare complaint.

Tonal descriptions of tinnitus can help in the evaluation of a patient for a specific diagnosis or treatment.

- A high-pitched continuous tone is by far the most commonly described type of tinnitus. High-pitched tinnitus is frequently a result of a sensorineural hearing loss or may suggest cochlear injury.
- Low-pitched tinnitus is often seen in patients with Meniere disease, although it also can be idiopathic.

Physical examination — A complete head and neck examination, including cranial nerve examination and evaluation of the tympanic membrane, should be performed in all patients. Palatal myoclonus may be suppressed upon wide jaw opening; thus, its absence on oral examination does not rule out the diagnosis (nasopharyngoscopy may be indicated when suspicion is high).

In patients with suspected vascular tinnitus, auscultation over the neck, periauricular area, temple, orbit, and mastoid should be performed in various positions. The effects of positioning and vascular compression of the neck on the involved side should be noted. Tinnitus of venous origin can often be suppressed by careful pressure on the jugular vein.

Specialized testing

Suspected vascular tinnitus — Patients with infrequent episodes of pulsatile tinnitus or those with short-duration, mild tinnitus can be initially observed.

However, because frequent or constant pulsatile tinnitus can herald a potentially life-threatening illness, all of these patients require evaluation by an otolaryngologist or neurotologist. When physical examination does not reveal a specific vascular or musculoskeletal source in these patients, further investigation to rule out a central nervous system lesion such as a dural arteriovenous fistula (AVF), arteriovenous malformation (AVM) or aneurysm, or a skull base tumor should be carried out [34].

The gold standard for AVF diagnosing intracranial vascular lesions is angiography. These lesions often can also be diagnosed noninvasively with magnetic resonance (MR) angiography [35] or computed tomographic (CT) angiography [36]. High-resolution CT scanning is required to delineate the extent of involvement of the skull base if a paraganglioma is suspected and may be sufficient to evaluate other central nervous system lesions in selected patients. MRI can diagnose a Chiari malformation, vasculitis, central nervous system tumors, and multiple sclerosis and may indicate the presence of increased intracranial pressure (such as that seen in pseudotumor cerebri) or tumors. Many patients require both contrast MRI and contrast CT because of the varied nature of disorders that cause pulsatile tinnitus. If both of these studies are normal, and suspicion for a vascular lesion remains high, angiography or MR angiography is warranted.

Our protocol involves audiometric testing followed by an extensive history and physical exam, which guides additional diagnostic testing. When an intracranial vascular lesion is suspected, we obtain an MRI with contrast initially, followed by CT/CT angiography and subsequent interventional angiography in appropriate circumstances.

Suspected auditory system tinnitus — For patients with tinnitus associated with hearing loss or a change in hearing, audiometric tests may help determine if the tinnitus originates within the auditory system and are essential in the evaluation. Any patient with constant unilateral or bilateral tinnitus persistent for six months or more should also be referred for a formal audiology evaluation [37].

Initial audiometric tests should include a pure-tone audiogram, tympanometry, auditory reflex testing, determination of speech discrimination abilities, and otoacoustic emissions testing. These tests identify asymmetries between the two ears and indicate abnormalities in the middle ear, cochlea, and brainstem; as well, they can define the site of abnormality within the auditory system or confirm normal functioning. Such testing is performed in an audiologist's office, ideally one affiliated with an otolaryngology department or practice.

Asymmetry in hearing function, reflex testing, or otoacoustic emissions, in patients with no identified otologic abnormality, should be followed-up with auditory brainstem response testing (ABR) and imaging studies (eg, MRI) to rule out inner ear anomalies, central nervous system lesions, and neurologic disease. Further workup may involve neurologic or neurosurgical consultation, endocrine evaluation, or angiography.

SOCIETY GUIDELINE LINKS

Links to society and government-sponsored guidelines from selected countries and regions around the world are provided separately. (See "Society guideline links: Hearing loss and hearing disorders in adults".)

INFORMATION FOR PATIENTS

UpToDate offers two types of patient education materials, "The Basics" and "Beyond the Basics." The Basics patient education pieces are written in plain language, at the 5th to 6th grade reading level, and they answer the four or five key questions a patient might have about a given condition. These articles are best for patients who want a general overview and who prefer short, easy-to-read materials. Beyond the Basics patient education pieces are longer, more sophisticated, and more detailed. These articles are written at the 10th to 12th grade reading level and are best for patients who want in-depth information and are comfortable with some medical jargon.

Here are the patient education articles that are relevant to this topic. We encourage you to print or e-mail these topics to your patients. (You can also locate patient education articles on a variety of subjects by searching on "patient info" and the keyword(s) of interest.)

- Basics topic (see "Patient education: Tinnitus (ringing in the ears) (The Basics)")
- Beyond the Basics topic (see "Patient education: Tinnitus (ringing in the ears) (Beyond the Basics)")

SUMMARY AND RECOMMENDATIONS

- Tinnitus affects 50 million people in the United States and interferes with daily activity in a quarter of those affected. Prevalence is greater in men and increases with age. (See 'Epidemiology' above.)
- Pulsatile tinnitus is most commonly vascular in origin and requires thorough evaluation.
  - Vascular tinnitus can be unilateral or bilateral; when bilateral, it is typically louder on the side of the pathology. Differential diagnosis includes intracranial arteriovenous malformation (AVM), arteriovenous fistula (AVF), arterial bruit, and paraganglioma. (See 'Vascular disorders' above.)
  - Clicking pulsatile tinnitus may indicate a neurologic disorder causing myoclonus of palatal muscles or of the muscles in the inner ear. Tinnitus can be either unilateral or bilateral; when unilateral, symptoms are ipsilateral to the site of the muscle spasm. (See 'Neurologic disorders' above.)
- Tinnitus most commonly is a result of abnormalities within the auditory system, often with unexplained etiology. It may be associated with sensorineural hearing loss, ototoxic medications, infection, vascular ischemia, or acoustic neuroma. (See 'Tinnitus originating from the auditory system' above.)
- All sensorineural tinnitus is believed to be generated within the central nervous system,

with cochlear abnormalities leading to loss of inhibition of cortical auditory neurons. Serotonergic neurotransmitters may play a role. (See 'Pathogenesis' above.)

- Evaluation of tinnitus should include a thorough history, an examination including auscultation for bruits in patients with possible vascular tinnitus, and a complete head and neck examination in all patients. (See 'Diagnosis' above.)

- Patients with pulsatile tinnitus, other than those with infrequent intermittent symptoms, should have otolaryngologic investigation and may require contrast computed tomography (CT) scanning, contrast magnetic resonance (MR) scanning, and/or angiography. (See 'Suspected vascular tinnitus' above.)

- For patients with tinnitus suspected of arising within the auditory system, and for those with unilateral tinnitus, audiometric testing is indicated. (See 'Suspected auditory system tinnitus' above.)

Aminoglycoside antibiotics
ACE inhibitors
Antimalarial drugs (eg, chloroquine, hydroxychloroquine)
Benzodiazepines
Bismuth
Calcium channel blockers
Carbamazepine
Chlordiazepoxide
Cisplatin
Clarithromycin
COX-2 inhibitors
Cyclobenzaprine
Dapsone
Doxazosin
Doxepin
Fluoroquinolone antibiotics
Isotretinoin
Lidocaine and other local anesthetics
Loop diuretics
Nitroprusside
Prazosin
Proton pump inhibitors
Quinidine
Salicylates and NSAIDs
Sertraline
Sibutramine

Tricyclic antidepressants
Tolbutamide
Valproic acid

ACE: angiotensin-converting enzyme; COX: cyclooxygenase; NSAIDs: nonsteroidal antiinflammatory drugs.

WHO, Environmental Noise Guidelines for the European Region (2018)

February 22, 2023

World Health Organization
REGIONAL OFFICE FOR Europe

ENVIRONMENTAL NOISE GUIDELINES

for the European Region

Abstract

Noise is an important public health issue. It has negative impacts on human health and well-being and is a growing concern. The WHO Regional Office for Europe has developed these guidelines, based on the growing understanding of these health impacts of exposure to environmental noise. The main purpose of these guidelines is to provide recommendations for protecting human health from exposure to environmental noise originating from various sources: transportation (road traffic, railway and aircraft) noise, wind turbine noise and leisure noise. They provide robust public health advice underpinned by evidence, which is essential to drive policy action that will protect communities from the adverse effects of noise. The guidelines are published by the WHO Regional Office for Europe. In terms of their health implications, the recommended exposure levels can be considered applicable in other regions and suitable for a global audience.

Foreword

Noise is one of the most important environmental risks to health and continues to be a growing concern among policy-makers and the public alike. Based on the assessment threshold specified in the Environmental Noise Directive of the European Union (EU), at least 100 million people in the EU are affected by road traffic noise, and in western Europe alone at least 1.6 million healthy years of life are lost as a result of road traffic noise.

At the request of Member States at the Fifth Ministerial Conference on Environment and Health in Parma, Italy, in March 2010, the WHO Regional Office for Europe has developed these guidelines, based on the growing understanding of the health impacts of exposure to environmental noise. They provide robust public health advice, which is essential to drive policy action that will protect communities from the adverse effects of noise.

These WHO guidelines – the first of their kind globally – provide recommendations for protecting human health from exposure to environmental noise originating from various sources. They not only offer robust public health advice but also serve as a solid basis for future updates, given the growing recognition of the problem and the rapid advances in research on the health impacts of noise. The comprehensive process of developing the guidelines has followed a rigorous methodology; their recommendations are based on systematic reviews of evidence that consider more health outcomes of noise exposure than ever before. Through their potential to influence urban, transport and energy policies, these guidelines contribute to the 2030 Agenda for Sustainable Development and support WHO's vision of creating resilient communities and supportive environments in the European Region.

Following the publication of WHO's community noise guidelines in 1999 and night noise guidelines for Europe in 2009, these latest guidelines represent the next evolutionary step, taking advantage of the growing diversity and quality standards in this research domain. Comprehensive and robust, and underpinned by evidence, they will serve as a sound basis for action. While these guidelines focus on the WHO European Region and provide policy guidance to Member States that is compatible with the noise indicators used in the EU's Environmental Noise Directive, they still have global relevance. Indeed, a large body of the evidence underpinning the recommendations was derived not only from noise effect studies in Europe but also from research in other parts of the world – mainly in Asia, Australia and the United States of America.

I am proud to present these guidelines as another leading example of the normative work undertaken in our Region in the area of environment and health. On behalf of the WHO Regional Office for Europe and our European Centre for Environment and Health in Bonn, Germany, which coordinated the development of the guidelines, I would like to express my gratitude to the large network of experts, partners, colleagues and consultants who have contributed to this excellent publication. I would also like to thank Switzerland and Germany for providing financial support to this complex project, and look forward to following the influence of the guidelines on policy and research in the years to come.

Dr Zsuzsanna Jakab

WHO Regional Director for Europe

Acknowledgements

The WHO Regional Office for Europe thanks all members of the Steering Group, Guideline Development Group, Systematic Review Team and External Review Group for their invaluable contributions in the guidelines development process.

The WHO Regional Office for Europe, through its European Centre for Environment and Health, coordinated the development of these guidelines. The project was coordinated by Marie-Eve Héroux and Dorota Jarosinska, under the overall supervision of Elizabet Paunovic, Head of the European Centre for Environment and Health.

The members of the Steering Group were: Shelly Chadha, Carlos Dora, Rokho Kim, Jurgita Lekaviciute, Srdan Matic, Julia Nowacki, Poonum Wilkhu and Joerdis Wothge (see Annex 1 Table A1.1 for affiliations).

The members of the Guideline Development Group were: Stephen Stansfeld (Chair), Wolfgang Babisch, Goran Belojevic, Mark Brink, Sabine Janssen, Peter Lercher (2013–2014), Marco Paviotti, Göran Pershagen, Kerstin Persson Waye, Anna Preis, Martin van den Berg and Jos Verbeek (methodologist) (see Annex 1 Table A1.2 for affiliations).

The Systematic Review Team comprised the following experts: Mathias Basner, Lex Brown, Charlotte Clark, Payam Dadvand, Maria Foraster, Rainer Guski, Sarah McGuire, Mark Nieuwenhuijsen, Katarina Paunovic, Göran Pershagen, Gordana Ristovska, Maribel Casas Sanahuja, Dirk Schreckenberg, Rudolf Schuemer, Mariola Sliwinska-Kowalska, Kamil Rafal Zaborowski, Irene Van Kamp and Elise van Kempen (see Annex 1 Table A1.3 for affiliations).

The project's External Review Group had the following members: Gunn Marit Aasvang, Bernard Berry, Dick Botteldooren, Stephen Conaty, Yvonne de Kluizenaar, Ulrike Gehring, Truls Gjestland, Mireille Guay, Ayse Güven, Anna Hansell, Stelios Kephalopoulos, David Michaud, Arnaud Norena, Enembe Okokon, Dieter Schwela, Daniel Shepherd, Mette Sörensen, Rupert Thornley-Taylor and David Welch (see Annex 1 Table A1.4 for affiliations).

The WHO Regional Office for Europe gratefully acknowledges funding and in-kind contributions from the Swiss Federal Office for the Environment; the German Federal Ministry for the Environment, Nature Conservation and Nuclear Safety; and the German Environment Agency for this activity.

Glossary of acoustic terms

A-weighting	A frequency-dependent correction that is applied to a measured or calculated sound of moderate intensity to mimic the varying sensitivity of the ear to sound for different frequencies
C-weighting	A frequency-dependent correction that is applied to a measured or calculated sound of moderate intensity to mimic the varying sensitivity of the ear to sound for different frequencies – C-weighting is usually used for peak measurements
FAST	Fast response has a time constant of 125 milliseconds on a sound level meter
$L_{Aeq,T}$	A-weighted, equivalent continuous sound pressure level during a stated time interval starting at t_1 and ending at t_2, expressed in decibels (dB), at a given point in space[1]
$L_{A,max}$	Maximum time-weighted and A-weighted sound pressure level within a stated time interval starting at t_1 and ending at t_2, expressed in dB[1]
L_{AF}	A-weighted sound pressure level with FAST time constant as specified in IEC 61672-1[1]
$L_{AF,max}$	Maximum time-weighted and A-weighted sound pressure level with FAST time constant within a stated time interval starting at t_1 and ending at t_2, expressed in dB
$L_{AS,max}$	Maximum time-weighted and A-weighted sound pressure level with SLOW time constant within a stated time interval starting at t_1 and ending at t_2, expressed in dB
L_E	Sound energy density level is the logarithmic ratio of the time-averaged sound energy per unit volume to the reference sound energy density Eo = 10-12 J/m^3.
$L_{ex,8h}$	L_{eq} (equivalent continuous sound level) corrected for the length of the working shift, in this case 8 hours
L_{day}	Equivalent continuous sound pressure level when the reference time interval is the day[1]
L_{den}	Day-evening-night-weighted sound pressure level as defined in section 3.6.4 of ISO 1996-1:2016[1]
L_{dn}	Day-night-weighted sound pressure level as defined in section 3.6.4 of ISO 1996-1:2016[1]
$L_{evening}$	Equivalent continuous sound pressure level when the reference time interval is the evening[1]

[1] *Source*: ISO (2016).

L_{night}	Equivalent continuous sound pressure level when the reference time interval is the night[1]
$L_{peak,C}$	Level of peak sound pressure with C-weighting, within a specified time interval
$L_{peak,lin}$	Level of peak sound pressure with linear frequency weighting, within a specified time interval
Sound pressure level	the logarithm of the ratio of a given sound pressure to the reference sound pressure in dB is 20 times the logarithm to the base ten of the ratio.
SLOW	Slow response has a time constant of 10 000 milliseconds on a sound level meter

Executive summary

Environmental noise is an important public health issue, featuring among the top environmental risks to health. It has negative impacts on human health and well-being and is a growing concern among both the general public and policy-makers in Europe.

At the Fifth Ministerial Conference on Environment and Health in Parma, Italy, in 2010, WHO was requested by the Member States in the European Region to produce noise guidelines that included not only transportation noise sources but also personal electronic devices, toys and wind turbines, which had not yet been considered in existing guidelines. Furthermore, European Union Directive 2002/49/EC relating to the assessment and management of environmental noise (END) and related technical guidance from the European Environment Agency both elaborated on the issue of environmental noise and the importance of up-to-date noise guidelines.

The WHO Regional Office for Europe has therefore developed environmental noise guidelines for the European Region, proposing an updated set of public health recommendations on exposure to environmental noise.

Objectives

The main purpose of these guidelines is to provide recommendations for protecting human health from exposure to environmental noise originating from various sources: transportation (road traffic, railway and aircraft) noise, wind turbine noise and leisure noise. Leisure noise in this context refers to all noise sources that people are exposed to due to leisure activities, such as attending nightclubs, pubs, fitness classes, live sporting events, concerts or live music venues and listening to loud music through personal listening devices. The guidelines focus on the WHO European Region and provide policy guidance to Member States that is compatible with the noise indicators used in the European Union's END.

The following two key questions identify the issues addressed by the guidelines.

- In the general population exposed to environmental noise, what is the exposure–response relationship between exposure to environmental noise (reported as various indicators) and the proportion of people with a validated measure of health outcome, when adjusted for confounders?
- In the general population exposed to environmental noise, are interventions effective in reducing exposure to and/or health outcomes from environmental noise?

In light of these questions, the guidelines set out to define recommended exposure levels for environmental noise in order to protect population health.

Methods used to develop the guidelines

The process of developing the WHO guidelines followed a rigorous methodology involving several groups with separate roles and responsibilities. Throughout the process, the Grading of

Recommendations Assessment, Development and Evaluation (GRADE) approach was followed. In particular, the different steps in the development of the guidelines included:

- formulation of the scope and key questions of the guidelines;
- review of the pertinent literature;
- selection of priority health outcome measures;
- a systematic review of the evidence;
- assessment of certainty of the bodies of evidence resulting from systematic reviews;
- identification of guideline exposure levels; and
- setting of the strength of recommendations.

Based on the defined scope and key questions, these guidelines reviewed the pertinent literature in order to incorporate significant research undertaken in the area of environmental noise and health since the community noise guidelines and night noise guidelines for Europe were issued (WHO, 1999; WHO Regional Office for Europe, 2009). In total, eight systematic reviews of evidence were conducted to assess the relationship between environmental noise and the following health outcomes: cardiovascular and metabolic effects; annoyance; effects on sleep; cognitive impairment; hearing impairment and tinnitus; adverse birth outcomes; and quality of life, mental health and well-being. A separate systematic review of evidence was conducted to assess the effectiveness of environmental noise interventions in reducing exposure and associated impacts on health.[2] Once identified and synthesized, the quality of the evidence of the systematic reviews was assessed by the Systematic Review Team. Subsequently, the Guideline Development Group (GDG) formulated recommendations, guided by the Systematic Review Team's assessment and informed by of a number of additional contextual parameters. To facilitate the formulation of recommendations, the GDG first defined priority health outcomes and then selected the most relevant health outcome measures for the outcomes. Consecutively, a process was developed to identify the guideline exposure levels with the help of the exposure–response functions provided by the systematic reviews. To reflect the nature of the research (observational studies) underpinning the relationship between environmental noise and health, the GRADE procedures were adapted to the requirements of environmental exposure studies where needed.

Noise indicators

From a scientific point of view, the best noise indicator is the one that performs best in predicting the effect of interest. There are, however, a number of additional criteria that may influence the choice of indicator. For example, various indicators might be suitable for different health end-points. Some considerations of a more political nature can be found in the European Commision's Position paper on EU noise indicators (EC, 2000).

[2] All systematic reviews are publicly available online in the *International Journal of Environmental Research and Public Health*. A detailed list of links to the individual reviews is provided in section 2.3.2 and in Annex 2 of these guidelines.

The current guidelines are intended to be suitable for policy-making in the WHO European Region. They therefore focus on the most used noise indicators L_{den} and/or L_{night} (see the glossary of acoustic terms for further details). They can be constructed using their components (L_{day}, $L_{evening}$, L_{night} and the duration in hours of L_{night}), and are provided for exposure at the most exposed façade, outdoors. The L_{den} and L_{night} indicators are those generally reported by authorities and are widely used for exposure assessment in health effect studies.

Recommendations

Specific recommendations have been formulated for road traffic noise, railway noise, aircraft noise, wind turbine noise and leisure noise. Recommendations are rated as either strong or conditional.

Strength of recommendation

- A **strong** recommendation can be adopted as policy in most situations. The guideline is based on the confidence that the desirable effects of adherence to the recommendation outweigh the undesirable consequences. The quality of evidence for a net benefit – combined with information about the values, preferences and resources – inform this recommendation, which should be implemented in most circumstances.
- A **conditional** recommendation requires a policy-making process with substantial debate and involvement of various stakeholders. There is less certainty of its efficacy owing to lower quality of evidence of a net benefit, opposing values and preferences of individuals and populations affected or the high resource implications of the recommendation, meaning there may be circumstances or settings in which it will not apply.

Alongside specific recommendations, several guiding principles were developed to provide generic advice and support for the incorporation of recommendations into a policy framework. They apply to the implementation of all of the specific recommendations.

Guiding principles: reduce, promote, coordinate and involve

- Reduce exposure to noise, while conserving quiet areas.
- Promote interventions to reduce exposure to noise and improve health.
- Coordinate approaches to control noise sources and other environmental health risks.
- Inform and involve communities potentially affected by a change in noise exposure.

The recommendations, source by source, are as follows.

Road traffic noise

Recommendation	Strength
For average noise exposure, the GDG strongly recommends reducing noise levels produced by road traffic below **53 decibels (dB)** L_{den}, as road traffic noise above this level is associated with adverse health effects.	Strong
For night noise exposure, the GDG strongly recommends reducing noise levels produced by road traffic during night time below **45 dB** L_{night}, as night-time road traffic noise above this level is associated with adverse effects on sleep.	Strong
To reduce health effects, the GDG strongly recommends that policy-makers implement suitable measures to reduce noise exposure from road traffic in the population exposed to levels above the guideline values for average and night noise exposure. For specific interventions, the GDG recommends reducing noise both at the source and on the route between the source and the affected population by changes in infrastructure.	Strong

Railway noise

Recommendation	Strength
For average noise exposure, the GDG strongly recommends reducing noise levels produced by railway traffic below **54 dB** L_{den}, as railway noise above this level is associated with adverse health effects.	Strong
For night noise exposure, the GDG strongly recommends reducing noise levels produced by railway traffic during night time below **44 dB** L_{night}, as night-time railway noise above this level is associated with adverse effects on sleep.	Strong
To reduce health effects, the GDG strongly recommends that policy-makers implement suitable measures to reduce noise exposure from railways in the population exposed to levels above the guideline values for average and night noise exposure. There is, however, insufficient evidence to recommend one type of intervention over another.	Strong

Aircraft noise

Recommendation	Strength
For average noise exposure, the GDG strongly recommends reducing noise levels produced by aircraft below **45 dB** L_{den}, as aircraft noise above this level is associated with adverse health effects.	Strong
For night noise exposure, the GDG strongly recommends reducing noise levels produced by aircraft during night time below **40 dB** L_{night}, as night-time aircraft noise above this level is associated with adverse effects on sleep.	Strong
To reduce health effects, the GDG strongly recommends that policy-makers implement suitable measures to reduce noise exposure from aircraft in the population exposed to levels above the guideline values for average and night noise exposure. For specific interventions the GDG recommends implementing suitable changes in infrastructure.	Strong

Wind turbine noise

Recommendation	Strength
For average noise exposure, the GDG conditionally recommends reducing noise levels produced by wind turbines below **45 dB** L_{den}, as wind turbine noise above this level is associated with adverse health effects.	Conditional
No recommendation is made for average night noise exposure L_{night} of wind turbines. The quality of evidence of night-time exposure to wind turbine noise is too low to allow a recommendation.	
To reduce health effects, the GDG conditionally recommends that policy-makers implement suitable measures to reduce noise exposure from wind turbines in the population exposed to levels above the guideline values for average noise exposure. No evidence is available, however, to facilitate the recommendation of one particular type of intervention over another.	Conditional

Leisure noise

Recommendation	Strength
For average noise exposure, the GDG conditionally recommends reducing the yearly average from all leisure noise sources combined to **70 dB** $L_{Aeq,24h}$ as leisure noise above this level is associated with adverse health effects. The equal energy principle[3] can be used to derive exposure limits for other time averages, which might be more practical in regulatory processes.	Conditional
For single-event and impulse noise exposures, the GDG conditionally recommends following existing guidelines and legal regulations to limit the risk of increases in hearing impairment from leisure noise in both children and adults.	Conditional
Following a precautionary approach, to reduce possible health effects, the GDG strongly recommends that policy-makers take action to prevent exposure above the guideline values for average noise and single-event and impulse noise exposures. This is particularly relevant as a large number of people may be exposed to and at risk of hearing impairment through the use of personal listening devices. There is insufficient evidence, however, to recommend one type of intervention over another.	Strong

Target audience

The guidelines are published by the WHO Regional Office for Europe. In terms of their health implications, the recommended exposure levels can be considered applicable in other regions and suitable for a global audience, as a large body of the evidence underpinning the recommendations was derived not only from European noise effect studies but also from research in other parts of the world – mainly in America, Asia and Australia.

[3] The equal energy principle states that the total effect of sound is proportional to the total amount of sound energy received by the ear, irrespective of the distribution of that energy in time (WHO, 1999).

1. Introduction

Environmental noise features among the top environmental risks to physical and mental health and well-being, with a substantial associated burden of disease in Europe (WHO Regional Office for Europe & JRC, 2011; Hänninen et al., 2014). It has negative impacts on human health and well-being and is a growing concern among both the general public and policy-makers in Europe.

WHO published community noise guidelines (CNG) and night noise guidelines (NNG) for Europe in 1999 and 2009, respectively (WHO, 1999; WHO Regional Office for Europe, 2009). Since then, significant new evidence has accumulated on the health effects of environmental noise.

The need for updated health-based guidelines originates in part from commitments made at the Fifth Ministerial Conference on Environment and Health in Parma, Italy, in 2010, where Member States asked WHO to produce appropriate noise guidelines that would include additional noise sources such as personal electronic devices, toys and wind turbines (WHO Regional Office for Europe, 2010). Furthermore, European Union (EU) Directive 2002/49/EC relating to the assessment and management of environmental noise (the END – EC, 2002a) and related technical guidance from the European Environment Agency (EEA) both elaborated on the issue of environmental noise and the importance of up-to-date noise guidelines (EEA, 2010).

The WHO Regional Office for Europe has therefore developed environmental noise guidelines for the European Region, proposing an updated set of public health recommendations on exposure to environmental noise. The main purpose of these guidelines is to provide recommendations for protecting human health from exposure to environmental noise originating from various sources: transportation (road traffic, railway and aircraft) noise, wind turbine noise and leisure noise. The guidelines focus on the WHO European Region and provide policy guidance to Member States that is compatible with the noise indicators used in the EU's END.

The following two key questions identify the issues addressed by the guidelines.

- In the general population exposed to environmental noise, what is the exposure–response relationship between exposure to environmental noise (reported as various indicators) and the proportion of people with a validated measure of health outcome, when adjusted for confounders?
- In the general population exposed to environmental noise, are interventions effective in reducing exposure to and/or health outcomes from environmental noise?

1.1 The public health burden from environmental noise

Exposure to noise can lead to auditory and nonauditory effects on health. Through direct injury to the auditory system, noise leads to auditory effects such as hearing loss and tinnitus. Noise is also a nonspecific stressor that has been shown to have an adverse effect on human health, especially following long-term exposure. These effects are the result of psychological and physiological distress, as well as a disturbance of the organism's homeostasis and increasing allostatic load (Basner et al., 2014). This is further outlined in the WHO narrative review of the biological mechanisms of nonauditory effects (Eriksson et al., 2018).

The evidence of the association between noise exposure and health effects is based on experimental work regarding biological plausibility and, in observational studies, consistency among study results, presence of an exposure–response relationship and the magnitude of the effect. Environmental noise risk assessment and risk management relies on established exposure–response relationships (Babisch, 2014).

In 2011 the WHO Regional Office for Europe and the European Commission (EC) Joint Research Centre (JRC) published a report on the burden of disease from environmental noise that quantified the healthy years of life lost in western Europeam countries as a result of environmental noise (WHO Regional Office for Europe & JRC, 2011). The burden of disease is calculated, in a single measure of disability-adjusted life-years (DALYs), as the sum of the years of life lost from premature mortality and the years lived with disability for people living with the disease or health condition or its consequences in the general population (WHO, 2014a).

Sufficient information was deemed available to quantify the burden of disease from environmental noise for cardiovascular disease, cognitive impairment in children, sleep disturbance, tinnitus and annoyance. The report, based on a limited set of data, estimated that DALYs lost from environmental noise in western European countries are equivalent to 61 000 years for ischaemic heart disease (IHD), 45 000 years for cognitive impairment in children, 903 000 years for sleep disturbance, 22 000 years for tinnitus and 654 000 years for annoyance (WHO Regional Office for Europe & JRC, 2011). These results indicate that at least one million healthy years of life are lost every year from traffic-related environmental noise in western Europe. Sleep disturbance and annoyance, mostly related to road traffic noise, constitute the bulk of this burden. Available assessments place the burden of disease from environmental noise as the second highest after air pollution (WHO Regional Office for Europe & JRC, 2011; Hänninen et al., 2014; WHO 2014b). However, a lack of noise exposure data in the central and eastern parts of the WHO European Region means that it is not possible to assess the burden of disease from environmental noise for the whole Region.

1.2 The environmental noise policy context in the EU

The EU has been working to develop a harmonized noise policy for more than two decades. 1993 saw the start of the EC's Fifth Environment Action Programme, which stated that "no person should be exposed to noise levels which endanger health and quality of life" (EC, 1993). This was followed by a Green Paper on future noise policy (EC, 1996), which reinforced the importance of noise as one of the main environmental problems in Europe and proposed a new framework for noise policy development.

The Sixth Environment Action Programme had as one of its objectives: "to achieve a quality of environment where the levels of man-made contaminants do not give rise to significant impacts on, or risks to, human health" (EC, 2002b). This paved the way for the Commission to adopt and implement the END in 2002 (EC, 2002a). The main aim of the Directive is "to define a common approach intended to avoid, prevent or reduce on a prioritized basis the harmful effects, including annoyance, due to exposure to environmental noise".

The END obliges the EC to adapt its Annexes I–III (I on noise indicators in addition to L_{den}[4] and L_{night}[5], II on noise assessment methods and III on methods for assessing harmful effects of noise) to technical and scientific progress. While work on revising Annex II was finalized in 2015 and common noise assessment methods were introduced (EC, 2015), revisions of Annex III to establish methods to assess the harmful effects of noise only started in 2015. Annex III would primarily define what exposure–response relationships should be used to assess the effect of noise on populations. EU Member States have already expressed the view that the recommendations from these environmental noise guidelines for the WHO European Region will guide the revision of Annex III. Beside this main directive, few other legislative documents cover different noise sources and other related issues in the EU (EEA, 2014: Annex I).

The Seventh Environment Action Programme, which guides European environment policy until 2020 (EC, 2014a), is committed to safeguarding the EU's citizens from environment-related risks to health by ensuring that by 2020 "noise pollution in the Union has significantly decreased, moving closer to WHO-recommended levels". A particular requirement for achieving this is "implementing an updated EU noise policy aligned with the latest scientific knowledge, and measures to reduce noise at source, and including improvements in city design".

In addition to the EU's END, several national governments also have legislation and/or limit values that apply at national and/or regional levels (WHO Regional Office for Europe, 2012). The EEA, through its European Topic Centre on Land Use and Spatial Information, gathers noise exposure data and maintains the Noise Observation and Information Service for Europe, based on strategic noise maps provided by Member States (EEA, 2018). A total of 33 EEA countries, in addition to six cooperating countries in south-eastern Europe, report information on noise exposure to the EEA, following the requirements of the END. The quality and availability of noise exposure assessment differs between EU and non-EU Member States where, even if noise legislation has been harmonized with the Directive, noise mapping and action plans are still at the planning stage (EEA, 2014; 2017a; WHO Regional Office for Europe, 2012).

1.2.1 Definition of indicators in the END

The END specifies a number of noise indicators to be applied by Member States in noise mapping and action planning. The most important are L_{den} and L_{night}.

The L_{den} indicator is an average sound pressure level over all days, evenings and nights in a year (EEA, 2010). This compound indicator was adopted by the EU in the END (EC, 2002a). The L_{den} in decibels (dB) is defined by a specific formula, where:

- L_{day} is the A-weighted long-term average sound level as defined in ISO 1996-1: 2016, determined over all the day periods of a year;
- $L_{evening}$ is the A-weighted long-term average sound level as defined in ISO 1996-1: 2016, determined over all the evening periods of a year; and
- L_{night} is the A-weighted long-term average sound level as defined in ISO 1996-1: 2016, determined over all the night periods of a year (ISO, 2016).

4 Day-evening-night-weighted sound pressure level as defined in section 3.6.4 of ISO 1996-1:20161 (ISO, 2016).
5 Equivalent continuous sound pressure level when the reference time interval is the night.

The L_{night}, according to the definition in the END, is an equivalent outdoor sound pressure level, measured at the most exposed façade, associated with a particular type of noise source during night time (at least eight hours), calculated over a period of a year (WHO Regional Office for Europe, 2009).

Annex I of the END gives technical definitions for L_{den} and L_{night}, as well as supplementary noise indicators, which might be useful for monitoring special noise situations. For example, in the case of noisy but short-lived noise like shooting noise or noise emitted by trains, $L_{A,max}$ is often used. This is a measure of the maximum sound pressure reached during a defined measurement period. It is used to set noise limits and is sometimes considered in studies to determine certain health effects (such as awakening reactions).

1.3 Perceptions of environmental noise in the WHO European Region

1.3.1 Trends at the regional level

The general population greatly values the benefits of clean and quiet environments. In Europe, people perceive noise as an important issue that affects human health and well-being (EC, 2008; 2014b). In recent years, several Europe-wide surveys have examined the perception of noise as an issue among the population. Overall, these surveys ask about generic noise, referring to “neighbourhood noise” or “noise from the street”. This type of noise differs significantly in its definition from what is considered “environmental noise” in these guidelines. Nevertheless, in the absence of specific large surveys on perceptions of environmental noise as defined in these guidelines, the results provide insight into the public perception of this issue.

The European quality-of-life surveys, carried out every four years, are unique, pan-European surveys examining both the objective circumstances of lives of European citizens and how they feel about those circumstances and their lives in general. The last (fourth) survey was conducted in 2016–2017, involving nearly 37 000 citizens from all EU Member States and the five candidate countries (Albania, Montenegro, Serbia, the former Yugoslav Republic of Macedonia and Turkey). Respondents were asked whether they had major, moderate or no problems with noise in the immediate neighbourhood of their home. Almost one third (32%) reported problems with noise (ranging from 14% to 51% in individual countries), mainly in cities or city suburbs (49%) (Eurofound, 2017).

A 2010 survey of the then 27 countries in the EU, requested by the EC, showed that 80% of respondents (n = 26 602) believed that noise affects their health, either to some or to a great extent (EC, 2010).

A Eurobarometer report on attitudes of European citizens towards the environment (EC, 2014b) compiled opinions on various environmental risks from almost 28 000 respondents in 28 EU countries. Results showed that for 15% of respondents, noise pollution is one of the top five environmental issues they are worried about. Furthermore, 17% of respondents said that they lack information about noise pollution.

1.3.2 Trends at the national level

Data on perception of specific sources of environmental noise as a problem are not available for the entire WHO European Region. Nevertheless, some countries – including France, Germany, the Netherlands, Slovakia and the United Kingdom – conduct national surveys on noise annoyance, either regularly or on demand (Sobotova et al., 2006; Lambert & Philipps-Bertin, 2008; van Poll et al., 2011; Centraal Bureau voor de Statistiek, 2012; Notley et al., 2014; Umweltbundesamt, 2017).

According to these large-scale surveys, road traffic noise is the most important source of annoyance, generally followed closely by neighbour noise. Aircraft noise can also be a substantial source of annoyance. Railway noise and industrial noise are enumerated less frequently. Only limited data are available on the population's perception of newer sources of noise, such as wind turbines.

While perception surveys do not provide information on actual quantitative relationships between noise exposure and health outcomes, it is important to note that the results of such surveys represent people's preferences and values regarding environmental noise. Despite limitations and an incomplete picture, the available data on perception of environmental noise as a public health problem show concern in Europe. People are not always aware of the health impacts of noise, especially of those related to long-term noise exposure at lower levels. Greater awareness of the issue may further increase positive values and preferences.

1.4 Target audience

The environmental noise guidelines for the European Region serve as a reference for an audience made up of different groups, with varied areas of expertise including decision-making, research and advocacy. More specifically, this covers:

- various technical experts and decision-makers at the local, national or international levels, with responsibility for developing and implementing regulations and standards for noise control, urban planning and housing, and other relevant environment and health domains;
- health impact assessment and environmental impact assessment practitioners and researchers;
- national and local authorities responsible for developing and implementing relevant measures and for risk communication;
- nongovernmental organizations and other advocacy groups involved in risk communication and general awareness-raising.

These guidelines are published by the WHO Regional Office for Europe. In terms of their health implications, the recommended exposure levels can be considered applicable in other regions and suitable for a global audience, as a large body of the evidence underpinning the recommendations was derived not only from European noise effect studies but also from research in other parts of the world – mainly in America, Asia and Australia.

2. Development of the guidelines

2.1 Overview

The process of developing WHO guidelines follows a rigorous methodology and involves several groups with well defined roles and responsibilities (WHO, 2014c). These include: formulation of the scope and key questions of the guidelines; review of the pertinent literature; selection of priority health outcome measures; a systematic review of the evidence; an assessment of certainty of the bodies of evidence resulting from systematic reviews; identification of guideline exposure levels; and setting of the strength of recommendations. Throughout the process, the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach was followed (Morgan et al., 2016).

The development of environmental noise guidelines started in 2013. Following WHO's procedures, the WHO Regional Office for Europe, through its European Centre for Environment and Health in Bonn, Germany, obtained planning approval and established a Steering Group and a Guideline Development Group (GDG). The former was primarily involved in initiating, structuring and executing the guideline development process; the latter was composed of leading experts and end-users, responsible for the process of scoping the guidelines and developing the evidence-based recommendations. During the initiation meeting in October 2013 in Bonn, the GDG members defined the scope of the guidelines, decided on the key questions to be addressed, prioritized health outcomes and set a timeline for completion of the work. Furthermore, authors were appointed for background papers, systematic reviews and different guideline background chapters.

In October 2014 a main evidence review meeting was held between the GDG and the Systematic Review Team in Bern, Switzerland, to discuss the evidence review drafts. In October 2014 and May 2015 the GDG met in Bern and Bonn, respectively, to refine the scope and draft recommendations. The revision and finalization of the systematic reviews of evidence was completed in early 2017. Through a series of remote meetings and teleconferences, the GDG discussed and addressed the remaining outstanding issues and feedback from the peer review of the draft guidelines, and decided on the final formulation of the recommendations. The following sections describe the steps of the guideline development process in detail.

2.2 Scope of the guidelines

Defining the scope of the guidelines included the selection of noise sources to be considered, as well as situations in which people are exposed, and noise indicators used for the formulation of recommendations. These guidelines separately consider outdoor exposure to environmental noise from road traffic, railway traffic, aircraft, wind turbines as well as outdoor and indoor exposure during leisure activities (such as attending nightclubs, pubs, fitness classes, live sporting events, concerts or live music venues and listening to loud music through personal listening devices). The guidelines are source specific and not environment specific. They therefore cover all settings where people spend a significant portion of their time, such as residences, educational institutions, workplaces and public venues, although hospital noise is exempted from the list of public institutions owing to the unique characteristics of the population involved.

The GDG agreed not to develop specific recommendations for occupational and industrial noise. Industrial noise can affect both people working at an industrial site and those living in its vicinity. The guidelines do not consider workers' exposure to noise in industrial environments, as these are regulated by workplace standards and may, in some cases, require the wearing of protective equipment or application of other preventive and protective measures. Further, the guidelines do not explicitly consider industrial noise as an environmental noise source, affecting people living in the vicinities of industrial sites. This is mainly due to the large heterogeneity and specific features of industrial noise, and the fact that exposure to industrial noise has a very localized character in the urban population.

Likewise, the current guidelines do not provide specific recommendations for the prevention of health effects linked to neighbourhood noise. Neighbourhood noise may stem from various potential sources of noise (such as ventilation systems; church bells; animals; neighbours; commercial, recreational and occupational activities; or shooting/military). As the sources may be located in close proximity to where people live, they can cause considerable concern even at low levels (Omlin et al., 2011). Several of these sources can also produce low-frequency noise, and as such, require indoor measurements for proper exposure assessment. In general, little scientific research is available on exposure and health outcomes related to neighbourhood noise.

Moreover, the guidelines do not include recommendations about any kind of multiple exposures. In everyday life people are often exposed to noise from several sources at the same time. In Germany, for example, 44% of the population are annoyed by at least two and up to five sources of noise (Umweltbundesamt, 2015). For some health outcomes, such as obesity, new evidence indicates that combined exposure to noise from several means of transportation is particularly harmful (Pyko et al., 2015; 2017).

Research indicates that, alongside exposure to more than one source of noise, combined exposure to different factors – for example, noise and vibration or noise and air pollution – has gained increasing relevance in recent years (Sörensen et al., 2017). The EC estimates that the social cost of noise and air pollution is up to €1 trillion every year (EC, 2016a). WHO acknowledges the need to develop comprehensive models to quantify the effects of multiple exposures on human health. As the main body of evidence on environmental noise still focuses on source-specific impacts of noise on health outcomes and does not incorporate combined exposure effects of multiple noise sources or other pollutants, however, the current guidelines provide recommendations for each source of noise specifically. No attempt has been made to combine noise from multiple sources for any particular health outcome.

2.2.1 Key questions

The environmental noise guidelines for the WHO European Region seek to address two main questions, which define the issues addressed by the guideline recommendations.

- In the general population exposed to environmental noise, what is the exposure–response relationship between exposure to environmental noise (reported as various indicators) and the proportion of people with a validated measure of health outcome, when adjusted for confounders?
- In the general population exposed to environmental noise, are interventions effective in reducing exposure to and/or health outcomes from environmental noise?

2.2.2 Environmental noise indicators used in the guidelines

From a scientific point of view, the best noise indicator is the one that performs best in predicting the effect of interest. There are, however, a number of additional criteria that may influence the choice of indicator because, for example, various indicators might be suitable for different health end-points and some indicators are more practical to use or easier to calculate than others. Some of these considerations are of a more political nature, as mentioned in the EC's Position paper on EU noise indicators (EC, 2000).

The current guidelines are intended to be suitable for policy-making primarily in the WHO European Region. They are therefore based on the most frequently used average noise indicators in Europe: L_{den} and L_{night}. These are often reported by authorities and are used widely for exposure assessment in health effect studies and noise impact assessments in the Region. The L_{den} (also referred to as "DENL") indicator can be calculated as the A-weighted average sound pressure level, measured over a 24-hour period, with a 10 dB penalty added to the average level in the night (23:00–07:00 or 22:00–06:00), a 5 dB penalty added to the evening (19:00–23:00 or 18:00–22:00) and no penalty added to the daytime period (07:00–19:00 or 06:00–18:00). The penalties are introduced to indicate people's extra sensitivity to noise during the evening and night. The L_{night} indicator is the A-weighted average sound pressure level, measured over an eight-hour period during night time, usually between 23:00 and 07:00 (EC, 2002a).

In these guidelines, L_{den} and L_{night} refer to a measurement or calculation of noise exposure at the most exposed façade, outdoors, reflecting the long-term average exposure. Thus, L_{den} and L_{night} represent all the single noise events due to a specific noise source that occur over a longer period of time, such as during a year. Moreover, most health outcomes considered in these guidelines are expected to occur as a result of long-term exposure. It is generally accepted that the most relevant parts of the whole day or night, which especially account for the time when a person is at home, are correctly attributed when using average indicators like L_{den} or L_{night}.

The majority of studies that form the body of evidence for the recommendations in these guidelines – among them large-scale epidemiological studies and socioacoustic surveys on annoyance and self-reported sleep disturbance – refer to noise exposure measured outdoors, usually at the most exposed façade of dwellings. Virtually all noise exposure prediction models in use today estimate free-field exposure levels outdoors, and most noise abatement regulations refer to outdoor levels as well. These are the practical reasons why the GDG decided not to recommend any guideline values for noise indoors. Nevertheless, in certain cases it could be helpful to estimate indoor levels based on outdoor values. The differences between indoor and outdoor levels are usually estimated at around 10 dB for open, 15 dB for tilted or half-open and about 25 dB for closed windows. When considering more accurate estimation of indoor levels, using a range of different predictors, the relevant scientific literature can be consulted (Locher et al., 2018).

The GDG was aware of the fact that many countries outside the EU are not bound by the terms of the END (EC, 2002a) and/or use noise indicators other than L_{den} or L_{night} in their noise regulations. They still can make use of these guidelines, however, because energy-based average noise indicators are usually highly correlated and "rule of thumb" transformations from one indicator to another are possible with acceptable uncertainty, as long as the conversion accounts for the long-term average of populations, rather than individual exposure situations. Empirically derived generic conversion terms between a wide range of different noise indicators (including L_{den}, L_{dn}, L_{day}, L_{night} and $L_{Aeq,24h}$; see the glossary of acoustic terms for further details), with their uncertainty estimates, were published recently (Brink et al., 2018). The GDG encourages the use of these conversions, should the need arise.

In many situations, average noise levels like the L_{den} or L_{night} indicators may not be the best to explain a particular noise effect. Single-event noise indicators – such as the maximum sound pressure level ($L_{A,max}$)[6] and its frequency distribution – are warranted in specific situations, such as in the context of night-time railway or aircraft noise events that can clearly elicit awakenings and other physiological reactions that are mostly determined by $L_{A,max}$. Nevertheless, the assessment of the relationship between different types of single-event noise indicators and long-term health outcomes at the population level remains tentative. The guidelines therefore make no recommendations for single-event noise indicators.

Different noise sources – for example, road traffic noise and railway noise – can be characterized by different spectra, different noise level rise times of noise events, different temporal distributions of noise events and different frequency distributions of maximum levels. Because of the extensive differences in the characteristics of individual noise sources, these guidelines only consider source-specific exposure–response functions (ERFs) and, therefore, formulate only source-specific recommendations.

2.3 Evidence base

Based on the overall scope and key questions the current guidelines review the relevant literature in the area of environmental noise and health in order to incorporate significant research undertaken since the publication of previous guidelines. The process of evidence search and retrieval involved several steps. These include the identification, retrieval and synthesis of the evidence, followed by a systematic review and assessment (described in section 2.4).

2.3.1 Identification, retrieval and synthesis of evidence

As a first step, the GDG identified key health outcomes associated with environmental noise. Next, it rated the relevance of these health outcomes according to the following three categories:

- critical for assessing environmental noise issues
- important, but not critical for assessing environmental noise issues
- unimportant.

The GDG rated the relevance based on the seriousness and prevalence of the outcomes and the anticipated availability of evidence for an association with noise exposure. The following health outcomes were selected as either critical or important for developing recommendations on the health impacts of environmental noise.

[6] $L_{A,max}$ is the maximum time-weighted and A-weighted sound pressure level within a stated time interval starting at t1 and ending at t2, expressed in dB.

Critical health outcome	Important health outcome
Cardiovascular disease	Adverse birth outcomes
Annoyance[7]	Quality of life, well-being and mental health
Effects on sleep	Metabolic outcomes
Cognitive impairment	
Hearing impairment and tinnitus	

The GDG noted that research into the relationship between noise exposure and its effects on humans brings into focus several questions concerning the definition of health and the boundary between normal social reaction to noise and noise-induced ill health. As stated in WHO's Constitution: "Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" (WHO, 1946). Accordingly, documenting physical health does not present a complete picture of general health; and being undisturbed by noise in all activities, including sleep, constitutes an asset worthy of protection. Therefore, in accordance with the above definition, the GDG regarded (long-term) annoyance and impaired well-being, as well as self-reported sleep disturbance due to noise, as health outcomes.

Regarding sleep disturbance, the health outcome measures considered in these guidelines largely disregard "objective" indicators of sleep disturbance, such as the probability of awakening reactions or other polysomnography parameters. The main reason for this is the nature of the body of evidence on acute, objectively measured effects of noise during sleep. Studies of physiological effects of sleep and especially polysomnographic investigations are complex and resource-demanding; they therefore include only a small number of participants, who are often healthy young volunteers not representative of the general population. For these reasons, the majority of such studies do not meet the requirements for inclusion in the GRADE framework and full-scale meta-analysis, including adjustment for confounders. Furthermore, it is currently unclear how acute physiological reactions that affect the microstructure of sleep but are less well correlated with global sleep parameters, such as total sleep time, are related to long-term health impediments, especially considering the large interindividual differences in susceptibility to noise (Basner et al., 2011).

As sleeping satisfies a basic need and the absence of undisturbed sleep can have serious effects on human health (WHO Regional Office for Europe, 2009), the GDG set self-reported sleep disturbance, in line with the WHO definition of health, as a primary health outcome. Even though self-reported sleep disturbance might differ considerably from objectively measured parameters of sleep physiology, it constitutes a valid indicator in its own right, as it reflects the effects on sleep perceived by an individual over a longer period of time (WHO Regional Office for Europe & JRC, 2011). The importance of considering both annoyance and self-reported sleep disturbance as health outcomes is further supported by evidence indicating that they may be part of the causal pathway of noise-induced cardiovascular and metabolic diseases. This is further elaborated in the narrative review on biological mechanisms (Eriksson et al., 2018).

[7] Noise annoyance is defined as a feeling of displeasure, nuisance, disturbance or irritation caused by a specific sound (Ouis, 2001). In the current guidelines, "annoyance" refers to long-term noise annoyance.

The second step in the evidence retrieval process constituted formulation of the key questions for the critical and important health outcomes and identification of the areas of evidence to be reviewed, following the PICOS/PECCOS approach defined in the WHO handbook for guideline development (WHO, 2014c). PICOS/PECCOS is an evidence-based technique that frames health care-related questions to facilitate the search for suitable studies that can provide answers to the questions at hand (Huang et al., 2006). The PICOS approach divides intervention questions into five elements: population, intervention, comparator, outcome and study design. In exposure studies, PICOS becomes PECCOS, which stands for population, exposure, comparator, confounder, outcome and study design. The specification of the elements of PICOS/PECCOS serves to construct the body of evidence that underpins each recommendation. Due to the complex nature of environmental noise, several distinct areas of evidence were defined to address each of the scoping questions comprehensively.

For each of the critical and important health outcomes a systematic review was conducted (see also section 2.3.2). Health outcomes regarded as important were given less weight in the decision-making process than critical ones. Inclusion and exclusion criteria to be regarded in the systematic evidence reviews were defined in accordance with the PICOS/PECCOS framework for the evaluation of evidence (see Table 1). All evidence that met the inclusion criteria was included in the systematic reviewing process. A detailed description of the types of measure for each of the health outcomes under consideration is provided in the protocol for conducting the systematic reviews (Héroux & Verbeek, 2018a). See Annex 2 for details of all background documents and systematic reviews used in preparation of these guidelines.

Table 1. Inclusion and exclusion criteria for evidence reviews of health effects of environmental noise

Category	Inclusion criteria	Exclusion criteria
Populations	• Members of the general population • Specific segments of the population particularly at risk (children or vulnerable groups) • People exposed to noise in occupational settings (if relevant with combined exposure to environmental noise)	• Does not meet inclusion criteria
Exposure	• Noise exposure levels, either measured or calculated and expressed in dB values • Representative of the individual exposure of study participants (for most observational studies the dwelling location or home) • Calculated levels for transportation noise (road, rail, air) based on traffic data reflecting the use of roads, railway lines and in- and outbound flight routes at airports	• Does not meet inclusion criteria; in particular: - studies using hearing loss or hearing impairment as a proxy for (previous) noise exposure - surveys assessing noise exposure or number of listening hours based on subjective ratings given by subjects in a questionnaire
Confounders	• No inclusion criteria applied since the relationship between exposure to noise and a health outcome can be confounded by other risk factors; however, possible confounders taken into account were assessed for every study	• No exclusion criteria applied; however, possible confounders taken into account were assessed for every study

Table 1. contd.

Category	Inclusion criteria	Exclusion criteria
Outcomes	• Adverse birth outcomes • Annoyance • Cardiovascular disease • Cognitive impairment • Effects on sleep • Hearing impairment and tinnitus • Metabolic outcomes • Quality of life, mental health and well-being	• Does not meet inclusion criteria
Study types	• Cohort studies • Case-control studies • Cross-sectional studies • Ecological studies (only for cardiovascular disease)	• Does not meet inclusion criteria

Alongside the systematic reviews of the critical and important health outcomes, the GDG decided to review the evidence on health effects from noise mitigation measures and interventions to reduce noise levels in order to inform and complement the recommendations.

Interventions on environmental noise were defined according to five broad categories based on the available intervention literature and the experience of decades of environmental noise management (see Table 2 and Brown & van Kamp, 2017).

Table 2. Types of noise intervention

Intervention type	Intervention category	Intervention subcategory
A	Source intervention	• change in emission levels of sources • time restrictions on source operations
B	Path intervention	• change in the path between source and receiver • path control through insulation of receiver/receiver's dwelling
C	New/closed infrastructure	• opening of a new infrastructure noise source • closure of an existing one • planning controls between (new) receivers and sources
D	Other physical intervention	• change in other physical dimensions of dwelling/neighbourhood
E	Behaviour change intervention	• change in individual behaviour to reduce exposure • avoidance or duration of exposure • community education, communication

The GDG recognized that nonacoustic factors are an important possible confounder in both ERFs between noise levels and critical health effects and the effects of acoustic interventions on health outcomes. Whereas the inclusion criteria for confounders were not specified in PECCOS for the systematic reviews of evidence, they were considered at the stage of assessing the quality of evidence, using the GRADE approach. Depending on the health effect under investigation, possible nonacoustic factors may include:

- gender
- age
- education
- subjective noise sensitivity
- extroversion/introversion
- general stress score
- co-morbidity
- length of residence
- duration of stay at dwelling in the day
- window orientation of a bedroom or living room towards the street
- personal evaluation of the source
- attitudes towards the noise source
- coping capacity with respect to noise
- perception of malfeasance by the authorities responsible
- body mass index
- smoking habits.

In noise annoyance studies nonacoustic factors may explain up to 33% of the variance (Guski, 1999). The higher the quality of evidence, the lower confounding effects of nonacoustic factors may be expected. Nevertheless, as with measurement errors, confounding cannot be avoided.

Based on the retrieval and evaluation of the pertinent literature, the GDG decided to address the association of environmental noise from different sources and health outcomes separately and individually for each source of noise, and for critical and important health outcomes.

In addition to the systematic reviews of the health effects of environmental noise, a narrative review of biological mechanisms of nonauditory effects was conducted (Eriksson et al., 2018). This covers literature related to pathways for nonauditory effects and provides supporting evidence on the association between environmental noise and health outcomes in humans, especially related to cardiovascular and metabolic diseases.

2.3.2 Systematic reviewing process

After the retrieval of the evidence based on the PICOS/PECCOS approach, systematic reviews were conducted for all critical and important health outcomes. To meet the demands of the diverse and broad nature of the evidence, it was agreed that systematic reviews could vary in type. For some areas of evidence, a novel and fully fledged systematic reviewing process was needed to summarize the existing evidence; for others, the reviewing process could build upon existing (and mostly published) systematic reviews and summaries of evidence. Thus, the process consisted of two phases.

First, a comprehensive search was conducted for available systematic reviews and meta-analyses on environmental noise effects published after 2000. Each of the reviews was assessed for both relevance and quality. To be included in the evidence review process, studies from these reviews were required to meet a high quality standard, judged according to high scores of the AMSTAR checklist.[8] In cases where quality criteria were met but the review was older than two years (published before 2012), the search of the systematic review was updated to include new papers. If no good quality systematic reviews were available, a new search for original papers was conducted. The Systematic Review Team decided how the results would affect the search strategy for individual studies as part of the second phase. This was based on the assessment of the quality of the systematic reviews and on the coherence between the main research questions of the systematic reviews and the scope of the work of the guidelines.

In the second phase a search for individual papers was conducted, with the search strategy adapted according to the outcome of the first phase. As availability of systematic reviews and meta-analyses differed for the various health outcomes considered in the guidelines, this process varied for each evidence review. The search included cohort studies, case-control studies and cross-sectional studies of people exposed to environmental noise. Where relevant – for example, for the health outcome cardiovascular disease – the search also included ecological studies.

Due to the individualized retrieval of evidence for each of the systematic reviews, the time frames of the literature included varied. An indication of the temporal coverage of the studies included in different systematic review is provided in the relevant tables in Chapter 4.

A detailed description of the methodology used to conduct the systematic evidence reviews, including individual protocols for the reviews of health effects resulting from environmental noise and from noise interventions, is available (Héroux & Verbeek, 2018b). Furthermore, all systematic reviews conducted in the guideline development process are publicly available in the open-access journal *International Journal of Environmental Research and Public Health*:

- systematic review of transport noise interventions and their impacts on health (Brown & van Kamp, 2017);
- systematic review on environmental noise and adverse birth outcomes (Nieuwenhuijsen et al, 2017);
- systematic review on environmental noise and annoyance (Guski et al., 2017);
- systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018);
- systematic review on environmental noise and cognition (Clark & Paunovic, 2018);
- systematic review on environmental noise and effects on sleep (Basner & McGuire, 2018);
- systematic review on environmental noise and permanent hearing loss and tinnitus (Śliwińska-Kowalska & Zaborowski, 2017);
- systematic review on mental health and well-being (Clark & Paunovic, in press).

[8] AMSTAR is an instrument used to assess quality of evidence; it stands for "A MeaSurement Tool to Assess systematic Reviews" (Shea et al., 2007).

2.4 From evidence to recommendations

Once the evidence had been identified and synthesized, the Systematic Review Team assessed its quality. Subsequently, the GDG formulated recommendations, guided by this assessment and consideration of a number of other factors recognized as important. To facilitate the formulation of recommendations, it first prioritized the health outcome measures of the critical and important outcomes. A process was developed to identify the guideline exposure levels from each of the ERFs provided by the systematic reviews of evidence.

The following sections describe the assessment of the overall quality of the evidence based on the GRADE approach, selection of priority health outcome measurements, identification of guideline exposure levels and setting the strength of recommendations.

2.4.1 Assessment of overall quality of a body of evidence: the GRADE approach

As set out in the WHO handbook for guideline development (WHO, 2014c), the main framework for producing evidence-informed recommendations is the GRADE approach (Guyatt et al., 2008). This is used to assess the quality of a body of evidence synthesized in a systematic review. The assessment facilitates judgements about the certainty of effect estimates, which increases with the quality of the body of evidence. The quality can be rated high, moderate, low or very low (see Box 1).

Box 1 GRADE interpretations of quality of evidence

- **High quality:** further research is very unlikely to change the certainty of the effect estimate
- **Moderate quality:** further research is likely to have an important impact on the certainty of the effect estimate and may change the estimate
- **Low quality:** further research is very likely to have an important impact on the certainty of the effect estimate and is likely to change the estimate
- **Very low quality:** any effect estimate is uncertain

The original GRADE approach was developed specifically to rate the body of evidence resulting from a review of intervention studies. The initial quality level is set by study design: randomized control trials (RCTs) are considered high quality, whereas observational (nonrandomized) study designs are low quality. Then five factors are considered for downgrading the quality of the body of evidence resulting from RCTs or observational studies, and three factors are considered for upgrading the body of evidence resulting from observational studies alone.

The following five factors are used for downgrading the quality of evidence by one or two levels:

- study limitations or risk of bias in all studies that make up the body of evidence
- inconsistency of results between studies
- indirectness of evidence in the studies
- imprecision of the pooled effect estimate
- publication bias detected in a body of evidence.

The following three factors are used for upgrading the quality of evidence:

- high magnitude of the pooled effect
- direction of residual confounding and biases opposes an effect (i.e. when all plausible confounders are anticipated to reduce the estimated effect and there is still a significant effect)
- exposure–response gradient.

The GRADE approach was originally developed for application in the field of clinical medicine, where the majority of studies are randomized trials. However, to assess health effects resulting from an exposure such as environmental noise, randomized controlled trials are not applicable, as it would be unethical to expose participants deliberately to possibly harmful risk factors. The limitations of the application of GRADE to environmental health have been recognized and discussed in the literature (Morgan et al., 2016). Other types of study design dominate the evidence base in the domain of environmental noise research, so it was necessary to adapt the original GRADE approach to the subject of the current guidelines, as follows.

Instead of using the RCT study design as the starting-point for the quality rating, the study design most applicable and available for the field of research at hand was used. Thus, for evidence on the association between noise exposure and clinical health outcome measures, the rating of an evidence base consisting of cohort and case-control studies[9] was initially rated high quality. Cross-sectional studies and ecological studies were rated low quality and very low quality, respectively. This initial point of departure was only adapted for the evidence of the association between noise exposure and annoyance and sleep disturbance. Here, cross-sectional studies were rated high quality because annoyance and sleep disturbance are regarded as an immediate effect of exposure to environmental noise. Finally, in accordance with the original GRADE approach, the starting-point for evidence on the effect of interventions was rated low quality for observational studies. After determining the point of departure, the evidence base was rated down or up whenever one or more of the criteria for downgrading or upgrading (described above) were met. Each of the systematic reviews commissioned for these guidelines includes a detailed report on the assessment of the quality of the evidence.

A detailed discussion of the adaptations of GRADE is provided in the separate methodology publication (Héroux & Verbeek, 2018b).

2.4.2 Selection of priority health outcomes

In line with the WHO handbook for guideline development (WHO, 2014c), the GDG selected the key health outcomes associated with environmental noise at the beginning of the evidence retrieval process, and the systematic reviews were commissioned accordingly. The selection of health outcomes was based on the available evidence for the association between environmental noise and the specific outcome, as well as public concern about the health outcome resulting from noise exposure. The following health outcomes were rated critical: cardiovascular disease, annoyance,

[9] In the context of the current guidelines, “cohort studies” refer to longitudinal studies in which the occurrence of the outcome of interest in an exposed group is compared to the occurrence of that outcome in a reference group with no or lower exposure over time.

effects on sleep, cognitive impairment and hearing impairment and tinnitus. Adverse birth outcomes, quality of life, well-being and mental health, and metabolic outcomes were rated important (see also section 2.3.1).

Since all these health outcomes can be measured in various ways, the GDG evaluated each individually and prioritized different outcome measures for each in terms of their representativeness and validity. These measures were used to derive the guideline exposure levels; their prioritization was based on the impact of the disease and the disability weights (DWs) associated with the health outcome measure.[10]

The critical health outcomes, priority outcome measures identified and justifications for their selection are listed in Table 3.

Table 3. Critical health outcomes, outcome measures identified and justifications for selection

Critical health outcome	Critical health outcome measures (priority measures marked in bold)	Justification for selection
Cardiovascular disease (L_{den})	Self-reported or measured prevalence, **incidence**, hospital admission or mortality due to: • **ischaemic heart disease (IHD) (including angina pectoris and/or myocardial infarction)** • **hypertension** • stroke	Except for self-reports, these are objective measures of the outcome, affect a large proportion of the population, have important health consequences and can lead to more severe diseases and/or mortality. DW for IHD: 0.405. DW for hypertension: 0.117.
Effects on sleep (L_{night})	• **percentage of the population highly sleep-disturbed (%HSD)**, self-reported, assessed with a standardized scale • polysomnography measured outcomes (probability of additional awakenings) • cardiac and blood pressure outcome measures during sleep • motility measured sleep outcomes in adults • sleep disturbance in children	This is the most meaningful, policy-relevant measure of this health outcome. Self-reported sleep disturbances are a very common problem in the general population: they affect quality of life directly and may also lead to subsequent health impediments. Effects on sleep may be in the causal pathway to cardiovascular disease. This measure is not a proxy for physiological sleep quality parameters but is an important outcome in its own right. DW for %HSD: 0.07.
Annoyance (L_{den})	• **percentage of the population highly annoyed (%HA), assessed with standardized scale** • percentage annoyed, preferably assessed with standardized scale	This is the most objective measure of this health outcome. Large proportions of the population are affected by noise annoyance, even at relatively low exposure levels. Annoyance may be in the causal pathway to cardiovascular disease. DW for %HA: 0.02.

⇨

[10] DWs are ratings that vary between 0 and 1, in which 0 indicates no disability and 1 indicates the maximum amount of disability. The rates are derived from large population surveys in which people are asked to rank a specific disease for its impact on several abilities. The DWs have been proven useful in calculating the burden of disease.

Table 3. contd.

Critical health outcome	Critical health outcome measures (priority measures marked in bold)	Justification for selection
Cognitive impairment (L_{den})	• **reading and oral comprehension, assessed with tests** • impairment assessed with standardized tests • short and long-term memory deficit • attention deficit • executive function deficit (working memory capacity)	This outcome measure is the most meaningful: it can affect vulnerable individuals (children) and have a significant impact later in life. DW for impaired reading and oral comprehension: 0.006.
Hearing impairment and tinnitus (L_{Aeq}[11] and $L_{AF,max}$[12])	• **permanent hearing impairment, measured by audiometry** • permanent tinnitus	This outcome measure can affect vulnerable individuals (children) and have a significant impact later in life. It is the most objective measure for which there is an ISO standard (ISO, 2013), specifying how to estimate noise-induced hearing loss. DW for mild severity level (threshold at 25 dB) for childhood onset: 0.0150.

Table 4 provides a list of the important health outcomes along with the corresponding health outcome measures included in the systematic reviews. There was no prioritization of health outcome measures leading to justification of selection, since important health outcomes had less impact on the development of recommendations.

Table 4. Important health outcomes and health outcome measures reviewed

Important health outcome	Health outcome measures reviewed
Adverse birth outcomes (L_{den})	• pre-term delivery • low birth weight • congenital anomalies
Quality of life, well-being and mental health (L_{den})	• self-reported health and quality of life • medication intake for depression and anxiety • self-reported depression, anxiety and psychological distress • interviewer-assessed depressive and anxiety disorders • emotional and conduct disorders in children • children's hyperactivity • other mental health outcomes
Metabolic outcomes (L_{den})	prevalence, incidence, hospital admission or mortality due to: • type 2 diabetes • obesity

11 L_{Aeq} is an A-weighted, equivalent continuous sound pressure level during a stated time interval starting at t1 and ending at t2, expressed in dB, of a noise at a given point in space.
12 $L_{AF,max}$ is the maximum time-weighted and A-weighted sound pressure level with FAST time constant within a stated time interval starting at t1 and ending at t2, expressed in dB.

2.4.3 Identification of guideline exposure levels for each noise source

The GDG agreed to set guideline exposure levels based on the definition: "noise exposure levels above which the GDG is confident that there is an increased risk of adverse health effects". The identification of guideline values for each of the specific noise sources involved five distinct steps:

1. assessment of the validity of ERFs resulting from the systematic reviews of the effects of noise on each of the critical and important health outcomes;
2. assessment of the lowest noise level measured in the studies included in each of the corresponding systematic reviews;
3. assessment of the smallest risk or relative risk (RR) increase for each of the adverse health outcomes considered relevant;
4. determination of the guideline exposure level based on the ERF, starting from the lowest level measured (see step 2) and associated with the smallest relevant risk increase for adverse health outcomes (see step 3);
5. comparison of the guideline exposure levels calculated for each of the critical health outcomes of one source (for example, incidence of IHD, incidence of hypertension, %HA, permanent hearing impairment and reading and oral comprehension for road traffic noise): selection of the guideline exposure level for each noise source was based on the priority health outcome measure with the lowest exposure level for that source.

To define an "increased risk" to set the guideline exposure level, the GDG made a judgement about the smallest risk or RR of the adverse health effect it considered relevant for each of the priority health outcome measures. It is important to note that the relevant risk increases are benchmark values. The GDG agreed to set them in accordance with the guiding principles it had developed, to provide guideline values that illustrate an increased risk of adverse health effects. It used expert judgements for the determination of the benchmark values; these are elaborated further in section 2.4.3.2.

The guideline exposure levels presented are therefore not meant to identify effect thresholds (the lowest observed adverse effect levels for different health outcomes). This is a difference in approach from prior WHO guidelines, like the night noise guidelines for Europe (WHO Regional Office for Europe, 2009), which explicitly aimed to define levels indicating no adverse health effects. The approach to making choices about relevant risk increases is outlined below and summarized in Table 5.

For IHD and hypertension, RR increases were considered; for annoyance and sleep disturbance, absolute risks of %HA and %HSD were considered; and for reading and oral comprehension an average delay of reading age was defined. For the cardiovascular outcomes, incidence measures were prioritized, although much of the epidemiological evidence was based on prevalence data – particularly for hypertension – where almost no longitudinal studies were available. Prevalence data are generally derived from cross-sectional studies, where the temporal aspects are difficult to determine.

Table 5. Priority health outcomes and relevant risk increases for setting guideline levels

Priority health outcome measure (associated DW)	Relevant risk increase considered for setting of guideline level
Incidence of IHD (DW: 0.405)	5% RR increase
Incidence of hypertension (DW: 0.117)	10% RR increase
%HA (DW: 0.02)	10% absolute risk
%HSD (DW: 0.07)	3% absolute risk
Permanent hearing impairment (DW: 0.0150)	No risk increase due to environmental noise
Reading and oral comprehension (DW: 0.006)	One-month delay in terms of reading age

The DWs used to rank the priority critical health outcomes measures were retrieved from the relevant literature. For cardiovascular disease as a group and for hypertension, the burden of disease from environmental noise values (WHO Regional Office for Europe & JRC, 2011) were not considered applicable by the GDG for these guidelines. Thus, for cardiovascular disease, the DW value (DW: 0.405) specifically applied to acute myocardial infarction in the publication outlining the data sources, methods and results of the global burden of disease in 2002 (Mathers et al., 2003) was retained. Since hypertension is mainly viewed as an important risk factor and not as a health outcome, no general DW has been developed. The only other available DW value available is the DW of 0.117 for hypertensive episodes in pregnancy (Mathers et al., 1999). In the absence of any general DW, the GDG agreed on a conservative approach and decided to use this value.

The DWs for high sleep disturbance (DW: 0.07), high annoyance (DW: 0.02) and impaired reading and oral comprehension (DW: 0.006) were developed in the context of calculating the burden of disease from environmental noise (WHO Regional Office for Europe & JRC, 2011). The DW for hearing impairment was not included in that publication, but it was available from the technical paper on the burden of disease from environmental noise (WHO, 2013); the DW for permanent hearing impairment ranged from 0.0031 to 0.3342, depending on severity level. Environmental noise (leisure noise) contributes to the cumulative total noise exposure throughout the life-course, which may lead to permanent hearing impairment and cause more severe disability in the later years of life. As a result, the GDG selected a DW of 0.0150 for moderate severity level ("has difficulty following a conversation in a noisy environment, but no other hearing problems"). For cognitive impairment, the DW was derived from the estimates of the burden of disease from environmental noise (WHO Regional Office for Europe & JRC, 2011). This was at a very conservative value (DW: 0.006) for noise-related impairment of children's cognition, equivalent to a DW for contemporaneous cognitive deficit in the context of a range of cognitive impairments in children ranging from 0.468 for Japanese encephalitis to 0.024 for iron deficiency anaemia (Lopez et al., 2006).

2.4.3.1 Development of ERFs

The systematic reviews of evidence provided either an ERF or other noise exposure value/metric that could be related to a risk increase of the health outcome measure. These ERFs were used to develop guideline exposure levels; however, only those functions where noise exposure demonstrated a statistically significant effect were used.

To obtain the starting level of the ERFs derived in the systematic reviews, a weighted average of the lowest exposure values measured in the individual studies included in the meta-analyses was calculated. The weighting used the inverse of the variance of the effect estimate of the study. Thus, the lowest exposure value of studies with a small variance (usually with the largest sample size) contributed the most to the assumed onset of the ERF.

2.4.3.2 Relevant risk increase of adverse health effects

The following sections describe in detail the rationale for the selection of the relevant relative risk (RR) increase percentage for each of the priority health outcome measures considered.

Cardiovascular disease: IHD and hypertension

High-quality epidemiological evidence described in the systematic review on cardiovascular and metabolic effects of environmental noise indicates that exposure to road traffic noise increases the risk of IHD (van Kempen et al., 2018). The GDG was confident that health risks result from exposure at an RR increase in the order of 5–10% in the incidence of IHD. This is similar to the reasoning in the WHO air quality guidelines for fine particulate matter ($PM_{2.5}$) (WHO, 2006). To determine a relevant risk increase for IHD, the GDG took as a starting-point the RR increase of 5% measured in epidemiological studies of environmental noise or air pollution. Taking into account the incidence of IHD and the seriousness of the disease, it considered lowering the RR increase for IHD to 1%, as a 5% RR increase might imply a comparatively high absolute risk from a population perspective. To decide on the final benchmark value for IHD, several aspects were considered: the number of people in a population affected by IHD; whether health risks caused by noise would make up a large part of the incidence of the disease; other examples of health risks of similar magnitude leading to preventive action. For IHD, in an average EU country with 20 million inhabitants, an RR increase of 5% for IHD would lead to several thousand extra cases attributable to noise yearly. This corresponds to a proportion of cases of IHD attributable to noise exposure of less than 10%, which is still relatively small. After extensive discussion at the very end of the guideline development process, the GDG decided to adhere to 5% as the relevant risk increase.

Hypertension is a common condition and is an important risk indicator for IHD and other cardiovascular diseases. Thus, the hypertension risk increase can be transformed into a risk increase for cardiovascular disease. To derive a relevant risk increase, the GDG focused on the incidence of hypertension, owing to the nature and quality of epidemiological evidence. Since hypertension is less serious than IHD, and not all people with hypertension will progress to cardiovascular disease, the relevant risk increase in the incidence of hypertension needed to be higher than that for IHD. Therefore, the GDG agreed on an RR increase of 10% for hypertension.

Self-reported sleep disturbance and annoyance

The GDG initially considered 5%HSD and 10%HA due to noise as relevant absolute risks, not be exceeded at the guideline level. After discussion, however, members agreed that these absolute risks were too large, since a considerable proportion of the population would still be affected; they decided to lower the relevant risk from 5% being highly sleep-disturbed to 3%. In doing so, the GDG referred to the WHO night noise guidelines (WHO, 2009), which concluded that while there was insufficient evidence that physiological effects at noise levels below 40 dB L_{night} are harmful to health, there were observed adverse health effects at levels starting from 40 dB L_{night}. At 40 dB, about 3–4%

(depending on the noise source) of the population still reported being highly sleep-disturbed due to noise, which was considered relevant to health. The GDG considered it important that this level is consistent with the previous health-based approach adopted by the WHO night noise guidelines, and agreed that the absolute risk associated with the guideline value selected should not exceed 3%HSD to be health protective.

For annoyance, which is considered a less serious health effect than self-reported sleep disturbance (as indicated by the respective DWs), the relevant risk remained at 10%HA. This means the absolute risk associated with the guideline value selected should be closest to, but not above 10%HA, to be health protective.

Cognitive impairment: reading and oral comprehension

Acquiring skills in reading and oral comprehension at a young age is important for further development: a delay in acquiring these skills can have an impact later in life (Wilson & Lonigan, 2010). This impact cannot be predicted very accurately, but the GDG considered a delay of one month a relevant absolute risk.

Permanent hearing impairment

The literature on hearing impairment as a result of occupational noise exposure is extensive. A noise exposure level beyond 80 dB during 40 years of working a 40 hour work week can give rise to permanent hearing impairment. Given that environmental exposure to noise is much lower than these levels and that noise-related hearing impairments are not reversible, the GDG considered that there should be no risk of hearing impairment due to environmental noise and considered any increased risk of hearing impairment relevant.

2.4.4 Strength of the recommendations

Finally, having determined the guideline exposure levels based on the ranking of prioritized health outcome measures, setting the strength of the recommendation was set as the final step of the guideline development process. This was also guided by the GRADE methodology (Alonso-Coello et al., 2016a; 2016b). According to this approach, strength of recommendation can be set as either strong or conditional (WHO, 2014c).

- A **strong** recommendation can be adopted as policy in most situations. The guideline is based on the confidence that the desirable effects of adherence to the recommendation outweigh the undesirable consequences. The quality of evidence for a net benefit – combined with information about the values, preferences and resources – inform this recommendation, which should be implemented in most circumstances.
- A **conditional** recommendation requires a policy-making process with substantial debate and involvement of various stakeholders. There is less certainty of its efficacy owing to lower quality of evidence of a net benefit, opposing values and preferences of individuals and populations affected or the high resource implications of the recommendation, meaning there may be circumstances or settings in which it will not apply.

The GRADE approach defines a number of parameters that should be assessed to determine the strength of recommendations: quality of evidence, balance of benefits and harms, values and preference related to the outcomes of interventions to exposure, resources implications, priority of the problem, equity and human rights, acceptability and feasibility (Box 2; Morgan et al., 2016).

Box 2 Parameters determining the strength of a recommendation

Quality of evidence further represents the confidence in the estimates of effect of the evaluated evidence, across outcomes critical and important to decision-making. The higher the quality of evidence, the greater the likelihood of a strong recommendation.

Balance of benefits and harms requires an evaluation of the absolute effects of both benefits and harms (or downsides) of the intervention or exposure and their importance. The greater net benefit or net harm associated with an intervention or an exposure, the greater the likelihood of a strong recommendation in favour or against an intervention or exposure.

Values and preferences related to the outcomes of an intervention or exposure set out the relative importance assigned to health outcomes by those affected by them; how such importance varies within and across populations; and whether this importance or variability is surrounded by uncertainty. The less uncertainty or variability there is about the values and preferences of people experiencing the critical or important outcomes, the greater the likelihood of a strong recommendation.

Resource implications take into consideration how resource-intensive and how cost-effective and substantially beneficial an intervention or exposure is. The more advantageous or clearly disadvantageous the resource implications are, the greater the likelihood of a strong recommendation either for or against the intervention or exposure.

The priority of the problem is determined by its importance and frequency (the burden of disease, disease prevalence or baseline risk). The greater the importance of the problem, the greater the likelihood of a strong recommendation.

Equity and human rights considerations are an important aspect of the process. The greater the likelihood that the intervention will reduce inequities, improve equity or contribute to the realization of one or several human rights as defined under the international legal framework, the greater the likelihood of a strong recommendation.

Acceptability plays a prominent role: the greater the acceptability of an option to all or most stakeholders, the greater the likelihood of a strong recommendation.

Feasibility overlaps with values and preferences, resource considerations, existing infrastructures, equity, cultural norms, legal frameworks and many other considerations. The greater the feasibility of an option from the standpoint of all or most stakeholders, the greater the likelihood of a strong recommendation.

The GDG evaluated the strength of the recommendations based on these parameters, following a two-step procedure. Initially, the strength of each recommendation was set as strong or conditional based on an assessment of the quality of evidence. The GDG then identified and assessed contextual parameters that might have a contributory role (see Box 2 above). Based on this qualitative evaluation, the initial recommendation strength was either adapted or confirmed. It is important to note that while the initial parameter "quality of evidence" was informed by comprehensive systematic reviewing processes, the remaining contextual parameters were assessed by the informed qualitative expert judgement of the GDG.

Furthermore, the GDG agreed to decision-making rules, applied when formulating the recommendations. An evidence rating of low quality or very low quality would lead only to a conditional recommendation. Setting a strong recommendation was only considered if the evidence was at least moderate quality. The final recommendations were formulated based on the consideration of all the parameters and decision rules adopted by the GDG. A detailed exploration of all the recommendations is set out in Chapter 3.

2.5 Individuals and partners involved in the guideline development process

The process of WHO guideline development is conducted by several groups with clearly defined roles and responsibilities. Comprising WHO staff members, experts and stakeholders, these are the Steering Group, the GDG, the Systematic Review Team and the External Review Group.

The **Steering Group** includes WHO staff members with different affiliations but whose work experience is relevant to the topic of environmental noise and associated health outcomes. It is involved at all stages of planning, selecting members of the GDG and External Review Group, reviewing evidence and developing potential recommendations at the main expert meetings, as well as ongoing consultation on revisions following peer review. Details of the members of the Steering Group are listed in Table A1.1 in Annex 1.

The **GDG** consists of a group of content experts gathered to investigate all aspects of evidence contributing to the recommendations, including expertise in evidence-based guideline development. This Group defined the key questions and priorities of the research, chose and ranked outcomes and provided advice on any modifications of the scope as established by the Steering Group. The members also outlined the systematic review methods; appraised the evidence used to inform the guidelines; and advised on the interpretation of this e idence, with explicit consideration of the overall balance of benefits and harms. Ultimately the GDG formulated the final recommendations, taking into account the diverse values and preferences of individuals and populations affected. It also determined the strength of the results and responded to external peer reviews. The complete list of GDG members and their specific roles, affiliations and areas of expertise are listed in Table A1.2 in Annex 1.

The **Systematic Review Team** includes experts in the field of environmental health, commissioned by WHO staff to undertake systematic reviews of evidence. The GDG recommended a number of authors to conduct the evidence reviews and summary chapters, based on their expertise. Details of the members of the Systtematic Review Team are included in Table A1.3 in Annex 1.

The **External Review Group** is composed of technical content experts and end-users as well as stakeholders, and is balanced geographically and by gender. The experts and end-users were selected for their expertise in the field, and the Group also included representatives of professional groups and industry associations, who will be implementing the guidelines. Members were asked to review the material at different stages of the development process. The list of technical experts and stakeholders is provided in Tables A1.4 and A1.5, respectively, in Annex 1.

Management of conflict of interest is an integral part of WHO's guideline development procedure. All members of the GDG and authors of the evidence reviews completed WHO declaration of interest forms. These were reviewed by the WHO Secretariat for potential conflicts of interest. A number of conflicts of interest were declared in the forms, but following a standardized management review it was not found necessary to exclude any members of the GDG or authors from their respective roles. Members of the External Review Group (technical experts only) were also asked to complete the form when invited to participate.

In addition, at the start of the meeting of the GDG all members of the GDG received a briefing about the nature of all types of conflict of interest (financial, academic/intellectual and nonacademic) and were asked to declare to the meeting any conflicts they might have. No member of the GDG or the Systematic Review Team was excluded from his/her respective role. A summary of the conflict of interest management is presented in Annex 3.

The GDG set its own rules on how it would work and how contentious issues should be resolved – for instance, by means of a vote. The main decision-making mechanism involved reaching consensus; if a vote was required, the experts involved in developing the underlying evidence for the specific recommendation were excluded from voting, and an agreement was reached via a two thirds majority of the rest of the group.

2.6 Previously published WHO guidelines on environmental noise

Prior to this publication, WHO published community noise guidelines (CNG) in 1999 (WHO, 1999) and night noise guidelines for Europe (NNG) in 2009 (WHO Regional Office for Europe, 2009).

2.6.1 CNG

The scope of WHO's efforts to develop the CNG in 1999 was similar to that for the current guidelines. The objective was then formulated as: "to consolidate scientific knowledge of the time on the health impacts of community noise and to provide guidance to environmental health authorities and professionals trying to protect people from the harmful effects of noise in nonindustrial environments" (WHO, 1999). The guidelines were based on studies carried out up to 1995 and a few meta-analyses from some years later.

The health risk to humans from exposure to environmental noise was evaluated and guideline values derived. At that time WHO had not yet developed its guideline development process, on which the current guidelines are based (WHO, 2014c). The main differences in content are that the previous guidelines were expert-based and provided more global coverage and applicability, such as issues of noise assessment and control that were addressed in detail. They included a discussion on noise sources and measurement, including the basic aspects of source characteristics, sound propagation and transmission. Adverse health effects of noise were characterized, and combined noise sources and their effects were considered. Furthermore, the guidelines included discussions of strategies and priorities in the management of indoor noise levels, noise policies and legislation, environmental noise impact and enforcement of regulatory standards; although there were no chapters on wind turbine noise and leisure noise.

2.6.2 NNG

In 2009 the WHO Regional Office for Europe published the NNG to provide scientifically based advice to Member States for the development of future legislation and policy action in the area of assessment and control of night noise exposure.

The NNG complement the previous CNG, incorporating the advancement of research on noise and sleep disturbance up to 2006. The working group of experts reviewed available scientific evidence on the health effects of night noise and derived health-based guideline values. Again, WHO had not yet introduced its evidence-based recommendations policy and the NNG were mainly expert-based. They considered the scientific evidence on the threshold of night noise exposure indicated by L_{night} as defined in the END (EC, 2002a), and the experts concluded that a L_{night} value of 40 dB should be the target of the NNG (for all sources) to protect the public, including the most vulnerable groups such as children, chronically ill and elderly people. Further, an L_{night} value of 55 dB was recommended as an interim target for countries that could not follow the guidelines in the short term for various reasons or where policy-makers chose to adopt a stepwise approach.

2.6.3 Differences from the prior noise guidelines

The current guidelines differ from the older ones, recommending levels of exposure unlike those previously outlined (especially by the NNG). The following major differences between the previous and current guidelines explain the novel set of recommended values.

- The development process for the current guidelines adhered to a new, rigorous, evidence-based methodology, as outlined in the WHO handbook for guideline development (WHO, 2014c). WHO adopted these internationally recognized standards to ensure high methodological quality and a transparent, evidence-based decision-making process in the guideline development.
- The current guidelines consider cardiovascular disease a critical health outcome measure.
- They also consider a broader set of health outcomes, including adverse birth outcomes, diabetes, obesity and mental well-being. Wherever applicable, incidence, prevalence and mortality were considered separately.
- The current guidelines cover two new noise sources: wind turbines and leisure noise.
- Critical and important health outcomes are considered separately for each of the noise sources.
- The guideline development process included the health effects of intervention measures to mitigate noise exposure from different noise sources for the first time.
- The style of recommendations differs: the current guidelines include an exact exposure value for every health outcome regarded as critical, for each noise source. Guideline recommendation values were set for each of the noise sources separately, based on the exact exposure values and a prioritization scheme, developed with the help of DWs.
- The current guidelines apply a 1 dB increment scheme, whereas prior guidelines (CNG and NNG) formulated or presented recommendations in 5 dB steps.

- In comparison to the 1999 CNG, which defined environment-specific exposure levels, the current guidelines are source specific. They recommend values for outdoor exposure to road traffic, railway, aircraft and wind turbine noise, and indoor as well as outdoor exposure levels for leisure noise.
- Except for leisure noise, all exposure levels recommended in the current guidelines are average sound pressure levels for outdoor exposure.
- The current guidelines make use of the noise indices defined in the END: L_{den} and L_{night}.

The definition of "community noise" used in the CNG in 1999 was also adapted. The GDG agreed to use the term "environmental noise" instead, and offered an operational definition of: "noise emitted from all sources except sources of occupational noise exposure in workplaces".

The current environmental noise guidelines for the European Region supersede the CNG from 1999. Nevertheless, the GDG recommends that all CNG indoor guideline values and any values not covered by the current guidelines (such as industrial noise and shopping areas) should remain valid.

Furthermore, the current guidelines complement the NNG from 2009. Two main aspects of the NNG constitute this complementarity: the different guiding principles and the comprehensive investigation of the immediate physiological effects of environmental noise on sleep. As guiding principles the NNG defined effect thresholds or "lowest observed adverse health effect levels" for both immediate physiological reactions during sleep (i.e. awakening reactions or body movements during sleep) and long-term adverse health effects (i.e. self-reported sleep disturbance). These guideline exposure levels defined a level below which no effects were expected to occur (corresponding to 30 dB L_{night}) and proceeded to define the level where adverse effects start to occur (corresponding to 40 dB L_{night}), with the aim of protecting the whole population, including – to some extent – vulnerable groups. The development of the NNG values relied on evidence-based expert judgement. In contrast, the current guidelines formulate recommendations more strictly based on the available evidence and following the guiding principle to identify exposure values based on a relevant risk increase of adverse health effects. Thus, the recommended guideline values might not lead to full protection of the population, including all vulnerable groups. The GDG stresses that the aim of the current guidelines is to define an exposure level at which effects certainly begin.

Secondly, the NNG comprehensively investigate the immediate short-term effects of environmental noise during sleep, including physiological reactions such as awakening reactions and body movements. They also provided threshold information about single-event noise indicators (such as the $L_{A,max}$). In contrast, the current guideline values for the night time are only based on the prevalence of self-reported sleep disturbance and do not take physiological effects into account. The causal link between immediate physiological reactions and long-term adverse health effects is complex and difficult to prove. Thus, the current guidelines are restricted to long-term health effects during night time and therefore only include recommendations about average noise indicators: L_{night}. Nevertheless, the evidence review on noise and sleep (Basner & McGuire, 2018) includes an overview of single-event exposure–effect relationships.

3. Recommendations

This chapter presents specific recommendations on guideline exposure levels and/or interventions to reduce exposure and/or improve health for individual sources of noise: road traffic, railway, aircraft, wind turbines and leisure noise. The strength of each recommendation is provided (strong or conditional) and a short rationale for how each of the guideline levels was achieved is given.

The GDG discussed extensively the best way to present guideline exposure levels – either as the exact values or in 5 dB steps – and the approach to rounding the values to the nearest integer. The 5 dB increment, rounded down from the exact exposure value to the nearest 5 dB level, was initially chosen as being commonly applied in noise legislation and used in prior guidelines (WHO, 1999; EC, 2002a; WHO Regional Office for Europe, 2009). It was also used to meet the principle of precaution, since imprecision in the exposure assessment in the field of epidemiology tends to attenuate the actual effects in the population.

Use of 5 dB increments resulted in uneven magnitude of rounding down, however, raising concerns of arbitrariness. It became apparent that inclusion of both exact values and the 5 dB rounded-down values might be confusing and could affect the applicability of the guidelines. Hence, the GDG ultimately decided that formulating recommendations based on the exact calculated values, rounded only to the nearest integer, would ensure more clarity and transparency. Furthermore, it noted that adhering to a 5 dB roster might not reflect the progress in the precision of exposure assessment methods in recent decades, which would justify application of a 1 dB step.

The GDG acknowledged that the recommendations might be presented as the exact guideline exposure levels only, leaving the use of 5 dB bands to the potential policy decisions to formulate or revise noise legislation, which are beyond the scope of this publication. The WHO guideline values are public health-oriented recommendations, based on scientific evidence on health effects and on an assessment of achievable noise levels. They are strongly recommended and as such should serve as the basis for a policy-making process in which policy options are quantified and discussed. It should be recognized that in that process additional considerations of costs, feasibility, values and preferences should also feature in decision-making when choosing reference values such as noise limits for a possible standard or legislation.

In addition to the source-specific recommendations in the following sections, a short rationale for the decision-making process by the GDG for developing a particular recommendation is provided, as well as an overview of the evidence considered. This includes a recapitulation of the specific PICOS/PECCOS question (see section 2.3.1), along with a summary of evidence for each of the critical and important health effects from exposure to each of the noise sources, and for the effectiveness of interventions.

Furthermore, a description is provided of the other factors considered according to the GRADE dimensions for the assessment of the strength of recommendations (see section 2.4.4). While the quality of evidence is central to determining this, the process of moving from evidence to recommendations involves several other considerations. These include values and preferences, balance of benefits and harms, consideration of the priority of the problem, resource implications, equity and human rights aspects, acceptability and feasibility (WHO, 2014c).

3.1 Road traffic noise

Recommendations

For average noise exposure, the GDG **strongly** recommends reducing noise levels produced by road traffic below **53 dB** L_{den}, as road traffic noise above this level is associated with adverse health effects.

For night noise exposure, the GDG **strongly** recommends reducing noise levels produced by road traffic during night time below **45 dB** L_{night}, as road traffic noise above this level is associated with adverse effects on sleep.

To reduce health effects, the GDG **strongly** recommends that policy-makers implement suitable measures to reduce noise exposure from road traffic in the population exposed to levels above the guideline values for average and night noise exposure. For specific interventions, the GDG recommends reducing noise both at the source and on the route between the source and the affected population by changes in infrastructure.

3.1.1 Rationale for the guideline levels for road traffic noise

The exposure levels were derived in accordance with the prioritization process of critical health outcomes described in section 2.4.3. For each of the outcomes, the exposure level was identified by applying the benchmark, set as relevant risk increase to the corresponding ERF. In the case of exposure to road traffic noise, the process can be summarized as follows (Table 6).

Table 6. Average exposure levels (L_{den}) for priority health outcomes from road traffic noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Incidence of IHD The 5% relevant risk increase occurs at a noise exposure level of 59.3 dB L_{den}. The weighted average of the lowest noise levels measured in the studies was 53 dB L_{den} and the RR increase per 10 dB is 1.08.	5% increase of RR	High quality
Incidence of hypertension One study met the inclusion criteria. There was no significant increase of risk associated with increased noise exposure in this study.	10% increase of RR	Low quality
Prevalence of highly annoyed population There was an absolute risk of 10% at a noise exposure level of 53.3 dB L_{den}.	10% absolute risk	Moderate quality
Permanent hearing impairment	No increase	No studies met the inclusion criteria
Reading skills and oral comprehension in children	One-month delay	Very low quality

In accordance with the prioritization process (see section 2.4.3), the GDG set a guideline exposure level of 53.3 dB L_{den} for average exposure, based on the relevant increase of the absolute %HA. It was confident that there was an increased risk for annoyance below this noise exposure level, but probably no increased risk for other priority health outcomes. In accordance with the defined rounding procedure, the value was rounded to 53 dB L_{den}. As the evidence on the adverse effects of road traffic noise was rated moderate quality, the GDG made the recommendation strong.

Next, the GDG assessed the evidence for night noise exposure and its effect on sleep disturbance (Table 7).

Table 7. Night-time exposure levels (L_{night}) for priority health outcomes from road traffic noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Sleep disturbance 3% of the participants in studies were highly sleep-disturbed at a noise level of **45.4 dB** L_{night}	3% absolute risk	Moderate quality

Based on the evidence of the adverse effects of road traffic noise on sleep disturbance, the GDG defined a guideline exposure level of 45.4 dB L_{night}. The exact exposure value was rounded to 45 dB L_{night}. As the evidence was rated moderate quality, the GDG made the recommendation strong.

The GDG also considered the evidence for the effectiveness of interventions. The results showed that:

- addressing the source by improving the choice of appropriate tyres, road surface, truck restrictions or by lowering traffic flow can reduce noise exposure;
- path interventions such as insulation and barrier construction reduce noise exposure, annoyance and sleep disturbance;
- changes in infrastructure such as construction of road tunnels lower noise exposure, annoyance and sleep disturbance;
- other physical interventions such as the availability of a quiet side of the residence reduce noise exposure, annoyance and sleep disturbance.

Given that it is possible to reduce noise exposure and that best practices already exist for the management of noise from road traffic, the GDG made a strong recommendation.

3.1.1.1 Other factors influencing the strength of recommendations

Other factors considered in the context of recommendations on road traffic noise included those related to values and preferences, benefits and harms, resource implications, equity, acceptability and feasibility; moreover, nonpriority health outcomes (the incidence of stroke and diabetes) were considered. Ultimately, the assessment of all these factors did not lead to a change in the strength of the recommendations. Further details are provided in section 3.1.2.3.

3.1.2 Detailed overview of the evidence

The following sections provide a detailed overview of the evidence constituting the basis for setting the recommendations on road traffic noise. It is presented and summarized separately for each of the critical health outcomes, and the GDG's judgement of the quality of evidence is indicated (for a detailed overview of the evidence on important health outcomes, see Annex 4). Research into health outcomes and effectiveness of interventions is addressed consecutively.

A comprehensive summary of all evidence considered for each of the critical and important health outcomes can be found in the eight systematic reviews published in the *International Journal of Environmental Research and Public Health* (see section 2.3.2 and Annex 2).

3.1.2.1 Evidence on health outcomes

The key question posed was: in the general population exposed to road traffic noise, what is the exposure–response relationship between exposure to road traffic noise (reported as various noise indicators) and the proportion of people with a validated measure of health outcome, when adjusted for main confounders? A summary of the PICOS/PECCOS scheme applied (see section 2.3.1) and the main findings is set out in Tables 8 and 9.

Table 8. PICOS/PECCOS scheme of critical health outcomes for exposure to road traffic noise

PECO	Description	
Population	General population	
Exposure	Exposure to high levels of noise produced by road traffic (average/night time)	
Comparison	Exposure to lower levels of noise produced by road traffic (average/night time)	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

Table 9. Summary of findings for health effects from exposure to road traffic noise (L_{den})

Noise metric	Priority health outcome measure	Quantitative risk for adverse health	Lowest level of exposure across studies	Number of participants (studies)	Quality of evidence
Cardiovascular disease					
L_{den}	Incidence of IHD	RR = 1.08 (95% confidence interval (CI): 1.01–1.15) per 10 dB increase	53 dB	67 224 (7)	High (upgraded for dose-response)
L_{den}	Incidence of hypertension	RR = 0.97 (95% CI: 0.90–1.05) per 10 dB increase	N/A	32 635 (1)	Low (downgraded for risk of bias and because only one study was available)
Annoyance					
L_{den}	%HA	Odds ratio (OR) = 3.03 (95% CI: 2.59–3.55) per 10 dB increase	40 dB	34 112 (25)	Moderate (downgraded for inconsistency)
Cognitive impairment					
L_{den}	Reading and oral comprehension	Not estimated	N/A	Over 2844 (1)	Very low (downgraded for inconsistency)
Hearing impairment and tinnitus					
L_{den}	Permanent hearing impairment	–	–	–	–

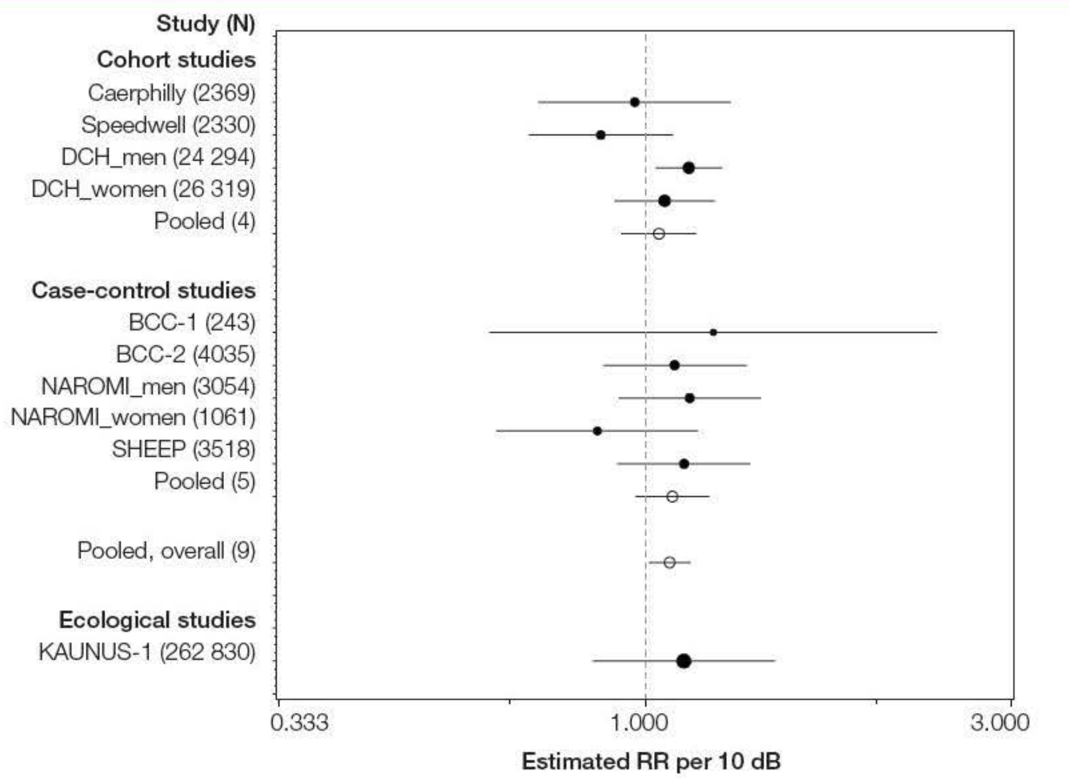
Cardiovascular disease

IHD

A total of three cohort (Babisch & Gallacher, 1990; Babisch et al., 1988; 1993a; 1993b; 1999; 2003; Caerphilly and Speedwell Collaborative Group, 1984; Sörensen et al., 2012a; 2012c) and four case-control studies (Babisch, 2004; Babisch et al., 1992; 1994; 2005a; Selander et al., 2009; Wiens, 1995) investigated the relationship between road traffic noise and the incidence of IHD. These involved a total of 67 224 participants, including 7033 cases. As identified in Fig. 1, the overall RR derived from the meta-analysis was 1.08 (95% CI: 1.01–1.15) per 10 dB L_{den} increase in noise levels, across a noise range of 40 dB to 80 dB. This evidence was rated high quality.

The data were supported by one ecological study conducted with 262 830 participants, including 418 cases, which also reported a statistically significant estimate (Grazuleviciene et al., 2004; Lekaviciute, 2007). In this study, a positive but nonsignificant association was found: RR of 1.12 (95% CI: 0.85–1.48) per 10 dB L_{den} increase in noise. This evidence was rated very low quality.

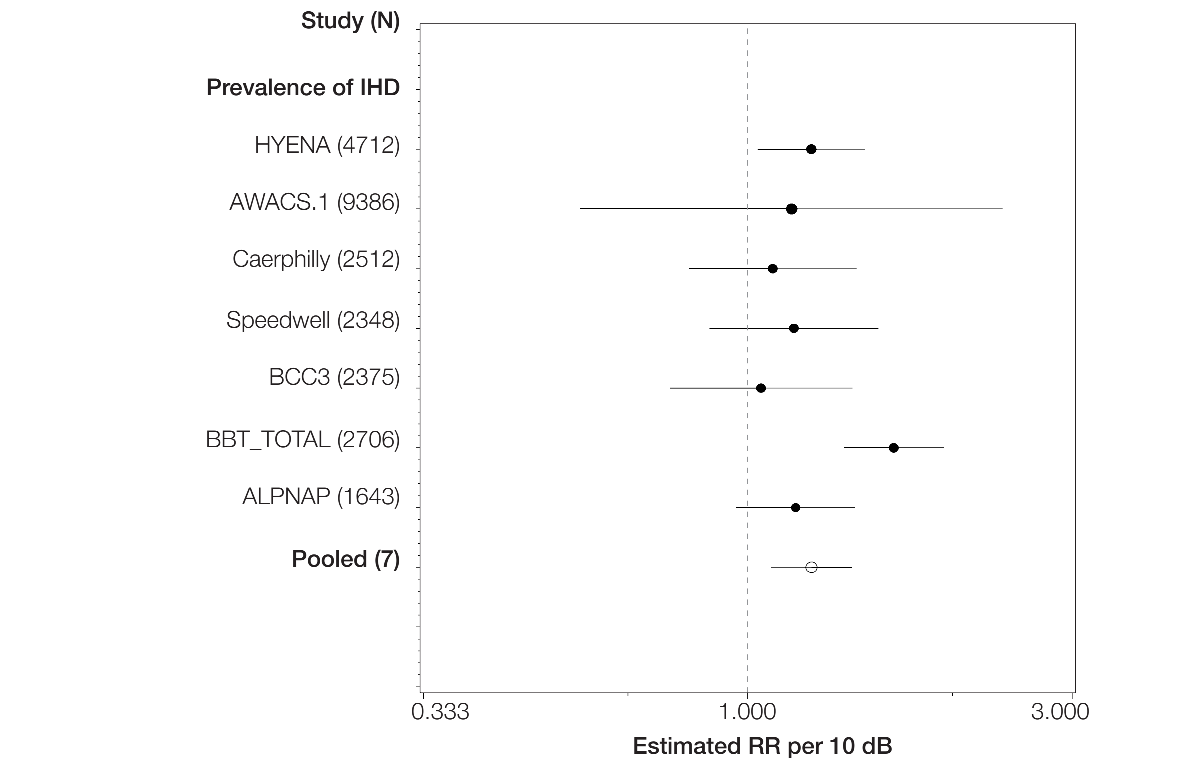
Fig. 1. The association between exposure to road traffic noise (L_{den}) and incidence of IHD



Notes: The dotted vertical line corresponds to no effect of exposure to road traffic noise. The black circles correspond to the estimated RR per 10 dB and 95% CI. The white circles represent the pooled random effect estimates and 95% CI. For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

Furthermore, additional evidence was available from eight cross-sectional studies that investigated the relationship between road traffic noise and prevalence of IHD (Babisch & Gallacher, 1990; Babisch et al., 1988; 1992; 1993a; 1993b; 1994; 1999; 2003; 2005a; 2008; 2012a; 2012b; Caerphilly and Speedwell Collaborative Group, 1984; Floud et al., 2011; 2013a; 2013b; Heimann et al., 2007; Jarup et al., 2005; 2008; Lercher et al., 2008; 2011; van Poll et al., 2014; Wiens, 1995). These studies involved a total of 25 682 participants, including 1614 cases. The overall RR was 1.24 (95% CI: 1.08–1.42) per 10 dB L_{den} increase in road traffic noise levels. The range in noise levels in the studies under evaluation was 30–80 dB. The results of the meta-analysis are presented in Fig. 2. This evidence was rated low quality.

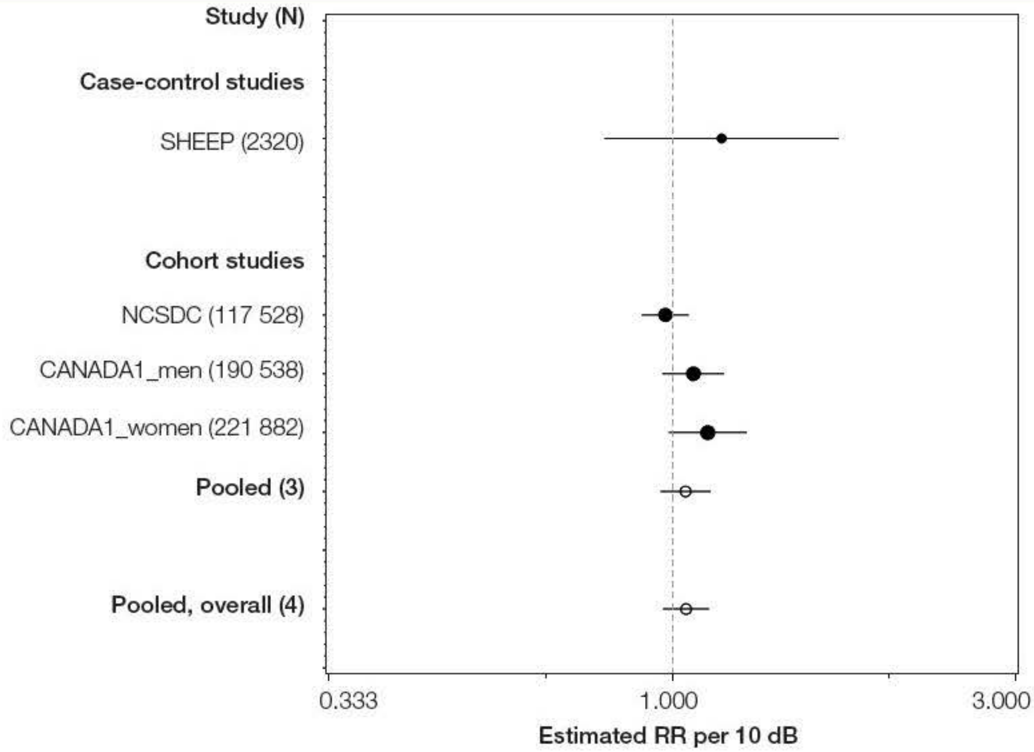
Fig. 2. The association between exposure to road traffic noise (L_{den}) and prevalence of IHD



Notes: The dotted vertical line corresponds to no effect of exposure to road traffic noise. The black circles correspond to the estimated RR per 10 dB and 95% CI. The white circle represents the pooled random effect estimates and 95% CI. For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

Mortality from IHD was also investigated in one case-control (Selander et al., 2009) and two cohort studies (Beelen et al., 2009; Gan et al., 2012), which involved 532 268 participants, including 6884 cases. The quantitative relationship between road traffic noise and mortality from IHD was RR = 1.05 (95% CI: 0.97–1.13) per 10 dB L_{den} increase in noise levels (see Fig. 3). This evidence was rated moderate quality.

Fig. 3. The association between exposure to road traffic noise (L_{den}) and mortality from IHD



Notes: The dotted vertical line corresponds to no effect of exposure to road traffic noise. The black circles correspond to the estimated RR per 10 dB and 95% CI. The white circles represent the pooled random effect estimates and 95% CI. For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

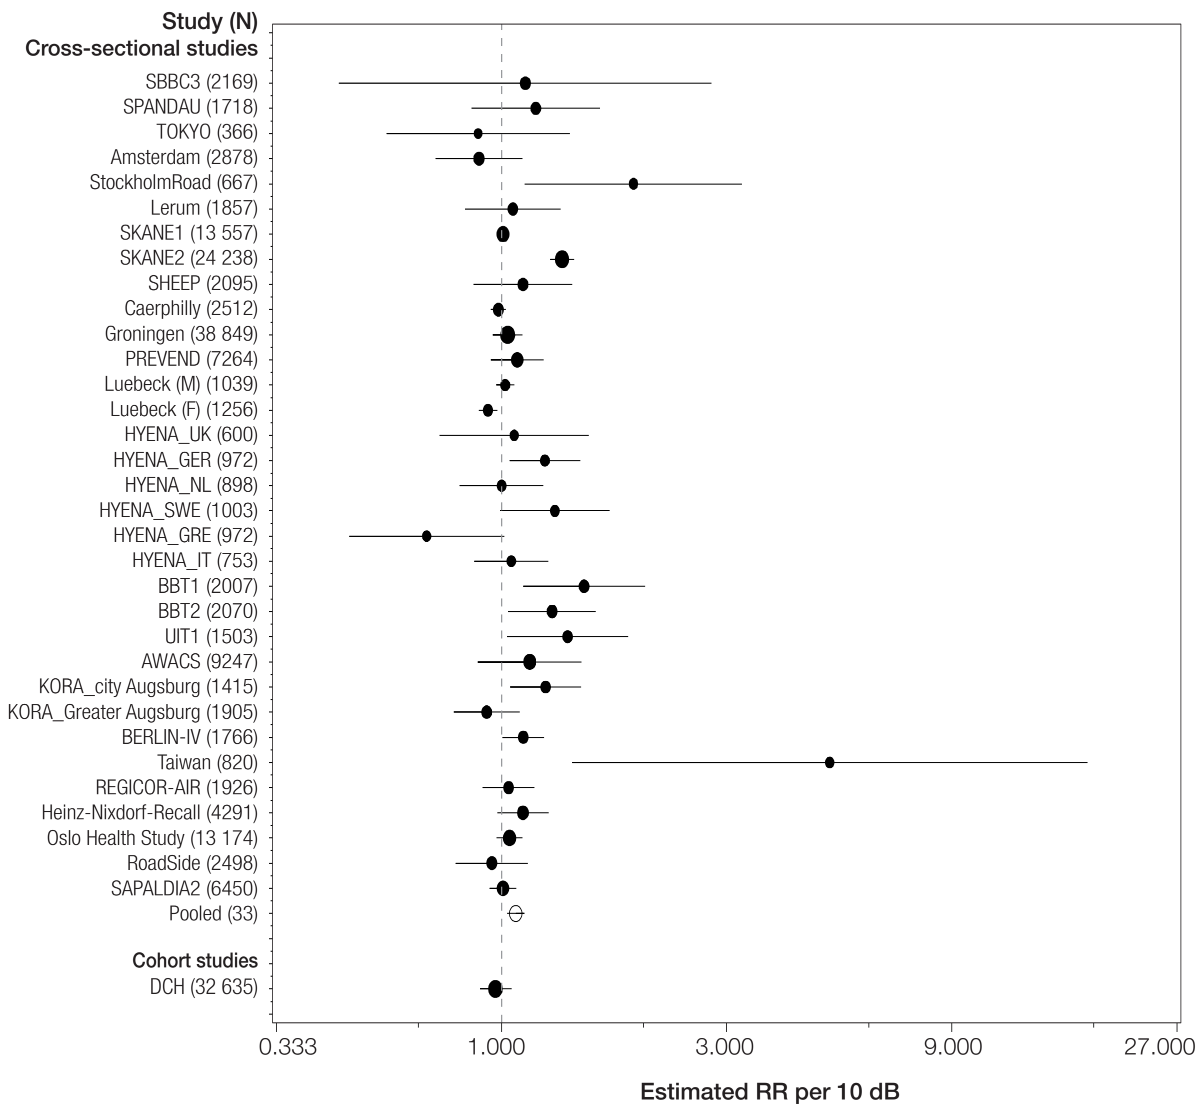
Hypertension

One cohort study into the relationship between road traffic noise and incidence of hypertension was identified; it involved 32 635 participants, including 3145 cases (Sörensen et al., 2011; 2012c). The study found a nonsignificant effect size of 0.97 (95% CI: 0.90–1.05) per 10 dB L_{den} increase in noise levels, which does not support an increased risk of hypertension due to exposure to road traffic noise. Because of the risk of bias and the availability of only one study, this evidence was rated low quality.

In addition, 26 cross-sectional studies were identified that looked at the association between road traffic noise and prevalence of hypertension (Babisch et al., 1988; 1992; 1994; 2005a; 2008; 2012a; 2012b; 2013a; 2013b; 2014b; 2014c; Barregard et al., 2009; Bjork et al., 2006; Bluhm et al., 2007; Bodin et al., 2009; Caerphilly and Speedwell Collaborative Group, 1984; Chang et al., 2011; 2014; de Kluizenaar et al., 2007a; 2007b; Dratva et al., 2012; Eriksson et al., 2012; Foraster et al., 2011; 2012; 2013; 2014a; 2014b; Fuks et al., 2011; Hense et al., 1989; Herbold et al., 1989; Jarup et al., 2005; 2008; Knipschild et al., 1984; Lercher et al., 2008; 2011; Maschke, 2003; Maschke & Hecht, 2005; Maschke et al., 2003; Oftedal et al., 2011; 2014; Selander et al., 2009; van Poll et al., 2014; Wiens, 1995; Yoshida et al., 1997). In total, these studies involved 154 398 participants, including 18 957 cases. The overall RR for prevalence of hypertension was 1.05 (95% CI: 1.02–1.08) per 10 dB L_{den} increase in noise levels. The noise range of the studies under evaluation was 20–85 dB. The overall evidence was rated very low quality.

Fig. 4 shows the association between road traffic noise and incidence and prevalence of hypertension.

Fig. 4. The association between exposure to road traffic noise (L_{den}) and hypertension



Notes: The dotted vertical line corresponds to no effect of exposure to road traffic noise. The black dots correspond to the estimated RR per 10 dB and 95% CI. The white circle represents the summary estimate and 95% CI. For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

Stroke

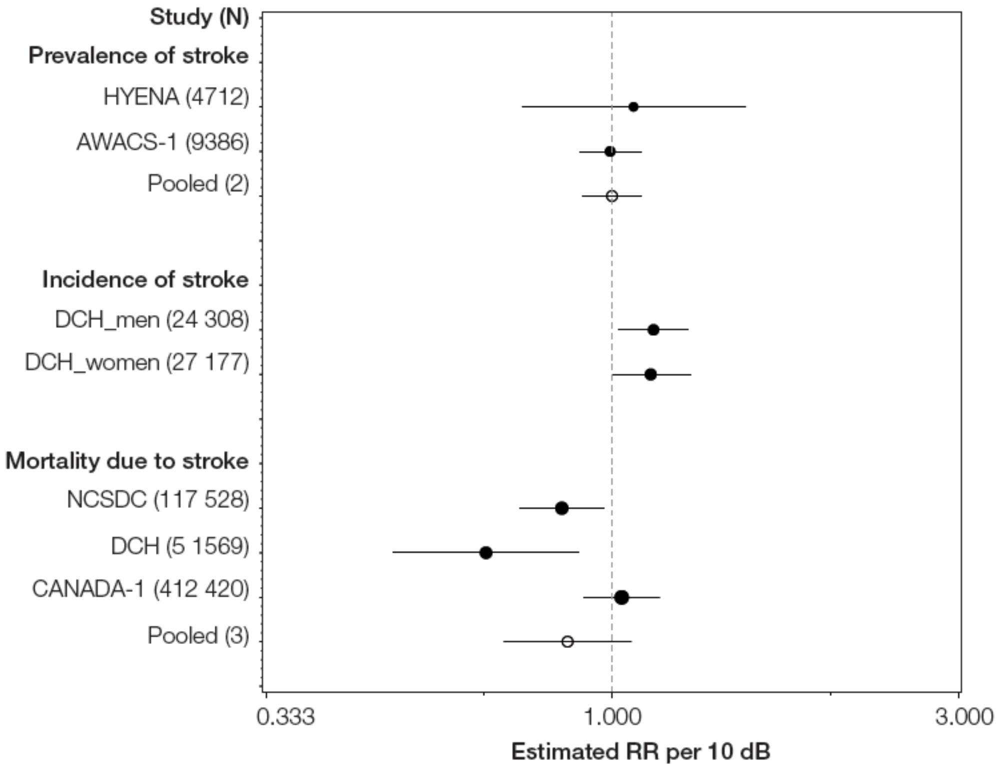
One cohort study into the relationship between road traffic noise and incidence of stroke was identified (Sörensen et al., 2011; 2012b; 2014). It involved 51 485 participants, including 1881 cases, and found an RR of 1.14 (95% CI: 1.03–1.25) per 10 dB L_{den} increase in noise levels, across a range of around 50–70 dB. The evidence was rated moderate quality.

Two cross-sectional studies on road traffic noise and prevalence of stroke involved 14 098 participants, including 151 cases (Babisch et al., 2005a; 2008; 2012a; 2012b; 2013a; Floud et al., 2011; 2013a; 2013b; Jarup et al., 2005; 2008; van Poll et al., 2014) yielded an estimated RR of 1.00 (95% CI: 0.91–1.10) per 10 dB L_{den} increase in noise levels. This evidence was rated very low quality.

Furthermore, three cohort studies investigated the relationship between road traffic noise and mortality due to stroke (Beelen et al., 2009; Gan et al., 2012; Sörensen et al., 2011; 2012b; 2014). These involved 581 517 participants, including 2634 cases, and their pooled estimate was a statistically nonsignificant RR = 0.87 (95% CI: 0.71–1.06) per 10 dB L_{den} increase in road traffic noise levels. This evidence was rated moderate quality.

Fig. 5 presents the results of the meta-analysis for road traffic noise and measures of stroke.

Fig. 5. The association between exposure to road traffic noise (L_{den}) and stroke



Notes: The dotted vertical line corresponds to no effect of exposure to road traffic noise. The black dots correspond to the estimated RR per 10 dB and 95% CI. The white circles represent the summary estimate and 95% CI.
For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

Children's blood pressure

Six cross-sectional studies investigated the change in systolic and diastolic blood pressure in children exposed to road traffic noise in residential settings (Belojevic & Evans, 2011; 2012; Bilenko et al., 2013; Liu et al., 2013; 2014; Regecova & Kellerova, 1995; van Kempen et al., 2006). In total, 4197 children were included in these studies; the number of cases was not reported. For each increase in 10 dB L_{den} in noise levels, there was a statistically nonsignificant increase in systolic and in diastolic blood pressure of 0.08 mmHg (95% CI: –0.48–0.64) and 0.47 mmHg (95% CI: –0.30–1.24), respectively. The overall evidence was rated very low quality.

Furthermore, five cross-sectional studies investigated the association between systolic and diastolic blood pressure in children and exposure to road traffic noise in educational settings (Belojevic & Evans, 2011; 2012; Bilenko et al., 2013; Clark et al., 2012; Paunovic et al., 2013; Regecova & Kellerova, 1995; van Kempen et al., 2006). In total, 4520 children were included in these studies; the number of cases was not reported. Systolic blood pressure decreased statistically nonsignificantly, at –0.60 mm (95% CI: –1.51–0.30) per 10 dB L_{den} increase in road traffic noise levels. Diastolic blood pressure increased statistically nonsignificantly, at 0.46 mm (95% CI: –0.60–1.53) per 10 dB L_{den} increase in road traffic noise levels. For both relationships, the evidence was rated very low quality.

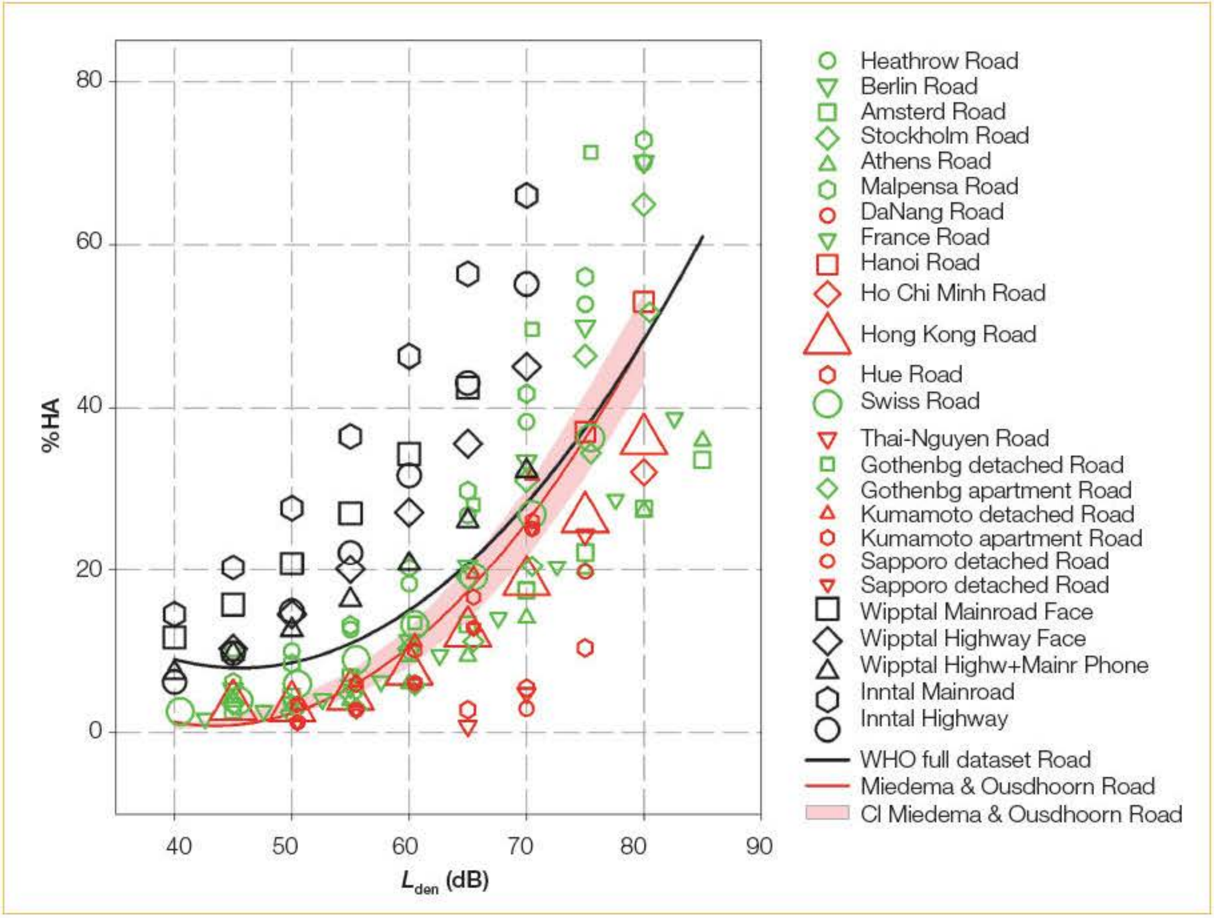
Annoyance

A vast amount of research proves the association between road traffic noise and annoyance. In total, 17 road traffic noise studies were identified that were used to model ERFs of the relationship between L_{den} and %HA (Babisch et al., 2009; Brink, 2013; Brink et al., 2016; Brown et al., 2014; 2015; Champelovier et al., 2003; Heimann et al., 2007; Lercher et al., 2007; Medizinische Universitaet Innsbruck, 2008; Nguyen et al., 2012a; Pierette et al., 2012; Sato et al., 2002; Shimoyama et al., 2014). These incorporated data from 34 112 study participants. The estimated data points of each of the studies are plotted in Fig. 6, alongside an aggregated ERF including the data from all the individual studies (see the black line for "WHO full dataset"). The lowest category of noise exposure considered in any of the studies, and hence included in the systematic review, is 40 dB, corresponding to approximately 9%HA. The benchmark level of 10%HA is reached at 53.3 dB L_{den} (see Fig 6).

Table 10 shows the %HA in relation to exposure to road traffic noise. The calculations are based on the regression equation $\%HA = 78.9270–3.1162 \times L_{den} + 0.0342 \times L_{den}^2$ derived from the systematic review (Guski et al., 2017). Even though there is a large evidence base substantiating the association of average road traffic noise and noise annoyance, the overall evidence had to be rated low quality. The main reasons for downgrading included limitations regarding the acoustical data provided, the nature of study design (most of the studies in the realm of annoyance research follow a cross-sectional approach), the inconsistency of results and the variety in the questions asked.

Nevertheless, the general quality of the evidence was substantiated with the help of additional statistical analyses that apply classic health outcome measures to estimate noise annoyance. When comparing road traffic noise exposure at 50 dB and 60 dB, the analyses revealed evidence rated moderate quality for an association between road traffic noise and %HA for an increase per 10 dB (OR = 2.74; 95% CI: 1.88–4.00). Moreover, there was evidence rated high quality for the increase of %HA per 10 dB increase in sound exposure, when data on all sound classes were included (OR = 3.03; 95% CI: 2.59–3.55).

Fig. 6. Scatterplot and quadratic regression of the relationship between road traffic noise (L_{den}) and annoyance (%HA)



Notes: The ERF by Miedema & Oudshoorn (2001) is added in red for comparison.
The size of the data points corresponds to the number of participants in the respective study (size = SQRT(N)/10).
If two results from different studies fall on the same data point, the last point plotted may mask the former one.
The black curve is derived from aggregated secondary data, while the red one is derived from individual data.
There is no indication of 95% CIs of the WHO full dataset, as a weighting based on the total number of participants for each 5 dB L_{den} sound class could not be calculated; weighting based on all participants of all sound classes proved to be unsuitable. The range of data included is illustrated by the distribution of data points.
For further details on the studies included in the figure please refer to the systematic review on environmental noise and annoyance (Guski et al., 2017).

Table 10. The association between exposure to road traffic noise (L_{den}) and annoyance (%HA)

L_{den} (dB)	%HA
40	9.0
45	8.0
50	8.6
55	11.0
60	15.1
65	20.9
70	28.4
75	37.6
80	48.5

Cognitive impairment

Evidence rated very low quality was available for the association between road traffic noise and reading and oral comprehension, assessed by tests. The review identified two papers that reported the results of the cross-sectional road traffic and aircraft noise exposure and children's cognition and health (RANCH) study, which examined exposure–effect relationships (Clark et al., 2006; Stansfeld et al., 2005). The study of over 2000 children aged 9–10 years, attending 89 schools around three major airports in the Netherlands, Spain and the United Kingdom did not find an exposure–effect relationship between road traffic noise exposure at primary school, which ranged from 31 to 71 dB $L_{Aeq,16h}$, and children's reading comprehension.

Few studies have investigated other health outcome measures related to cognition. Evidence rated low quality was available for an association between road traffic noise and cognitive impairment assessed through standardized tests (Cohen et al., 1973; Lukas et al., 1981; Pujol et al., 2014; Shield & Dockrell, 2008). There was evidence rated very low quality for an association between road traffic noise and long-term memory (Matheson et al., 2010; Stansfeld et al., 2005). No studies examined effects on short-term memory.

There was evidence rated very low quality, however, that road traffic noise does not have a considerable effect on children's attention (Cohen et al., 1973; Stansfeld et al., 2005). Further, there was evidence rated low quality that road traffic noise does not have a substantial effect on executive function (working memory), with studies consistently reporting no association (Clark et al., 2012; Matheson et al., 2010; Stansfeld et al., 2005; van Kempen et al., 2010; 2012).

Hearing impairment and tinnitus

No studies were found, and therefore no evidence was available for the association between road traffic noise and hearing impairment and tinnitus.

Sleep disturbance

For road traffic noise and self-reported sleep outcomes (awakenings from sleep, the process of falling asleep and sleep disturbance), 12 studies were identified that included a total of 20 120 participants (Bodin et al., 2015; Brown et al., 2015; Hong et al., 2010; Phan et al., 2010; Ristovska et al., 2009; Sato et al., 2002; Shimoyama et al., 2014); these were cross-sectional studies, conducted in healthy adults. The health outcome was measured by self-reporting via general health and noise surveys that included questions about sleep in general, and other questions about how noise affects sleep (see Table 11).

Table 11. Summary of findings for health effects from exposure to road traffic noise (L_{night})

Noise metric	Priority health outcome measure	Quantitative risk for adverse health	Lowest level of exposure across studies	Number of participants (studies)	Quality of evidence
Effects on sleep					
L_{night}	%HSD	OR: 2.13 (95% CI: 1.82–2.48) per 10 dB increase	43 dB	20 120 (12)	Moderate (downgraded for study limitations, inconsistency; upgraded for dose-response, magnitude of effect)

The model in the systematic review (Basner & McGuire, 2018) was based on outdoor L_{night} levels between 40 dB and 65 dB only; 40 dB was chosen as the lower limit because of possible inaccuracies of predicting lower noise levels. The range of noise exposure reported in the studies reviewed was 37.5–77.5 dB L_{night}. About 2% (95% CI: 0.90–3.15) of the population was characterized as highly sleep-disturbed at L_{night} levels of 40 dB. The %HSD at other, higher levels of road traffic noise is presented in Table 12. The association between road traffic noise and the probability of being highly sleep-disturbed was OR: 2.13 (95% CI: 1.82–2.48) per 10 dB increase in noise. This evidence was rated moderate quality.

Table 12. The association between exposure to road traffic noise (L_{night}) and sleep disturbance (%HSD)

L_{night} (dB)	%HSD	95% CI
40	2.0	0.9–3.15
45	2.9	1.40–4.44
50	4.2	2.14–6.27
55	6.0	3.19–8.84
60	8.5	4.64–12.43
65	12.0	6.59–17.36

Additional analyses were conducted for other health outcome measures related to sleep, which provided supporting evidence on the overall relationship between road traffic noise and sleep disturbance. When the noise source was not specified in the question, the relationship between road traffic noise and self-reported sleep outcomes was still positive but no longer statistically significant, with an OR of 1.09 (95% CI: 0.94–1.27) per 10 dB increase (Bodin et al., 2015; Brink, 2011; Frei et al., 2014; Halonen et al., 2012). This evidence was rated very low quality.

There was evidence rated moderate quality for an association between road traffic noise and sleep outcomes measured with polysomnography (probability of additional awakenings) with an OR of 1.36 (95% CI: 1.19–1.55) per 10 dB increase in indoor $L_{AS,max}$ [13] (Basner et al., 2006; Elmenhorst et al., 2012). Further, evidence rated low quality showed an association between road traffic noise and sleep outcomes measured as motility in adults (Frei et al., 2014; Griefahn et al., 2000; Oehrstroem et al., 2006a; Passchier-Vermeer et al., 2007; Pirrera et al., 2014). Finally, there was evidence rated very low quality for an association between road traffic noise and both self-reported and motility-measured sleep disturbance in children (Ising & Ising, 2002; Lercher et al., 2013; Oehrstroem et al., 2006a; Tiesler et al., 2013).

3.1.2.2 Evidence on interventions

This section summarizes the evidence underlying the recommendation on the effectiveness of interventions for road traffic noise exposure. The key question posed was: in the general population exposed to road traffic noise, are interventions effective in reducing exposure to and/or health outcomes from road traffic noise? A summary of the PICOS/PECCOS scheme applied and the main findings is set out in Tables 13 and 14.

Table 13. PICOS/PECCOS scheme of the effectiveness of interventions for exposure to road traffic noise

PICO	Description	
Population	**General population**	
Intervention(s)	The interventions can be defined as: (a) a measures that aim to change noise exposure and associated health effects; (b) a measures that aim to change noise exposure, with no particular evaluation of the impact on health; or (c) a measures designed to reduce health effects, but that may not include a reduction in noise exposure.	
Comparison	**No intervention**	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

[13] $L_{AS,max}$ is the maximum time-weighted and A-weighted sound pressure level with SLOW time constant within a stated time interval starting at t1 and ending at t2, expressed in dB.

Table 14. Summary of findings for road traffic noise interventions by health outcome

Type of intervention	Number of participants (studies)	Effect of intervention	Quality of evidence
Annoyance			
Type A – source interventions (change in traffic flow rate, improved road resurfacing, truck restriction strategy, complex set of barriers, road surfaces and other measures)	6096[a] (9)	• Changes in noise level ranged from around –15 dB to +15.5 dB (various noise metrics). • Most studies found that the intervention resulted in a change in annoyance.	Moderate (downgraded for study limitations; upgraded for dose-response)
Type B – path interventions (dwelling insulation, barrier construction, building intervention)	2970 (7)	• Changes in noise level ranged from –3 dB to –13 dB (various noise metrics). • All studies found that the intervention resulted in a change in annoyance, as estimated by an ERF.	Moderate (downgraded for study limitations; upgraded for dose-response)
Type C – changes in infrastructure (new road tunnel infrastructure)	1211 (2)	• Noise levels reduced by an average of –12 dB ($L_{Aeq,24h}$). • Both studies found lower annoyance responses post intervention, with no change in the controls.	Moderate (downgraded for study limitations; upgraded for dose-response)
Type D – other physical interventions (availability of quiet side to the dwelling, existence of nearby green space)	26 786 (6)	• Because of large variability in noise levels between most and least exposed façade (quiet side), access to quiet side and/or green space resulted in less annoyance.	Very low (downgraded for study limitations)
Sleep disturbance			
Type B – path interventions (1: façade insulation; 2: enlargement of motorway lanes but with dwelling insulation, barriers and quiet pavement)	1158 (2)	• 1: façade insulation resulted in a reduction of 7 dB for indoor noise level. • 2: enlargement led to reduction in the extent of population exposure at higher noise levels (55–65 dB) with an increase in lower levels (45–55 dB) • Both path interventions resulted in changes in sleep outcomes	Moderate (downgraded for study limitations)
Type C – changes in infrastructure (new road tunnel infrastructure)	166 (2)	• Noise levels reduced by an average of –12 dB ($L_{Aeq,24h}$). • Both studies found lower sleep disturbance indicators/ improvement in sleep post intervention, with no change in the controls.	Moderate (downgraded for study limitations)
Type D – other physical interventions (availability of quiet side to the dwelling)	100 (1)	• An absence of quiet façade resulted in increased reporting of difficulty in falling asleep.	Very low (downgraded for study limitations, inconsistency)
Cardiovascular disease			
Type D – other physical interventions (availability of quiet side to the dwelling)	9203 (4)	• Three studies found changes (including in self-reported hypertension) with and without a quiet side. One study found no change.	Very low (downgraded for study limitations)

Note: [a] This figure does not include number of participants from the studies by Langdon & Griffiths (1982) and Baughan & Huddart (1993), as the exact number of respondents was not reported.

Type A – source interventions

Most of the nine source intervention studies – Baughan & Huddart (1993), Brown (1987; 2015), Brown et al. (1985), Griffiths & Raw (1987; 1989), Kastka (1981), Langdon & Griffiths (1982), Pedersen et al. (2013; 2014), Stansfeld et al. (2009b) – showed an effect in annoyance due to changes in road traffic flow rates. In some cases these were combined with other measures like improved road resurfacing, truck restrictions or complex control measures, including barriers or road surfaces. A majority of the changes resulted in reductions of noise levels.

Regarding the strength of association between exposure and annoyance outcome, all intervention studies demonstrated that the response was of at least the magnitude estimated by a steady-state ERF. The limited available evidence on long-term effects shows that this excess response undergoes some attenuation but is largely maintained over several years. In spite of the high risk of bias in all studies, the evidence in the systematic review was initially assessed as high quality, due to an upgrade because of the dose-response effect. However, the GDG decided to downgrade this assessment in an effort to maximize consistency with the grading approach of the remaining systematic reviews. It was therefore rated moderate quality.

Type B – path interventions

Seven path intervention studies – Amundsen et al. (2011; 2013), Bendtsen et al. (2011), Gidloef-Gunnarsson et al. (2010), Kastka et al. (1995), Nilsson & Berglund (2006), Vincent & Champelovier (1993) – explored the effects on annoyance by interventions related to dwelling insulation, barrier constructions and a combination of both, as well as a full-scale building intervention. With the help of pre/post designs, the studies assessed changes in noise exposure achieved by the interventions over different periods of time. In six studies the path intervention was associated with a change in annoyance outcomes. Four of these showed that the annoyance response to the change was in the same direction and of at least the same magnitude estimated by the ERF. In spite of the high risk of bias in all studies, the evidence in the systematic review was initially assessed as high quality, due to an upgrade because of the dose-response effect. However, the GDG decided to downgrade this assessment in an effort to maximize consistency with the grading approach of the remaining systematic reviews. The evidence was therefore rated moderate quality.

Two of the studies (Amundsen et al., 2013; Bendtsen et al., 2011) assessed path interventions and sleep disturbance. The results showed a reduction in the %HSD after the interventions were conducted. One of the studies included a two-year follow-up, revealing the persistence of the effect. Risk of bias was assessed as high in both studies. The evidence was rated moderate quality.

Type C – new/closed infrastructure interventions

Two infrastructural intervention studies (Gidloef-Gunnarsson et al., 2013; Oehrstroem, 2004; Oehrstroem & Skanberg, 2000) evaluated the impact on annoyance of major reductions in road traffic flows, combined with other environmental improvements. One was a new road tunnel infrastructure, resulting in substantial traffic and noise levels reductions for residents near the previously heavy-traffic road. Both studies were pre/post designs using repeated measures of annoyance outcomes. Following the reduction in noise levels (around –12 dB $L_{Aeq,24h}$), both studies demonstrated a statistically significant lower degree of annoyance, while there was no change in the control group. Both also reported that the after-scores in the studies matched those estimated by the ERF, but both reported excess response, meaning that the response to change was in the direction estimated by the ERF but much steeper. In spite of the high risk of bias in all studies, the quality of the evidence in the systematic review was initially assessed as high, due to an upgrade because of the dose-response effect. However, the GDG decided to downgrade this assessment in an effort to maximize consistency with the grading approach of the remaining systematic reviews. The evidence was therefore rated moderate quality.

Two studies investigated the impact of new tunnels that removed traffic flow from surface roads on sleep disturbance (Oehrstroem, 2004; Oehrstroem & Skanberg, 2000; 2004). Subjective and objective measures of sleep quality were assessed before and after the intervention. Both studies demonstrated a statistically significant lower reporting of various sleep disturbance indicators post intervention. One study reported statistically significantly reduced time spent in bed after the intervention, which, according to the authors, could suggest increased sleep efficiency. Risk of bias was assessed as high, so this evidence was rated moderate quality.

Type D – other physical infrastructure interventions

No intervention studies were available to assess impacts on annoyance of other physical interventions. The only relevant studies (Babisch et al., 2012; de Kluizenaar et al, 2011; 2013; Gidloef-Gunnarsson & Oehrstroem 2007; van Renterghem & Botteldooren, 2012; 2010) did not provide direct evidence of an intervention. Instead, they provided indirect evidence on the magnitude of the likely effect of certain interventions (e.g. using the quiet side of the dwelling, green space in the neighbourhood) by comparing responses from groups with and without the intervention/feature of interest. All studies found an effect of the presence of the dimension investigated; in all but one, the effect was statistically significant. Risk of bias was assessed as high in all studies, so the evidence was rated very low quality.

One study investigated a subjective assessment of difficulty in falling asleep (van Renterghem & Botteldooren, 2012), before and after the intervention. The difference in the proportion of participants reporting difficulty falling asleep “at least sometimes” between homes with and without a quiet side was statistically significant. Absence of a quiet façade resulted in increased reporting of this sleep parameter. Confounding was adjusted for in the analyses of the ERFs, including noise sensitivity, window-closing behaviour and front-façade L_{den}. Risk of bias was assessed as high, so the evidence was rated very low quality.

Four studies that assessed the effect of other physical interventions on cardiovascular disease were identified (Babisch et al., 2012; 2014a; Bluhm et al., 2007; Lercher et al., 2011). Three of these found changes, including self-reported hypertension, with and without a quiet side of the dwelling; in two the difference was statistically significant. The risk of bias in these studies was generally high, so the evidence was rated very low quality.

3.1.2.3 Consideration of additional contextual factors

As the foregoing overview has shown, ample evidence about the adverse health effects of long-term exposure to road traffic noise exists. Based on the quality of the available evidence, the GDG set the strength of the recommendation on road traffic noise at strong. As a second step, it qualitatively assessed contextual factors to explore whether other considerations could have a relevant impact on the recommendation strength. These considerations mainly concerned the balance of harms and benefits, values and preferences, equity, and resource use and implementation.

When assessing the balance of harms and benefits of interventions to reduce exposure to road traffic noise, the GDG initially noted that road traffic is the most widespread source of noise pollution, measured in terms of the number of affected people both within and outside urban areas. The EEA estimates that more than 100 million people in Europe are exposed to L_{den} levels above 55 dB; for night-time road traffic noise, over 72 million Europeans are exposed to L_{night} levels above 50 dB (Blanes et al., 2017).[14] The amount of road traffic noise emitted is unlikely to decrease significantly: both transport demand, including for passenger cars (EC, 2016b), and the number of city inhabitants (Eurostat, 2016) are expected to increase. Considering the significant burden of disease attributable to exposure to road traffic noise (WHO Regional Office for Europe & JRC, 2011), the GDG expects substantial health benefits to evolve from implementing the recommendations to reduce population exposure to road traffic noise. Depending on the intervention measures used (such as restrictions of traffic), possible harms could include effects on the transportation of goods and on individual mobility of the population. Both can have impacts on local, national and international economies. Overall, the GDG estimated that the benefits gained from minimizing adverse health effects due to road traffic noise exposure outweigh the possible (economic) harms.

Considering values and preferences, it has been established that people appreciate quiet areas as beneficial for their health and well-being, especially in urban areas (Shepherd et al., 2013; Gidloef-Gunnarsson & Oehrstroem, 2007; Oehrstroem et al., 2006b). Nevertheless, the GDG recognized that the convenience of individual mobility with the help of passenger cars is valued overall by large parts of the population in the EU, as illustrated by the sustained high volume of passenger kilometres driven in Europe (EEA, 2016a; 2017a). In general, values and preferences are expected to vary throughout society, as exposure to environmental noise and continuous road traffic noise is not equally distributed: those of individuals directly affected by long-term road traffic exposure are likely to differ from those that are not affected. Individuals with a higher average sound pressure level of road traffic noise are, for example, more willing to pay to reduce their noise exposure (Bristow et al., 2014).

In light of the dimension of equity, the GDG highlighted the fact that the risk of exposure to road traffic noise is not equally distributed throughout society. People with lower socioeconomic status and other disadvantaged groups often live in more polluted and louder areas, including in proximity to busy roads (EC, 2016a). Moreover, socioeconomic factors are not only related to differences in exposure to environmental factors such as noise but are also associated with increased vulnerability and poorer coping capacities (Karpati et al., 2002).

With resource use and implementation considerations, the GDG recognized that no comprehensive cost–benefit analysis for the WHO European Region yet exists, so this assessment is based on informed expert judgement regarding the feasibility of implementing the recommendation for the majority of the population. As the systematic review of environmental noise interventions and their

[14] These are gap-filled figures based on the reported data and including the situation both within and outside cities, as defined by the END.

associated impact on health shows, various effective measures exist to reduce noise exposure from road traffic and improve health (Brown & van Kamp, 2017). The resources needed to implement these measures vary as they rely on the type of intervention and the context. The GDG pointed out the following four major solutions, which are known to be cost-effective: choice of appropriate tyres, use of low-noise road surfaces, building of noise barriers and installation of soundproof windows (CSES et al., 2016). Other types of intervention include limitations of speed or type of traffic allowed on roads.

Regarding feasibility of implementation, the GDG was convinced that many of the solutions can be planned as part of regular maintenance processes and accelerated fleet and road modernization. In particular, appropriate tyres and road surfaces are only slightly more expensive than existing products, and various countries have already considered or adopted similar interventions to reduce noise levels (Ohiduzzaman et al., 2016; Sirin, 2016). This indicates that solutions to achieve recommended noise levels can be implemented and carry a reasonable cost on a societal level. The GDG noted, however, that the feasibility of implementing measures can be hindered by the fact that costs and benefits are not evenly distributed. In most cases, the health benefits gained by interventions that reduce long-term road traffic exposure accrue to citizens, whereas the costs are borne by road users, private companies and public authorities. Furthermore, the GDG expects challenges in the implementation of all long-term measures that include changes in behaviour of the population, such as increased use of car-sharing or public transport. Even though the overall costs are expected to be significant, because of the large number of people affected, the benefit of implementation of the recommendation to minimize the risk of adverse health effects due to road traffic noise for a majority of the population exceeds the resources needed.

In light of the assessment of the contextual factors in addition to the quality of evidence, the recommendation remains strong.

Other nonpriority adverse health outcomes

As an additional consideration, although not priority health outcomes and coming from a single study, the GDG noted the evidence rated moderate quality for an association between road traffic noise and the prevalence of diabetes (van Kempen et al., 2018). The noise levels in the study identified ranged from around 50 dB to 70 dB L_{den}, so the recommendation proposed is thought to be protective enough for this health outcome. Thus, it did not lead to a change in the recommendation.

Additional considerations or uncertainties

Individual noise annoyance judgements of residents are to a large extent moderated by personal variables (such as noise sensitivity and coping capacity). However, further situational factors that apply to many residents should be taken into account when analysing noise annoyance from road traffic noise, as they may moderate the relationship. These include the type(s) of road being considered (highways, urban main roads, secondary roads and so on) and the related traffic composition (share of cars, motorcycles and heavy and loud trucks) and pattern (fluctuation, frequency, intermittency). Moreover, the location of settlements and/or individual dwellings, proximity to the road, and location and availability of a quiet façade can also influence the relationship when predicting health outcomes such as annoyance.

3.1.3 Summary of the assessment of the strength of the recommendations

Table 15 provides a comprehensive summary of the different dimensions for the assessment of the strength of the road traffic noise recommendations.

Table 15. Summary of the assessment of the strength of the road traffic noise recommendation

Factors influencing the strength of recommendation	Decision
Quality of evidence	**Average exposure** (L_{den}) *Health effects* • Evidence for a relevant RR increase for incidence of IHD at **59 dB** L_{den} was rated **high quality**. • Evidence for the incidence of hypertension was rated **low quality**. • Evidence for a relevant absolute risk of annoyance at **53 dB** L_{den} was rated **moderate quality**. • Evidence for a relevant RR increase for reading and oral comprehension was rated **very low quality**. *Interventions* • Evidence on effectiveness of interventions to reduce noise exposure and/or health outcomes from road traffic noise is of varying quality. **Night-time exposure** (L_{night}) *Health effects* • Evidence for a relevant absolute risk of sleep disturbance related to night noise exposure from road traffic at **45 dB** L_{night} was rated **moderate quality**. *Interventions* • Evidence on effectiveness of interventions to reduce noise exposure and/or sleep disturbance from road traffic noise is of varying quality.
Balance of benefits versus harms and burdens	Health benefits can be gained from markedly reducing exposure of the population to road traffic noise; benefits outweigh the harms of interventions to reduce continuous road traffic noise.
Values and preferences	Quiet areas are valued by the population, especially by those affected by continuous noise exposure. Some variability is possible between those who benefit from interventions to reduce road traffic noise and those who finance the interventions.
Equity	Risk of exposure to road traffic noise is not equally distributed.
Resource use and implications	No comprehensive cost–effectiveness analysis data are available; nevertheless, a wide range of solutions exists and several are being implemented, showing that effective interventions are both feasible and economically reasonable.
Decisions on recommendation strength	• **Strong** for guideline level for average noise exposure (L_{den}) • **Strong** for guideline value for average night noise exposure (L_{night}) • **Strong** for specific interventions to reduce noise exposure

3.2 Railway noise

Recommendations

For average noise exposure, the GDG **strongly** recommends reducing noise levels produced by railway traffic below **54 dB** L_{den}, as railway noise above this level is associated with adverse health effects.

For night noise exposure, the GDG **strongly** recommends reducing noise levels produced by railway traffic during night time below **44 dB** L_{night}, as railway noise above this level is associated with adverse effects on sleep.

To reduce health effects, the GDG **strongly** recommends that policy-makers implement suitable measures to reduce noise exposure from railways in the population exposed to levels above the guideline values for average and night noise exposure. There is, however, insufficient evidence to recommend one type of intervention over another.

3.2.1 Rationale for the guideline levels for railway noise

The exposure levels were derived in accordance with the prioritizing process of critical health outcomes described in section 2.4.3. For each of the outcomes, the exposure level was identified by applying the benchmark, set as relevant risk increase to the corresponding ERF. In the case of exposure to railway noise, the process can be summarized as follows (Table 16).

Table 16. Average exposure levels (L_{den}) for priority health outcomes from railway noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Incidence of IHD No studies were available and therefore incidence of IHD could not be used to assess the exposure level.	5% increase of RR	No studies met the inclusion criteria/no studies available
Incidence of hypertension One study met the inclusion criteria. There was no significant increase of risk associated with increased noise exposure in this study.	10% increase of RR	Low quality
Prevalence of highly annoyed population There was an absolute risk of 10% at a noise exposure level of 53.7 dB L_{den}.	10% absolute risk	Moderate quality
Permanent hearing impairment	No increase	No studies met the inclusion criteria/no studies available
Reading skills and oral comprehension in children	One-month delay	No studies met the inclusion criteria/no studies available

In accordance with the prioritization process (see section 2.4.3), the GDG set a guideline exposure level of 53.7 dB L_{den} for average exposure, based on the relevant increase of the absolute %HA. In accordance with the defined rounding procedure, the value was rounded to 54 dB L_{den}. As the evidence on the adverse effects of railway noise was rated moderate quality, the GDG made the recommendation strong.

Next, the GDG assessed the evidence for night noise exposure and its effect on sleep disturbance (Table 17).

Table 17. Night-time exposure levels (L_{night}) for priority health outcomes from railway noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Sleep disturbance 3% of the participants in studies were highly sleep-disturbed at a noise level of **43.7 dB** L_{night}	3% absolute risk	Moderate quality

Based on the evidence of the adverse effects of railway noise on sleep disturbance, the GDG defined a guideline exposure level of 43.7 dB L_{night}. The exact exposure value was rounded to 44 dB L_{night}. As the evidence was rated moderate quality, the GDG made the recommendation strong.

The GDG also considered the evidence for the effectiveness of interventions. The results showed that:

- intervening at the source by applying rail grinding procedures can reduce noise annoyance;
- behavioural interventions such as informing the community about noise interventions can reduce noise annoyance.

In light of the strong evidence about the adverse health effects, the GDG followed a precautionary approach and made a strong recommendation for interventions on railway noise, as it was confident that interventions are realizable and that best practices already exist for the management of noise from railways. Since the empirical evidence on the effectiveness of different types of intervention was rated either low or very low quality, the GDG felt that no recommendation could be made on the preferred type of intervention, and agreed not to recommend any specific type of intervention over another.

3.2.1.1 Other factors influencing the strength of recommendations

Other factors considered in the context of recommendations on railway noise included those related to values and preferences, benefits and harms, resource implications, equity, acceptability and feasibility; moreover, nonpriority health outcomes were considered. The assessment of all these factors – especially the values and preferences involved in railway noise – did not lead to a change in the strength of the recommendations. Further details are provided in Section 3.2.2.3.

3.2.2 Detailed overview of the evidence

The following sections provide a detailed overview of the evidence constituting the basis for setting the recommendations on railway noise. It is presented and summarized separately for each of the critical health outcomes, and the GDG's judgement of the quality of evidence is indicated (for a detailed overview of the evidence on important health outcomes, see Annex 4). Research into health outcomes and effectiveness of interventions is addressed consecutively.

A comprehensive summary of all evidence considered for each of the critical and important health outcomes can be found in the eight systematic reviews published in the *International Journal of Environmental Research and Public Health* (see section 2.3.2 and Annex 2).

3.2.2.1 Evidence on health outcomes

The key question posed was: in the general population exposed to railway noise, what is the exposure–response relationship between exposure to railway noise (reported as various noise indicators) and the proportion of people with a validated measure of health outcome, when adjusted for main confounders? A summary of the PICOS/PECCOS scheme applied and the main findings is set out in Tables 18 and 19.

Table 18. PICOS/PECCOS scheme of critical health outcomes for exposure to railway noise

PECO	Description	
Population	General population	
Exposure	Exposure to high levels of noise produced by railway traffic (average/night time)	
Comparison	Exposure to lower levels of noise produced by railway traffic (average/night time)	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

Table 19. Summary of findings for health effects from exposure to railway noise (L_{den})

Noise metric	Priority health outcome measure	Quantitative risk for adverse health	Lowest level of exposure across studies	Number of participants (studies)[a]	Quality of evidence
Cardiovascular disease					
L_{den}	Incidence of IHD	–	–	–	–
L_{den}	Incidence of hypertension	RR = 0.96 (95% CI: 0.88–1.04) per 10 dB increase	N/A	7249 (1)	Low (downgraded for risk of bias and availability of only one study)
Annoyance					
L_{den}	%HA	OR = 3.53 (95% CI: 2.83–4.39) per 10 dB increase	34	10 970 (10)	Moderate (downgraded for inconsistency, directness; upgraded for dose-response)
Cognitive impairment					
L_{den}	Reading and oral comprehension	–	–	–	–
Hearing impairment and tinnitus					
L_{den}	Permanent hearing impairment	–	–	–	–

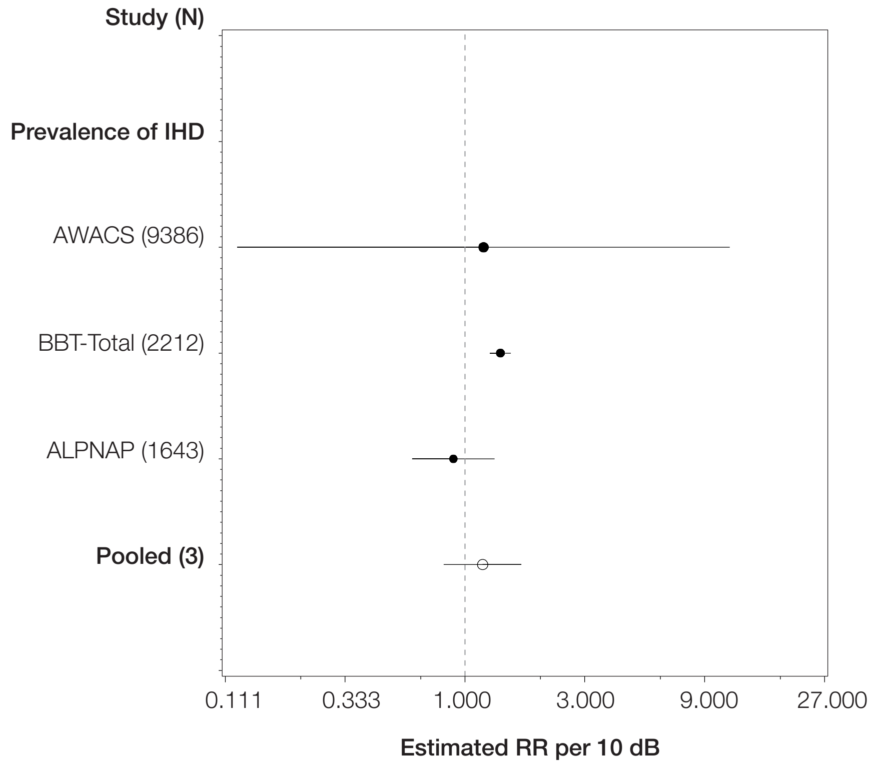
Note: [a] Results are partly derived from population-based studies.

Cardiovascular disease

IHD

No evidence was available on the relationship between railway noise and the incidence of or mortality from IHD. Four cross-sectional studies were identified, however, that assessed the prevalence of IHD in a total of 13 241 participants, including 283 cases (Heimann et al., 2007; Lercher et al., 2008; 2011; van Poll et al., 2014). The overall risk was not statistically significantly increased: the RR was 1.18 (95% CI: 0.82–1.68) per 10 dB L_{den} increase, with inconsistency across studies (see Fig. 7). The evidence was rated very low quality.

Fig. 7. The association between exposure to railway noise (L_{den}) and prevalence of IHD



Notes: The dotted vertical line corresponds to no effect of exposure to railway noise. The black circles correspond to the estimated RR per 10 dB and 95% CI. The white circle represents the pooled random effect estimates and 95% CI. For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

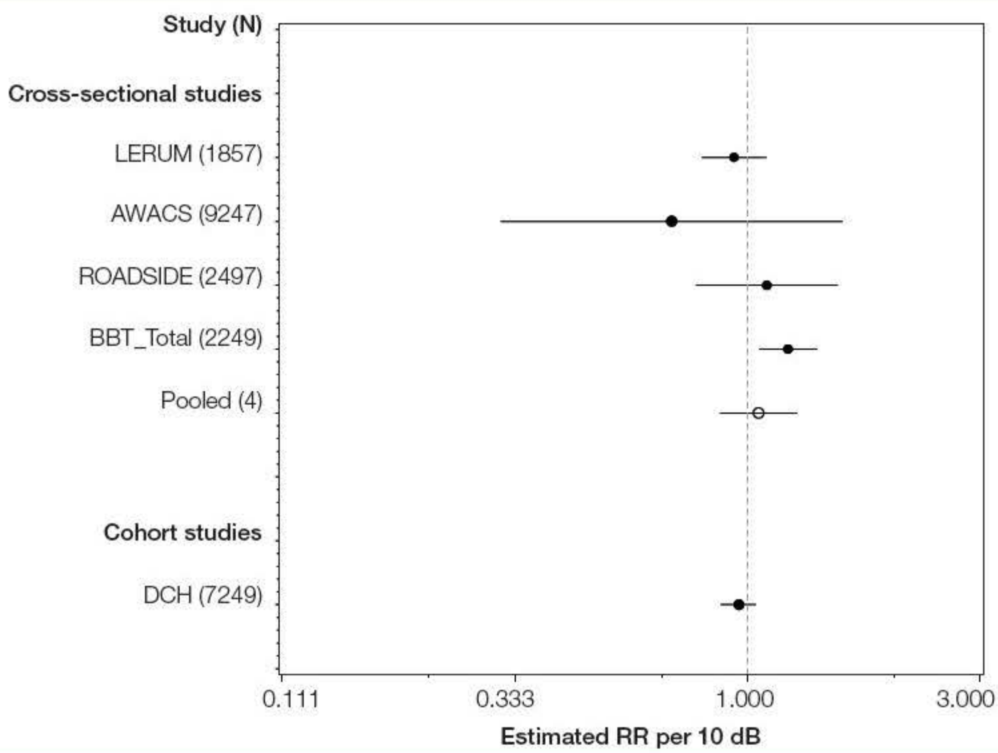
Hypertension

One cohort study on the relationship between railway noise and hypertension was identified; it assessed the incidence among people living in Denmark (Sörensen et al., 2011; 2012a). The study involved 7249 participants, including 3145 cases. The authors did not find an association between railway noise exposure and incidence of hypertension, with RR = 0.96 (95% CI: 0.88–1.04) per 10 dB L_{den} increase. This evidence was rated low quality.

In addition, five cross-sectional studies assessed the prevalence of hypertension in 15 850 participants, including 2059 cases (Barregard et al., 2009; Eriksson et al., 2012; Lercher et al., 2008; 2011; van Poll et al., 2014). The overall RR increase was not statistically significant, at 1.05 (95% CI: 0.88–1.26) per 10 dB L_{den} increase. Moreover, there was inconsistency among the results across studies. The evidence was rated very low quality.

Fig. 8 presents the studies investigating the relationship between railway noise and different measures of hypertension.

Fig. 8. The association between exposure to railway noise (L_{den}) and hypertension



Notes: The dotted vertical line corresponds to no effect of exposure to railway noise. The black dots correspond to the estimated RR per 10 dB and 95% CI. The white circle represents the summary estimate and 95% CI.
For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

Stroke

As for IHD, no evidence was available on the relationship between railway noise and incidence of or mortality from stroke. However, one cross-sectional study was identified that assessed the prevalence of stroke in 9365 participants, including 89 cases (van Poll et al., 2014). The overall risk was not statistically significantly increased, with RR = 1.07 (95% CI: 0.92–1.25) per 10 dB L_{den} increase. The evidence was rated very low quality.

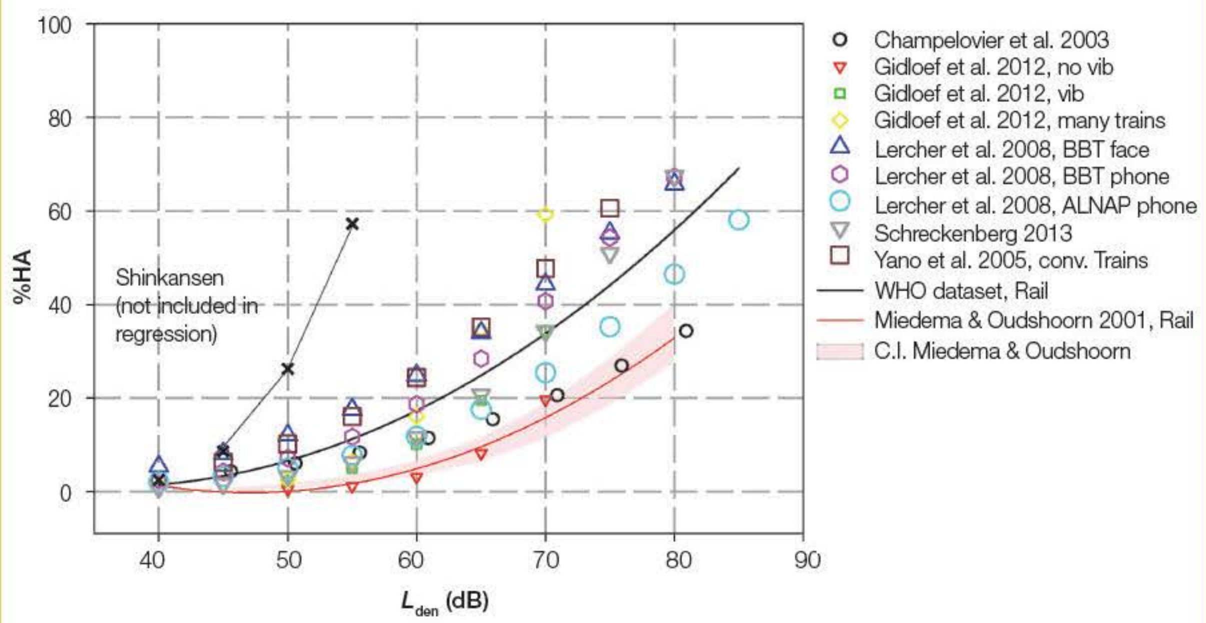
Children's blood pressure

No evidence was available for the association between railway noise and the systolic and/or diastolic blood pressure of children in residential and/or educational settings.

Annoyance

In total, 10 studies with ERFs on the association between railway noise and annoyance were included in analyses (Champelovier et al., 2003; Gidloef-Gunnarsson et al., 2012; Lercher et al., 2007; 2008; Sato et al., 2004; Schreckenberg, 2013; Yano et al., 2005; Yokoshima et al., 2008). The studies incorporated individual data from 10 970 participants. The estimated data points of each of these studies are plotted in Fig. 9, alongside an aggregated ERF including the data from all the individual studies (see the black line for "WHO dataset, Rail"). The lowest category of noise exposure considered in any of the studies, and hence included in the systematic review is 40 dB, corresponding to approximately 1.5%HA. The 10% benchmark for %HA is reached at 53.7 dB L_{den} (see Fig. 9).

Fig. 9. Scatterplot and quadratic regression of the relationship between railway noise (L_{den}) and annoyance (%HA)



Notes: The ERF by Miedema & Oudshoorn (2001) is added in red for comparison.
There is no indication of 95% CIs of the WHO dataset curve, as a weighting based on the total number of participants for each 5 dB L_{den} sound class could not be calculated; weighting based on all participants of all sound classes proved to be unsuitable. The range of data included is illustrated by the distribution of data points.
For further details on the studies included in the figure please refer to the systematic review on environmental noise and annoyance (Guski et al., 2017).

Table 20 shows the %HA for railway noise exposure. The calculations are based on the regression equation %HA = 38.1596–2.05538 × L_{den} + 0.0285 × $L_{den}{}^2$ derived from the systematic review (Guski et al., 2017). The overall evidence was rated moderate quality. Additional statistical analyses of annoyance outcomes supported these findings. When comparing railway noise exposure at 50 dB and 60 dB, the analyses revealed evidence rated moderate quality for an association between railway noise and %HA for an increase per 10 dB (OR = 3.40; 95% CI: 2.05–5.62). Moreover, evidence rated high quality was available for the increase in %HA per 10 dB increase in sound exposure, when data on all sound classes were included (OR = 3.53; 95% CI: 2.83–4.39).

Table 20. The association between exposure to railway noise (L_{den}) and annoyance (%HA)

L_{den} (dB)	%HA
40	1.5
45	3.4
50	6.6
55	11.3
60	17.4
65	25.0
70	33.9
75	44.3
80	56.1

Cognitive impairment

Studies of railway noise on children's reading and oral comprehension were lacking. Nevertheless, other measures of cognition yielded evidence rated very low quality for an association between railway noise and children with poorer performance on standardized assessment tests (Bronzaft, 1981; Bronzaft & McCarthy, 1975). Evidence for the association between railway noise and children having poorer long-term memory (Lercher et al., 2003) was rated very low quality. No studies examined effects on short-term memory.

There was no clear relation between railway noise and attention in children (Lercher et al., 2003), and this evidence was rated very low quality.

Hearing impairment and tinnitus

No studies were found, and therefore no evidence was available on the association between railway noise and hearing impairment and tinnitus.

Sleep disturbance

For railway noise and self-reported sleep outcomes (awakenings from sleep, the process of falling asleep and sleep disturbance), five studies were identified that included a total of 7133 participants (Bodin et al., 2015; Hong et al., 2010; Sato et al., 2004; Schreckenberg, 2013). The studies were cross-sectional and conducted on healthy adults. The health outcome was measured by self-reporting via general health surveys and noise surveys that included questions about sleep in general, and other questions about how noise affects sleep (Table 21).

Table 21. Summary of findings for health effects from exposure to railway noise (L_{night})

Noise metric	Priority health outcome measure	Quantitative risk for adverse health	Lowest level of exposure across studies	Number of participants (studies)	Quality of evidence
Effects on sleep					
L_{night}	%HSD	OR: 3.06 (95% CI: 2.38–3.93) per 10 dB increase	33 dB	7133 (5)	Moderate (downgraded for study limitations, inconsistency; upgraded for dose-response, magnitude of effect)

The model in the systematic review (Basner & McGuire, 2018) was based on outdoor L_{night} levels between 40 dB and 65 dB only; 40 dB was chosen as the lower limit because of possible inaccuracies in predicting lower noise levels. The range of noise exposure reported in the studies was 27.5–82.5 dB L_{night}. About 2% (95% CI: 0.79–3.48) of the population was characterized as highly sleep-disturbed for L_{night} levels of 40 dB. The %HSD at other, higher levels of railway noise is presented in Table 17. The association between railway noise and the probability of being sleep-disturbed was OR: 3.1 (95% CI: 2.4–3.9) per 10 dB increase in noise. This evidence was rated moderate quality.

Table 22. The association between exposure to railway noise (L_{night}) and sleep disturbance (%HSD)

L_{night} (dB)	%HSD	95% CI
40	2.1	0.79–3.48
45	3.7	1.63–5.71
50	6.3	3.12–9.37
55	10.4	5.61–15.26
60	17.0	9.48–24.37
65	26.3	15.20–37.33

Additional analyses were conducted for sleep quality measures, which provided supporting evidence on the overall relationship between railway noise and sleep. When the noise source was not specified in the question, the relationship between railway noise and self-reported sleep outcomes was still positive but no longer statistically significant, with an OR of 1.27 (95% CI: 0.89–1.81) per 10 dB increase (Bodin et al., 2015; Brink, 2011; Frei et al., 2014). This evidence was rated very low quality.

There was evidence rated moderate quality for an association between railway noise and the probability of additional awakenings, measured with polysomnography, with an OR of 1.35 (95% CI: 1.21–1.52) per 10 dB increase in indoor $L_{AS,max}$ (Elmenhorst et al., 2012). Finally, evidence rated low quality was available for an association between railway noise and sleep outcomes measured as motility in adults (Griefahn et al., 2000; Hong et al., 2006; Lercher et al., 2010; Passchier-Vermeer et al., 2007), and rated very low quality for an association between railway noise and both self-reported and motility-measured sleep disturbance in children (Ising & Ising, 2002; Lercher et al., 2013; Tiesler et al., 2013).

3.2.2.2 Evidence on interventions

This section summarizes the evidence underlying the recommendation on the effectiveness of interventions for railway noise exposure (Tables 23 and 24). The key question posed was: in the general population exposed to railway noise, are interventions effective in reducing exposure to and/or health outcomes from railway noise? A summary of the PICOS/PECCOS scheme applied and the main findings is set out in Tables 23 and 24.

Table 23. PICOS/PECCOS scheme of the effectiveness of interventions for exposure to railway noise

PICO	Description	
Population	**General population**	
Intervention(s)	The interventions can be defined as: (a) a measure that aims to change noise exposure and associated health effects; (b) a measure that aims to change noise exposure, with no particular evaluation of the impact on health; or (c) a measure designed to reduce health effects, but that may not include a reduction in noise exposure.	
Comparison	**No intervention**	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

Table 24. Summary of findings for railway noise interventions by health outcome

Type of intervention	Number of participants (studies)	Effect of intervention	Quality of evidence
Annoyance			
Type A – source interventions (rail grinding)	81 (1)	• Changes in noise level as a consequence of the intervention ranged from around –7dB to –8 dB. • Most studies found changes in annoyance outcomes, persisting more than 12 months after the intervention.	Very low (downgraded for study limitations, inconsistency, imprecision)
Type C – changes in infrastructure (new rail infrastructure)	6000[a] (1)	• A very small increase in total noise exposure was found (most had <+1 dB change; some had +2–4 dB change). • Original noise from road traffic overwhelmed the train noise for effectively all participants.	Very low (downgraded for study limitations, inconsistency, imprecision)
Type E – behaviour change interventions (informing the community about a noise intervention)	411 (1)	• Exposure levels were not reported; emission levels reduced by 1–2 dB. • A reduction in annoyance of the community as a result of the intervention was reported.	Very low (downgraded for study limitations, inconsistency, imprecision)

Note: [a] According to Lam & Au (2008), this records the number of invitation letters sent; the response rate was not reported.

Three studies on railway noise interventions met the criteria to be included in the evidence base. All studies consisted of a pre/post design and reported annoyance outcomes at people's dwellings (Lam & Au, 2008; Moehler et al., 1997; Schreckenberg et al., 2013). They could be categorized as a source intervention, a new/closed infrastructure intervention and a communication intervention. In two of the studies, the changes in exposure after the intervention were only small, although there were significant effects on noise annoyance. The study on source interventions and annoyance revealed that a change of –10 dB in noise exposure led to a significant reduction in annoyance, which persisted over a period of 12 months after the intervention. As confounding was not addressed, and railway noise was not the dominant sound source in the studies, the evidence was rated very low quality.

3.2.2.3 Consideration of additional contextual factors

As the foregoing overview has shown, sufficient evidence about the adverse health effects of long-term exposure to railway noise exists. Based on the quality of the available evidence, the GDG set the strength of recommendation on railway noise at strong. As a second step, it qualitatively assessed contextual factors to explore whether other considerations could have a relevant impact on the recommendation strength. These contextual considerations mainly concerned the balance of harms and benefits, values and preferences, and resource use and implementation.

When assessing the balance of harms and benefits of interventions to reduce exposure to railway noise and minimize noise-associated adverse health effects, the GDG recognized that railway transportation is the second most dominant source of environmental noise in Europe. Based on EEA estimates, the number of people exposed to L_{den} above 55 dB and L_{night} above 50 dB from railway noise is 17 million and 15 million, respectively (Blanes et al., 2017).[15] In light of the burden of disease from environmental noise, and railway noise in particular, the GDG agreed that the health benefits from a reduction of long-term railway noise exposure (especially during night time) to the recommended values would be significant. Considering possible harms related to adaptation of the recommended values, the GDG noted that reliance on railway transportation has increased in recent years in Europe and is expected to increase further, as an important component of the shift towards a greener economy. At a societal level, an environmental and economic benefit from the use of rail transportation is expected: trains contribute to lower environmental pollution and carbon emission than road transportation. Therefore, there is a need to balance the expected health benefits from reduced continuous railway noise exposure and the overall positive effects on the health of the population from increased reliance on the comparatively environmentally friendly mode of railway transportation. Overall, the GDG agreed that even though fewer people are exposed to railway noise than road traffic noise, it remains a major source of localized noise pollution; therefore, considerable benefits are gained by reducing exposure to railway noise.

When exploring values and preferences, the GDG acknowledged that, in general, people value rail as an alternative and more sustainable transportation method than air or road traffic (EEA, 2016a; 2016b; 2017b). Furthermore, the values and preferences in relation to implementation of the recommendation are expected to vary: those of individuals living in the vicinity of railway tracks are expected to differ from those of the rest of the population not exposed to railway noise on a long-term basis. Economic depreciation of housing and fear of adverse health effects were assumed

[15] These are gap-filled figures based on the reported data and including the situation both within and outside cities, as defined by the END.

to be two main aspects influencing the evaluation of affected individuals. This especially applies to areas where new railway tracks are being built, as this results in considerable change for local inhabitants. Moreover, the GDG acknowledged that preferences might also vary in the policy-making domain across different countries as the implementation of the recommendations would mean a renunciation of the so-called "railway bonus".[16]

On resource use and implementation considerations, the GDG pointed out that no comprehensive cost–benefit analysis for the WHO European Region has yet been conducted, so this assessment is based on informed qualitative expert judgement regarding the feasibility of implementing the recommendation for the majority of the population. The systematic review of environmental noise interventions and their associated impact on health shows that various measures to reduce continuous noise from railway traffic exist, although knowledge about their effectiveness remains limited (Brown & van Kamp, 2017). The GDG noted that the resources needed to implement different measures may vary considerably, as they depend on the situation and the type of intervention required. Implementation of some measures is expected to be most feasible during the development of new railway tracks; such as rail pads, bi-bloc sleepers, small noise barriers and – in extreme cases – tunnels, cuttings or earthwork barriers. Other interventions include acoustic rail grinding, noise barriers built alongside the tracks, construction of quieter locomotives and wagons and replacement of brakes on freight trains. The GDG assumed that most of these solutions could be planned as part of regular maintenance or, for instance, by speeding up fleet modernization and track modernization. Even though not broadly implemented, the solutions mentioned above have already been considered or adopted to reduce noise levels from railway noise exposure. Some EU countries (such as Germany), have programmes to replace old brake blocks from freight trains with newer, quieter ones and to ban all freight trains with old brake blocks from 2020 (Umweltbundesamt, 2017). This illustrates that solutions to achieve recommended noise levels can be implemented at a reasonable cost. Overall, the GDG agreed that the benefit of implementation of the recommendation to minimize the risk of adverse health effects due to railway noise for a majority of the population exceeds the (monetary) resources needed.

In light of the assessment of the contextual factors in addition to the quality of evidence, the recommendation remains strong.

Additional considerations or uncertainties

The GDG acknowledged that the main body of evidence for the recommendations on railway noise for average exposure was based on annoyance studies, conducted mainly in Asia and Europe. Studies are few for other priority health outcomes, and the evidence was generally rated low/very low quality. There is therefore uncertainty about the effects on health outcomes. Nevertheless, as a precautionary approach, a strong recommendation is made for average exposure to L_{den}, as a broad evidence base exists for health effects from exposure to other sources of transportation noise. However, the GDG stressed the importance of further research into health effects due to long-term exposure to railway noise.

Moreover, situational factors should be taken into account when analysing annoyance from railway noise. In particular, ground-borne vibrations are sometimes an additional exposure variable in railway

[16] The "railway bonus" is a correction factor commonly applied in the noise abatement policy domain in recent decades. It subsidizes the noise rating level for railway transportation by a predefined factor (Schuemer & Schuemer-Kohrs, 1991).

noise situations – especially in the case of annoyance – which may be difficult to separate from noise effects. In the set of 11 studies included in the systematic review on railway noise and annoyance, only two explicitly mentioned ground-borne vibrations as an additional source of annoyance.

Overall, the low-carbon, low-polluting nature of railway transport, especially using electric trains, means that rail is favoured over road and air traffic. However, night-time railway traffic on busy lines, including freight traffic, can be a significant source of sleep disturbance. Thus, guideline values should be set to encourage the development of rail traffic in Europe while at the same time giving adequate protection to residents from sleep disturbance.

3.2.3 Summary of the assessment of the strength of the recommendations

Table 25 provides a comprehensive summary of the different dimensions for the assessment of the strength of the railway noise recommendations.

Table 25. Summary of the assessment of the strength of the recommendation

Factors influencing the strength of recommendation	Decision
Quality of evidence	**Average exposure** (L_{den}) *Health effects* • Evidence for a relevant absolute risk of annoyance at **54 dB** L_{den} was rated **moderate quality.** • Evidence for a relevant RR increase of the incidence of hypertension was rated **low quality**. One study met the inclusion criteria but did not find a significant increase. *Interventions* • Evidence that different types of intervention reduce noise annoyance from railways was rated **very low quality**. **Night-time exposure** (L_{night}) *Health effects* • Evidence for a relevant absolute risk of sleep disturbance related to night noise exposure from railways at **44 dB** L_{night} was rated **moderate quality**. *Interventions* • No evidence was available on the effectiveness of interventions to reduce noise exposure and/or sleep disturbance from railway noise.
Balance of benefits versus harms and burdens	Railway noise is a major source of localized pollution. The health benefits of adapting the recommendation outweigh the harms. Nevertheless, it is important to consider the relevance of railways as an environmentally friendly mode of transportation.
Values and preferences	Quiet areas are valued by the population; especially by those affected by continuous noise exposure. Some variability is expected among those directly affected by railway noise and those not affected.
Resource implications	No comprehensive cost–effectiveness-analysis data are available, although a wide range of interventions exists, indicating that measures are both feasible and economically reasonable.
Decisions on recommendation strength	• **Strong** for guideline value for average noise exposure (L_{den}). • **Strong** for guideline value for night noise exposure (L_{night}). • **Strong** for specific interventions to reduce noise exposure.

3.3 Aircraft noise

Recommendations

For average noise exposure, the GDG **strongly** recommends reducing noise levels produced by aircraft below **45 dB** L_{den}, as aircraft noise above this level is associated with adverse health effects.

For night noise exposure, the GDG **strongly** recommends reducing noise levels produced by aircraft during night time below **40 dB** L_{night}, as aircraft noise above this level is associated with adverse effects on sleep.

To reduce health effects, the GDG strongly recommends that policy-makers implement suitable measures to reduce noise exposure from aircraft in the population exposed to levels above the guideline values for average and night noise exposure. For specific interventions the GDG recommends implementing suitable changes in infrastructure.

3.3.1 Rationale for the guideline levels for aircraft noise

The exposure levels were derived in accordance with the prioritization process of critical health outcomes described in section 2.4.3. For each of the outcomes, the exposure level was identified by applying the benchmark, set as relevant risk increase to the corresponding ERF. In the case of exposure to aircraft noise, the process can be summarized as follows (Table 26).

Table 26. Average exposure levels (L_{den}) for priority health outcomes from aircraft noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Incidence of IHD A relevant risk increase from exposure to aircraft noise occurs at 52.6 dB L_{den}. The weighted average of the lowest noise levels measured in the studies was 47 dB L_{den} and the corresponding RR in the meta-analysis was 1.09 per 10 dB.	5% increase of RR	Very low quality
Incidence of hypertension One study met the inclusion criteria. There was no significant increase of risk associated with increased noise exposure in this study.	10% increase of RR	Low quality
Prevalence of highly annoyed population There was an absolute risk of 10% at a noise exposure level of 45.4 dB L_{den}.	10% absolute risk	Moderate quality
Permanent hearing impairment	No increase	No studies met the inclusion criteria
Reading skills and oral comprehension in children A relevant risk increase was found at 55 dB L_{den}.	One-month delay	Moderate quality

Based on the evaluation of evidence on relevant risk increases from the prioritized health outcomes, the GDG set a guideline exposure level of 45.4 dB L_{den} for average exposure to aircraft noise, based on the absolute %HA. It was confident that there was an increased risk for annoyance below this exposure level, but probably no relevant risk increase for other priority health outcomes. In accordance with the defined rounding procedure, the value was rounded to 45 dB L_{den}. As the evidence on the adverse effects of aircraft noise was rated moderate quality, the GDG made the recommendation strong.

Next, the GDG considered the evidence for night noise exposure and its effect on sleep disturbance (Table 27).

Table 27. Night-time exposure levels (L_{night}) for priority health outcomes from aircraft noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Sleep disturbance 11% of participants were highly sleep-disturbed at a noise level of 40 dB L_{night}.	3% absolute risk	Moderate quality

Based on the evidence of the adverse effects of aircraft noise on sleep disturbance, the GDG defined a guideline exposure level of 40.0 dB L_{night}. It should be stressed that this recommendation for average aircraft noise levels at night far exceeds the benchmark of 3%HSD defined as relevant risk increase, but since no reliable acoustic data below this level were available, the GDG decided not to lower the guideline exposure level further, as an extrapolation of the exposure–response relationship to achieve these values would have been unavoidable. As the evidence was rated moderate quality, the GDG made the recommendation strong.

The GDG also considered the evidence for the effectiveness of interventions. The results showed that changes in infrastructure (opening and/or closing of runways, or flight path rearrangements) can lead to a reduction in aircraft noise exposure, as well as a decline in cognitive impairment in children and a reduction in annoyance. Moreover, examples of best practice already exist for the management of noise from aircraft, so the GDG made a strong recommendation.

3.3.1.1 Other factors influencing the strength of recommendations

Other factors considered in the context of recommendations on aircraft traffic noise included those related to values and preferences, benefits and harms, resource implications, equity, acceptability and feasibility; moreover, nonpriority health outcomes were considered. Ultimately, the assessment of all these factors did not lead to a change in the strength of the recommendations. Further details are provided in section 3.3.2.3.

3.3.2 Detailed overview of the evidence

The following sections provide a detailed overview of the evidence constituting the basis for setting the recommendations on aircraft noise. It is presented and summarized separately for each of the critical health outcomes, and the GDG's judgement of the quality of evidence is indicated (for a detailed overview of the evidence on important health outcomes, see Annex 4). Research into health outcomes and effectiveness of interventions is addressed consecutively.

A comprehensive summary of all evidence considered for each of the critical and important health outcomes can be found in the eight systematic reviews published in the *International Journal of Environmental Research and Public Health* (see section 2.3.2 and Annex 2).

3.3.2.1 Evidence on health outcomes

The key question posed was: in the general population exposed to aircraft noise, what is the exposure–response relationship between exposure to aircraft noise (reported as various noise indicators) and the proportion of people with a validated measure of health outcome, when adjusted for main confounders? A summary of the PICOS/PECCOS scheme applied and the main findings is set out in Tables 28 and 29.

Table 28. PICOS/PECCOS scheme of critical health outcomes for exposure to aircraft noise

PECO	Description	
Population	General population	
Exposure	Exposure to high levels of noise produced by aircraft traffic (average/night time)	
Comparison	Exposure to lower levels of noise produced by aircraft traffic (average/night time)	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

Table 29 .Summary of findings for health effects from exposure to aircraft noise (L_{den})

Noise metric	Priority health outcome measure	Quantitative risk for adverse health	Lowest level of exposure across studies	Number of participants (studies)[a]	Quality of evidence
Cardiovascular disease					
L_{den}	Incidence of IHD	RR = 1.09 (95% CI: 1.04–1.15) per 10 dB increase	47 dB	9 619 082[a] (2)	Very low (downgraded for risk of bias; upgraded for dose-response)
L_{den}	Incidence of hypertension	RR = 1.00 (95% CI: 0.77–1.30) per 10 dB increase	N/A	4712 (1)	Low (downgraded for risk of bias and because only one study available)
Annoyance					
L_{den}	%HA	OR = 4.78 (95% CI: 2.27–10.05) per 10 dB increase	33 dB	17 094 (12)	Moderate (downgraded for inconsistency)
Cognitive impairment					
L_{den}	Reading and oral comprehension	1–2-month delay per 5 dB increase	Around 55 dB	(4)	Moderate (downgraded for inconsistency)
Hearing impairment and tinnitus					
L_{den}	Permanent hearing impairment	–	–	–	–

Note: [a] Results are partly derived from population-based studies.

Cardiovascular disease

IHD

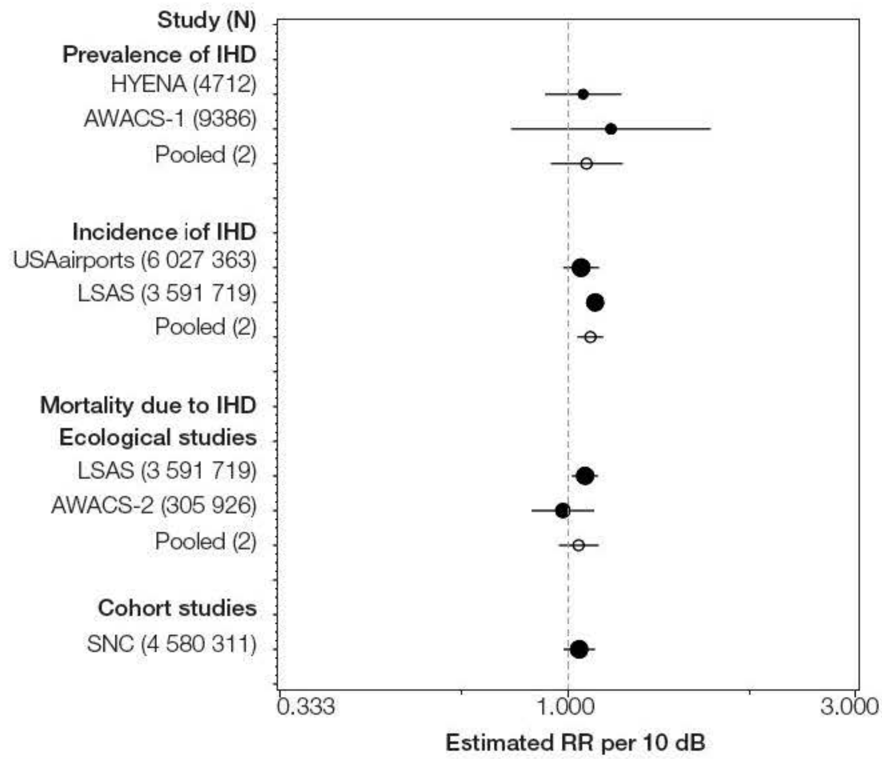
No cohort or case-control studies on the relationship between aircraft noise and IHD are available. However, two ecological studies were identified that provide information on the relationship between aircraft noise and incidence (hospital admission) of IHD (Correia et al., 2013; Hansell et al., 2013). These involved a total of 9 619 082 participants, including 158 977 cases. The RR was 1.09 (95% CI: 1.04–1.15) per 10 dB L_{den} increase, and the lowest exposure range was ≤51 dB and <45 dB. Given the weights in the meta-analysis of these two studies, the weighted average starting level was calculated as 47 dB. The evidence was rated very low quality.

Two cross-sectional studies were identified that assessed the prevalence of IHD in people living in cities located around airports in Europe. The studies involved 14 098 participants, including 340 cases (Babisch et al., 2005b; 2008; 2012a; 2012b; 2013a; Floud et al., 2011; 2013a; 2013b; Jarup et al., 2005; 2008; van Poll et al., 2014). The overall risk was RR = 1.07 (95% CI: 0.94–1.23) per 10 dB L_{den} increase. The evidence was rated low quality.

With regard to the relationship between aircraft noise and mortality due to IHD, one cohort study (Huss et al., 2010) and two ecological studies (Hansell et al., 2013; van Poll et al., 2014) were identified. The cohort study identified 4 580 311 participants, including 15 532 cases, living in Switzerland, and the authors found an RR of 1.04 (95% CI: 0.98–1.11) per 10 dB L_{den} increase in noise. The evidence was rated low quality. The two ecological studies identified a total of 3 897 645 participants, including 26 066 cases in the Netherlands and the United Kingdom. The overall RR was 1.04 (95% CI: 0.97–1.12) per 10 dB L_{den} increase in noise, and the evidence was rated very low quality.

Fig. 10 summarizes the results for the relationship between aircraft noise and different measures of IHD.

Fig. 10. The association between exposure to aircraft noise (L_{den}) and IHD



Notes: The dotted vertical line corresponds to no effect of exposure to aircraft noise. The black circles correspond to the estimated RR per 10 dB and 95% CI. The white circles represent the pooled random effect estimates and 95% CI. For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

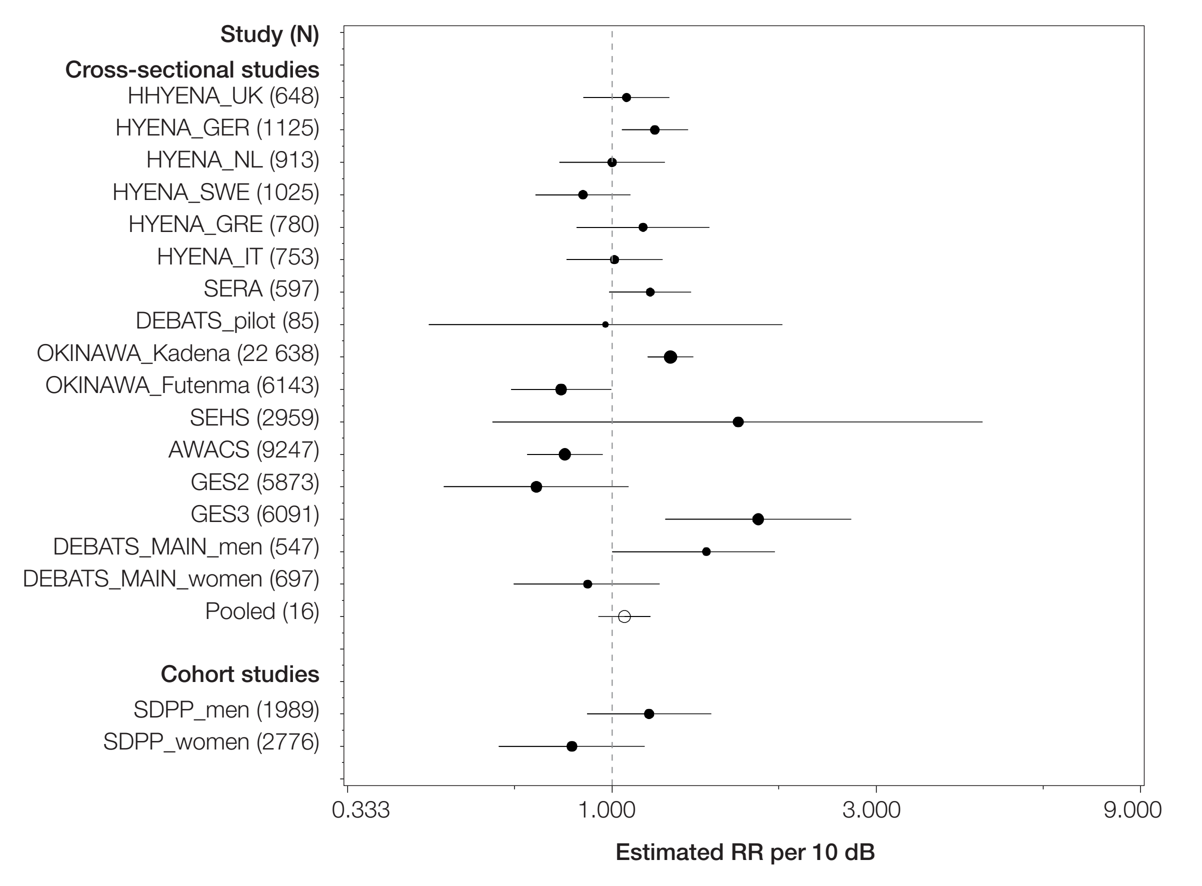
Hypertension

One cohort study was identified that assessed the relationship between aircraft noise and hypertension in people living in Sweden (Bluhm et al., 2004; 2009; Eriksson et al., 2007; 2010). The study involved 4712 participants, including 1346 cases. The authors found a nonstatistically significant effect size of RR = 1.00 (95% CI: 0.77–1.30) per 10 dB L_{den} increase. This evidence was rated moderate quality.

Furthermore, nine cross-sectional studies assessed the prevalence of hypertension in 60 121 participants, including 9487 cases (Ancona et al., 2010; Babisch et al., 2005b; 2008; 2012a; 2012b; 2013a; Breugelmans et al., 2004; Evrard et al., 2013; 2015; Houthuijs & van Wiechen, 2006; Jarup et al., 2005; 2008; Matsui, 2013; Matsui et al., 2001; 2004; Rosenlund et al., 2001; van Kamp et al., 2006; van Poll et al., 2014). The overall RR was 1.05 (95% CI: 0.95–1.17) per 10 dB L_{den} increase, with inconsistency across studies. The evidence was rated low quality.

Fig. 11 summarizes the results for both prevalence and incidence of hypertension.

Fig. 11. The association between exposure to aircraft noise (L_{den}) and hypertension in cross-sectional and cohort studies



Notes: The dotted vertical line corresponds to no effect of aircraft noise exposure. The black dots correspond to the estimated RR per 10 dB and 95% CI. The white circle represents the pooled summary estimate and 95% CI. For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

Stroke

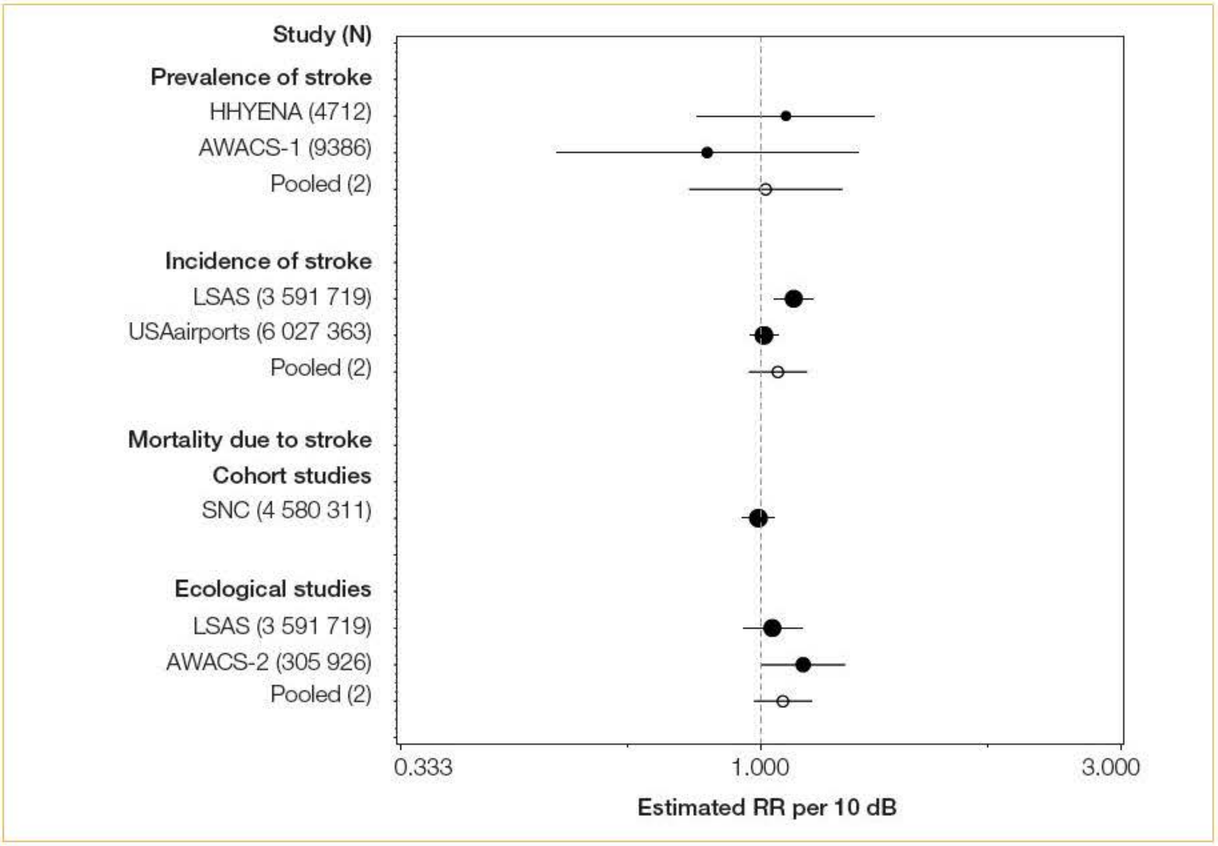
No cohort or case-control studies on the relationship between aircraft noise and incidence (hospital admission) of stroke were available, but two ecological studies were conducted in cities around airports in the United Kingdom and United States of America, involving 9 619 082 participants, including 97 949 cases (Correia et al., 2013; Hansell et al., 2013). An overall RR of 1.05 (95% CI: 0.96–1.15) per 10 dB L_{den} increase in noise was found. The evidence was rated very low quality.

Two cross-sectional studies were identified that assessed the prevalence of stroke in 14 098 participants, including 151 cases (Babisch et al., 2005b; 2008; 2012a; 2012b; 2013a; Floud et al., 2011; 2013a; 2013b; Jarup et al., 2005; 2008; van Poll et al., 2014). The overall RR was 1.02 (95% CI: 0.80–1.28) per 10 dB L_{den} increase. The evidence was rated very low quality.

On the relationship between aircraft noise and mortality due to stroke, one cohort study (Huss et al., 2010) and two ecological studies (Hansell et al., 2013; van Poll et al., 2014) were identified. The cohort study identified 4 580 311 participants, including 25 231 cases, living in Switzerland; the authors found an RR of 0.99 (95% CI: 0.94–1.04) per 10 dB L_{den} increase in noise. The overall evidence was rated moderate quality. The two ecological studies identified a total of 3 897 645 participants, including 12 086 cases, in the Netherlands and the United Kingdom. The overall RR was 1.07 (95% CI: 0.98–1.17) per 10 dB L_{den} increase in noise. The evidence was rated very low quality.

Fig. 12 summarizes the results for the relationship between aircraft noise and different measures of stroke.

Fig. 12. The association between exposure to aircraft noise (L_{den}) and stroke



Notes: The dotted vertical line corresponds to no effect of exposure to aircraft noise. The black dots correspond to the estimated RR per 10 dB and 95% CI. The white circle represents the summary estimate and 95% CI.
For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

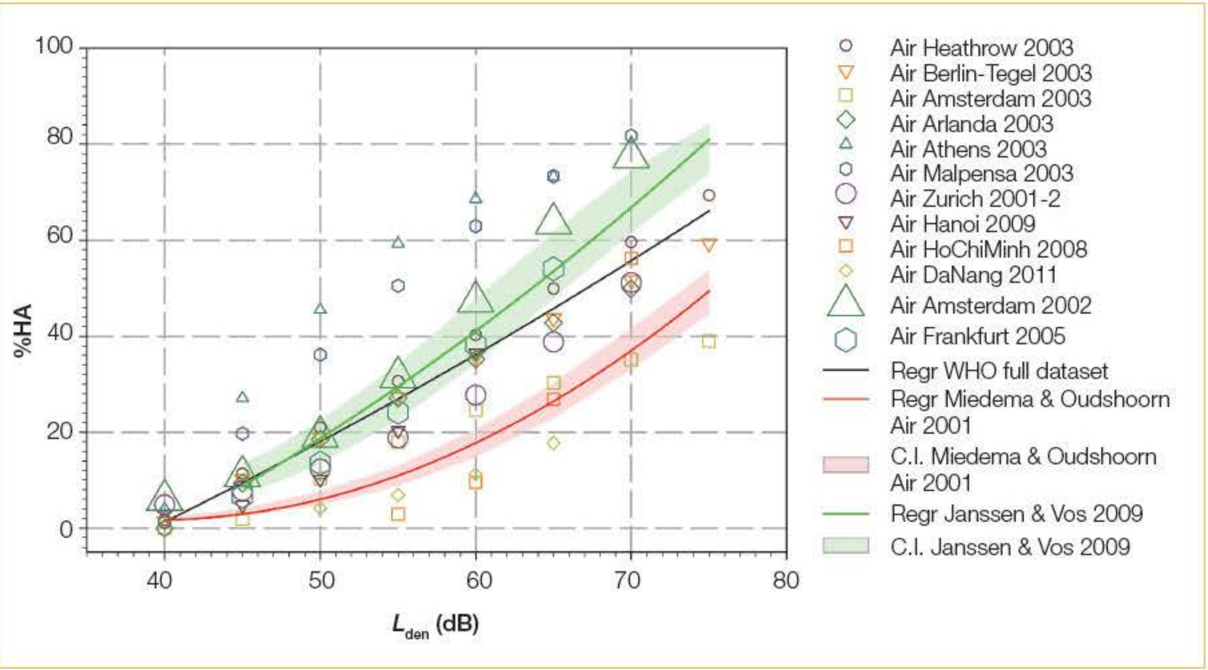
Children's blood pressure

For the association between aircraft noise and blood pressure in children, two cross-sectional studies were conducted in Australia, the Netherlands and the United Kingdom, including a total of 2013 participants (Clark et al., 2012; Morrell et al., 1998; 2000; van Kempen et al., 2006). The change in both systolic and diastolic blood pressure was assessed, in residential and/or educational settings. There was serious inconsistency in the results and therefore no overall estimate of the effect was developed. The evidence was rated very low quality.

Annoyance

A vast amount of evidence proves the association between aircraft noise and annoyance. In total, 12 aircraft noise studies were identified that were used to model ERFs of the relationship between L_{den} and %HA (Babisch et al., 2009; Bartels et al., 2013; Breugelmans et al., 2004; Brink et al., 2008; Gelderblom et al., 2014; Nguyen et al., 2011; 2012a; 2012b; Sato & Yano, 2011; Schreckenberg & Meis, 2007). These include data from 17 094 study participants. The estimated data points of each of the studies are plotted in Fig. 13, alongside an aggregated ERF including the data from all the individual studies (see the black line for "Regr WHO full dataset"). The lowest category of noise exposure considered in any of the studies, and hence included in the systematic review, is 40 dB, corresponding to approximately 1.2%HA. The benchmark level of 10%HA is reached at approximately 45 dB L_{den} (see Fig. 13).

Fig. 13. Scatterplot and quadratic regression of the relationship between aircraft noise (L_{den}) and annoyance (%HA)



Notes: ERFs by Miedema & Oudshoorn (2001, red), and Janssen & Vos (2009, green) are added for comparison.
There is no indication of 95% CIs of the WHO dataset curve, as a weighting based on the total number of participants for each 5 dB L_{den} sound class could not be calculated; weighting based on all participants of all sound classes proved to be unsuitable. The range of data included is illustrated by the distribution of data points. For further details on the studies included in the figure please refer to the systematic review on environmental noise and annoyance (Guski et al., 2017).

Table 30 shows the %HA in relation to exposure to aircraft traffic noise. It is based on the regression equation %HA = −50.9693 + 1.0168 × L_{den} + 0.0072 × L_{den}^2 derived from the systematic review (Guski et al., 2017). As the majority of the studies are cross-sectional, the evidence was rated moderate quality.

The general quality of the evidence was further substantiated with the help of additional statistical analyses that apply classical health outcome measures to estimate noise annoyance. When comparing aircraft noise exposure at 50 dB and 60 dB, the analyses revealed evidence rated high quality for an association between aircraft noise and %HA for an increase per 10 dB (OR = 3.40; 95% CI: 2.42–4.80). Moreover, there was evidence rated high quality for the increase of %HA per 10 dB increase in sound exposure, when data on all sound classes were included (OR = 4.78; 95% CI: 2.27–10.05).

Table 30. The association between exposure to aircraft noise (L_{den}) and annoyance (%HA)

L_{den} (dB)	%HA
40	1.2
45	9.4
50	17.9
55	26.7
60	36.0
65	45.5
70	55.5

Cognitive impairment

Evidence rated moderate quality was available for an association between aircraft noise and reading and oral comprehension, assessed by standardized tests. This is based on a narrative review of 14 studies that examined aircraft noise exposure effects on reading and oral comprehension (Clark et al., 2006; 2012; 2013; Evans & Maxwell, 1997; Haines et al., 2001a; 2001b; 2001c; Hygge et al., 2002; Klatte et al., 2014; Matsui et al., 2004; Seabi et al., 2012; 2013; Stansfeld et al., 2005; 2010). Of these studies, 10 were cross-sectional, and only four had a longitudinal and/or intervention design (Clark et al., 2013; Haines et al., 2001c; Hygge et al., 2002; Seabi et al., 2013). Most of the studies (10 of 14) demonstrated a statistically significant association or at least demonstrated a trend between higher aircraft noise exposure and poorer reading comprehension.

This relationship is supported by evidence on other health outcome measures related to cognition. Evidence rated moderate quality was available for an association between aircraft noise and children with poorer performance on standardized assessment tests (Eagan et al., 2004; FICAN, 2007; Green et al., 1982; Sharp et al., 2014). There was also evidence rated moderate quality on aircraft noise being associated with children having poorer long-term memory (Haines et al., 2001b). No studies examined the effects on short-term memory.

However, there was no substantial effect (evidence rated low quality) of aircraft noise on children's attention (Haines et al., 2001a; Hygge et al., 2002; Matsui et al., 2004; Stansfeld et al., 2005; 2010), or on executive function (working memory) (evidence rated very low quality), with studies consistently suggesting no association for aircraft noise (Clark et al., 2012; Haines et al., 2001a;

Haines et al., 2001b; Klatte et al., 2014; Matheson et al., 2010; Stansfeld et al., 2005; 2010; van Kempen et al., 2010; 2012).

Hearing impairment and tinnitus

No studies were found, and therefore no evidence was available on the association between aircraft noise and hearing impairment and tinnitus.

Sleep disturbance

For aircraft noise and self-reported sleep outcomes, six studies were identified that included a total of 6371 participants (Nguyen et al., 2009; 2010; 2011; 2012c; 2015; Schreckenberg et al., 2009; Yano et al., 2015). The majority of studies were cross-sectional by design and were conducted in otherwise healthy adults. The model was based on outdoor L_{night} levels between 40 dB and 65 dB only; the lower limit of 40 dB was set because of inaccuracies in predicting lower noise levels (Table 31).

Table 31. Summary of findings for health effects from exposure to aircraft noise (L_{night})

Noise metric	Priority health outcome measure	Quantitative risk for adverse health	Lowest level of exposure across studies	Number of participants (studies)	Quality of evidence
Effects on sleep					
L_{night}	%HSD	OR: 1.94 (95% CI: 1.61–2.33) per 10 dB increase	35 dB	6371 (6)	Moderate (downgraded for study limitations, inconsistency; upgraded for dose-response, magnitude of effect)

The range of noise exposure reported in studies was 37.5–62.5 dB. Over 11% (95% CI: 4.72–17.81) of the population was characterized as highly sleep-disturbed at L_{night} levels of 40 dB. The %HSD at other, higher levels of aircraft noise is presented in Table 27. The table is derived from the regression model in the systematic review specified as %HSD = 16.79–0.9293 × L_{night} + 0.0198 × L_{night}^2. The health outcome was measured in the studies by self-reporting, focusing on questions asking about awakenings from sleep, the process of falling asleep and/or sleep disturbance, where the question referred specifically to how noise affects sleep. The same relationship between aircraft noise and reporting being sleep-disturbed (all questions combined) can also be expressed as an OR of 1.94 (95% CI: 1.61–2.33) per 10 dB increase in noise. This evidence was rated moderate quality.

Table 32. The association between exposure to aircraft noise (L_{night}) and sleep disturbance (%HSD)

L_{night}	%HSD	95% CI
40	11.3	4.72–17.81
45	15.0	6.95–23.08
50	19.7	9.87–29.60
55	25.5	13.57–37.41
60	32.3	18.15–46.36
65	40.0	23.65–56.05

Additional analyses were included in the systematic review and provided supporting evidence on the association between aircraft noise and sleep. When the noise source was not specified in the survey question, the relationship between aircraft noise and self-reported sleep outcomes was still positive, although no longer statistically significant (OR: 1.17 (95% CI: 0.54–2.53) per 10 dB increase) (Brink, 2011). This evidence was rated very low quality.

Further, there was evidence rated moderate quality for an association between aircraft noise and polysomnography-measured outcomes (probability of additional awakenings), with an OR of 1.35 (95% CI: 1.22–1.50) per 10 dB increase in indoor $L_{AS,max}$ (Basner et al., 2006). Evidence rated low quality was also available for an association between aircraft noise and motility-measured sleep outcomes in adults (Passchier-Vermeer et al., 2002).

3.3.2.2 Evidence on interventions

The following section summarizes the evidence underlying the recommendation on the effectiveness of interventions for aircraft noise exposure. The key question posed was: in the general population exposed to aircraft noise, are interventions effective in reducing exposure to and/or health outcomes from aircraft noise? A summary of the PICOS/PECCOS scheme applied and the main findings is set out in Tables 33 and 34.

Seven studies examining different types of interventions on aircraft noise met the inclusion criteria to become part of the evidence base of the systematic review. Six of these investigated infrastructure interventions (Breugelmans et al., 2007; Brink et al., 2008; Fidell et al., 2002; Hygge et al., 2002), and one assessed a path intervention (Asensio et al., 2014). The majority of studies focused on annoyance as a health outcome, but two also included effects on sleep and one investigated the effects of path interventions on cognitive development in children.

Table 33. PICOS/PECCOS scheme of the effectiveness of interventions for exposure to aircraft noise

PICO	Description	
Population	**General population**	
Intervention(s)	The interventions can be defined as: (a) a measure that aims to change noise exposure and associated health effects; (b) a measure that aims to change noise exposure, with no particular evaluation of the impact on health; or (c) a measure designed to reduce health effects, but that may not include a reduction in noise exposure.	
Comparison	**No intervention**	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

Table 34. Summary of findings for aircraft noise interventions by health outcome

Type of intervention	Number of participants (studies)	Effect of intervention	Quality of evidence
Annoyance			
Type B – path interventions (retrofitting dwellings close to airports with acoustic insulation)	689 (1)	• Change in noise levels was not reported. • The study found a drop in annoyance following the insulation intervention	Very low (downgraded for study limitations, inconsistency, precision)
Type C – changes in infrastructure (opening and/or closing of runways, or flight path rearrangements)	2101 (3)	• There was a wide range of changes in noise levels (from −12 dB to +13.7 dB; most between ±1 dB and 2 dB; different noise indicators used). • All studies found changes in annoyance outcomes as a result of the intervention.	Moderate (downgraded for study limitations; upgraded for dose-response)
Sleep disturbance			
Type C – changes in infrastructure (flight path changes)	1707 (2)	• Changes in noise levels were mostly between ±1 dB and 2 dB. • Both studies found changes in sleep disturbance outcomes as a result of the intervention.	Low (downgraded for study limitations)
Cognitive development of children			
Type C – changes in infrastructure (opening and/or closing of runways, or flight path rearrangements)	326 (1)	• Changes in noise levels of +9 dB at the new airport and of −14 dB at the old airport were reported. • The study found various cognitive effects on children (for both the reduction and the increase in exposure). Effects disappeared when the old airport closed, emerging after the new airport opened.	Moderate (downgraded for inconsistency)

The largest body of research concentrated on the opening and closing of runways, leading to subsequent changes in flight paths (Breugelmans et al., 2007; Brink et al., 2008; Fidell et al., 2002). It showed that changes in noise exposure as a consequence of rearrangement of flight paths, step changes or increase or removal of over-flights resulted in statistically significant changes of the annoyance ratings of residents living in the vicinity of airports. The studies investigated both increases and reductions in exposure. Moreover, all the studies provided evidence that the change in response to noise exposure was an excess response to the intervention. As all the studies either adjusted for confounding or ruled out confounding by design, and the risk of bias was high in two studies but low in one, the evidence was rated moderate quality.

Two of these studies also investigated the effects of interventions on sleep disturbance. The results indicated that the percentage of sleep disturbance changed in association with the change in noise exposure caused by flight path adaptations (Breugelmans et al., 2007; Fidell et al., 2002). Both studies adjusted for confounding, but the risk of bias was assessed as high. Thus, the evidence was rated low quality.

One study examined the impact of rearranging flight paths on the cognitive effects on children (Hygge et al., 2002), showing various effects (for both the reduction and the increase in exposure).

The study ruled out confounding by study design and the risk of bias was assessed as low. The evidence was therefore rated moderate quality.

Alongside infrastructure interventions, a Spanish study presented evidence on path interventions (Asensio et al., 2014), showing a drop in annoyance following an insulation intervention. The study did not control for confounding and the risk of bias was assessed as high. The evidence was therefore rated very low quality.

3.3.2.3 Consideration of additional contextual factors

As the foregoing overview has shown, substantial evidence about the adverse health effects of long-term exposure to aircraft noise exists. Based on the quality of the available evidence, the GDG set the strength of the recommendation of aircraft noise at strong. As a second step, it qualitatively assessed contextual factors to explore whether other considerations could have a relevant impact on the recommendation strength. These considerations mainly concerned the balance of harms and benefits, values and preferences, equity, and resource use and implementation.

When assessing the balance of harms and benefits from implementing the recommendations on aircraft exposure, the GDG acknowledged that the number of people affected was lower than for road traffic or railway noise, since aircraft noise only affects the areas surrounding airports and under flight paths. Data from the EEA show that the estimated number of people in Europe exposed to L_{den} levels above 55 dB and L_{night} levels above 50 dB is 3 million and 1.2 million, respectively (Blanes et al., 2017).[17] Nevertheless, it remains a major source of localized noise pollution and has been predicted to increase (EASA et al., 2016). Furthermore, aircraft noise is regarded as more annoying than the other sources of transportation noise (Schreckenberg et al., 2015; Miedema & Oudshoorn, 2001); it is therefore associated with a significant burden on public health, and the GDG expects substantial health benefits for the population to evolve from implementing the recommendations to reduce exposure to aircraft traffic noise. Furthermore, the GDG noted that, depending on the intervention measure implemented (such as a night flight ban), additional health benefits could evolve, resulting from a simultaneous reduction in air pollution (EC, 2016a). The GDG also acknowledged that intervention measures like night flight bans might also reduce carbon emission, thereby positively influencing the shift towards a greener and more sustainable economy. Possible harms in relation to the applied noise abatement strategy, on the other hand, could include effects on the transportation of goods, as well as individual mobility of the population. Both could have impacts on local, national and international economies. Overall, the GDG estimated that the benefits gained from minimizing adverse health effects due to aircraft noise exposure outweigh the possible (economic) harms.

Considering values and preferences, the GDG noted that negative attitudes towards aircraft noise are especially prevalent in affected individuals who can see and hear aircraft from their house, or who fear that living in proximity of airports will have an impact on their health (Schreckenberg et al., 2015) or property value (economic loss) (Bristow et al., 2014). A lack of trust in the airport and government authorities can enhance these negative attitudes towards airports and aircraft noise (Borsky, 1979; Schreckenberg, 2017). Furthermore, the GDG recognized that values and preferences of individuals living in the vicinity of different airports may vary, as the infrastructural characteristics

[17] These are gap-filled figures based on the reported data and including the situation both within and outside cities, as defined by the END.

of airports have a significant effect on the evaluation of residents. Airports with a stable number of aircraft movements in the near past and no intention to change the number in the future can give rise to a different evaluation of values and preferences than airports with relatively sustained increases in the number of aircraft movements. This can result from the fact that opening new runways or increasing the number of flights usually means considerable change in the environment for inhabitants of the affected area. It has been postulated that the change of exposure itself may be an annoying factor, and this may explain why aircraft noise annoyance is generally higher than that for other sources of transportation noise at a comparable noise level (Brown & van Kamp, 2009). The GDG acknowledged that, in general, air travel is an important means of transportation relevant for businesses, the public and the economy. In Europe, aviation is projected to be the fastest-growing sector from passenger transport demand, by 2050 (EEA, 2016a). The general population tends to value the convenience of travel by air. Moreover, the GDG pointed out that exposure to aircraft noise is not equally distributed throughout society. The preferences of people living in the vicinity of airports are expected to differ from those of the general population that does not experience the same noise burden. This might facilitate variance in the values and preference of the population, as those benefiting from the services and revenues generated by an airport may regard noise reduction measures as an additional, unnecessary extra cost, while those living around an airport and affected by aircraft noise may be in favour of noise reductions, since this concerns their health and well-being. Despite these differences, however, the GDG was confident that a majority of the population would value the minimization of adverse health effects and therefor welcome the implementation of the recommendations.

Regarding the dimension of equity, the GDG highlighted that the risk of exposure to aircraft noise is not equally distributed throughout society. Members of society with a lower socioeconomic status and other disadvantaged groups often live in more polluted and louder areas, including in close proximity to airports (EC, 2016a). In addition to the increased risk of exposure to environmental noise, socioeconomic factors are also associated with increased vulnerability and poorer coping capacities (Karpati et al., 2002).

With resource use and implementation considerations, the GDG acknowledged that the economic evaluation of the health impacts of environmental noise is most elaborate and extensive for aircraft noise (Berry & Sanchez, 2014). Nevertheless, no comprehensive cost–benefit analysis for the WHO European Region yet exists, so this assessment is based on informed qualitative expert judgement regarding the feasibility of implementing the recommendation for the majority of the population. The systematic review of interventions and their associated impact on environmental noise and health shows that various measures to reduce continuous noise from aircraft exist. Moreover, the quality of the evidence was judged to be moderate (Brown & van Kamp, 2017). The GDG noted that the resources needed to implement different intervention measures may vary considerably, because they depend on the situation and the type of intervention required. The distribution of costs also differs from that for other modes of transportation, since exposure to aircraft noise is localized in a more agglomerated way, and overall the population affected is smaller compared to other modes of transportation. The GDG furthermore recognized that multiple cost-effective intervention strategies exist (EC, 2016b). Prohibition or discouragement strategies against citizens moving to the direct proximity of airports, for example, can be implemented in the context of urban planning. Likewise, diverting flight paths above less-populated areas can lead to a reduction in exposure. In principle, such intervention measures do not involve any direct costs, although safety concerns may limit the feasibility of these strategies. Passive noise abatement measures like the installation of soundproof windows at the dwelling were also regarded as feasible and economically reasonable by the GDG, as these are implemented at several airports already. In relation to active abatement measures, the GDG acknowledged the "balanced approach" elaborated by International Civil Aviation Organization, which states that noise reduction should take place first at the source. As indicated by the Clean Sky Programme, this could, for example, entail shifting towards the introduction of new aircraft. This broad European research programme estimates that, depending on type, the shift to newly produced aircraft could lead to a reduction of approximately 55–79% of the area affected by aircraft noise, and consequently the population exposed. As this solution has been put forward by the aviation sector, it is considered feasible. Overall, this indicates that solutions to achieve recommended noise levels can be implemented and at reasonable costs. The GDG agreed that implementation of the recommendation to minimize the risk of adverse health effects due to aircraft noise for a majority of the population would require a reasonable amount of (monetary) resources. It noted, however, that the feasibility of implementing the measures could be hindered by the fact that costs and benefits are not equally distributed. In most cases, the health benefits citizens gain from interventions that reduce aircraft exposure are borne by private companies and public authorities.

In light of the assessment of the contextual factors in addition to the quality of evidence, the recommendation remains strong.

Other nonpriority adverse health outcomes

Although not a priority health outcome and coming from a single study, the GDG noted the evidence rated moderate quality for the statistically significant association between aircraft noise and the change in waist circumference (Eriksson et al., 2014). The range of noise levels in the study identified was 48 to 65 dB L_{den}, and therefore the recommendation would also be protective enough for this health outcome.

In the context of aircraft noise, when considering the impacts of exposure on cognitive impairment in children, these guideline recommendations also apply particularly to the school setting. Noise exposure at primary school and at home is often highly correlated; however, the evidence base considered comes mainly from studies designed around sampling at school and not residences.

Additional considerations or uncertainties

There is additional uncertainty when characterizing exposure using the acoustical description of aircraft noise by means of L_{den} or L_{night}. Use of these average noise indicators may limit the ability to observe associations between exposure to aircraft noise and some health outcomes (such as awakening reactions); as such, noise indicators based on the number of events (such as the frequency distribution of $L_{A,max}$) may be better suited. However, such indicators are not widely used.

The GDG acknowledged that the guideline recommendation for L_{night} may not be fully protective of health, as it implies that around 11% (95% CI: 4.72–17.81) of the population may be characterized as highly sleep-disturbed at the recommended L_{night} level. This is higher than the 3% absolute risk considered for setting the guideline level. However, the high calculation uncertainty in predicting noise levels lower than 40 dB prevented the GDG from recommending a lower level. Furthermore, lower levels would probably require a ban on night or early morning flights altogether, which is not feasible in many situations, given that the general population tends to value the convenience of air travel.

3.3.3 Summary of the assessment of the strength of recommendation

Table 35 provides a comprehensive summary of the different dimensions for the assessment of the strength of the aircraft noise recommendations.

Table 35. Summary of the assessment of the strength of the recommendation

Factors influencing the strength of recommendation	Decision
Quality of evidence	**Average exposure (L_{den})** *Health effects* • Evidence for a relevant RR increase of the incidence of IHD at **52 dB** L_{den} was rated **very low quality.** • Evidence for a relevant RR increase of the incidence of hypertension was rated **low quality**. • Evidence for a relevant absolute risk of annoyance at **45 dB** L_{den} was rated **moderate quality**. • Evidence for a relevant RR increase of impaired reading and oral comprehension at **55 dB L_{den}** was rated **moderate quality**. *Interventions* • Evidence on effectiveness of interventions to reduce noise exposure and/or health outcomes from aircraft noise was of varying quality. **Night-time exposure (L_{night})** *Health effects* • Evidence for a relevant absolute risk of sleep disturbance related to night noise exposure from aircraft at **40 dB** L_{night} was rated **moderate quality**. *Interventions* • Evidence on effectiveness of changes in infrastructure (flight path changes) to reduce sleep disturbance from aircraft noise was rated **low quality**.
Balance of benefits versus harms and burdens	Aircraft noise is a major source of localized noise pollution. The health benefits of adapting the recommendations are expected to outweigh the harms.
Values and preferences	Quiet areas are valued by the population, especially by those affected by continuous aircraft noise exposure. Some variability is expected among those directly affected by aircraft noise and those not affected.
Equity	Risk of exposure to aircraft noise is not equally distributed.
Resource implications	No comprehensive cost–effectiveness analysis data are available; nevertheless, a wide variety of interventions exist (some at very low cost), indicating that measures are both feasible and economically reasonable.
Decisions on recommendation strength	• **Strong** for guideline value for average noise exposure (L_{den}) • **Strong** for guideline value for night noise exposure (L_{night}) • **Strong** for specific interventions to reduce noise exposure

3.4 Wind turbine noise

Recommendations

For average noise exposure, the GDG **conditionally** recommends reducing noise levels produced by wind turbines below **45 dB** L_{den}, as wind turbine noise above this level is associated with adverse health effects.

To reduce health effects, the GDG **conditionally** recommends that policy-makers implement suitable measures to reduce noise exposure from wind turbines in the population exposed to levels above the guideline values for average noise exposure. No evidence is available, however, to facilitate the recommendation of one particular type of intervention over another.

3.4.1 Rationale for the guideline levels for wind turbine noise

The exposure levels were derived in accordance with the prioritizing process of critical health outcomes described in section 2.4.3. For each of the outcomes, the exposure level was identified by applying the benchmark, set as relevant risk increase to the corresponding ERF. In the case of exposure to wind turbine noise, the process can be summarized as follows (Table 36).

Table 36. Average exposure levels (L_{den}) for priority health outcomes from wind turbine noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Incidence of IHD Incidence of IHD could not be used to assess the exposure level.	5% increase of RR	No studies were available
Incidence of hypertension Incidence of hypertension could not be used to assess the exposure level.	10% increase of RR	No studies were available
Prevalence of highly annoyed population Four studies were available. An exposure–response curve of the four studies revealed an absolute risk of 10%HA (outdoors) at a noise exposure level of 45 dB L_{den}.	10% absolute risk	Low quality
Permanent hearing impairment	No increase	No studies were available
Reading skills and oral comprehension in children	One-month delay	No studies were available

In accordance with the prioritization process, the GDG set a guideline exposure level of 45.0 dB L_{den} for average exposure, based on the relevant increase of the absolute %HA. The GDG stressed that there might be an increased risk for annoyance below this noise exposure level, but it could not state whether there was an increased risk for the other health outcomes below this level owing to a lack of evidence. As the evidence on the adverse effects of wind turbine noise was rated low quality, the GDG made the recommendation conditional.

Next, the GDG considered the evidence for night noise exposure to wind turbine noise and its effect on sleep disturbance (Table 37).

Table 37. Night-time exposure levels (L_{night}) for priority health outcomes from wind turbine noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Sleep disturbance Six studies were available; they did not reveal consistent results about effects of wind turbine noise on sleep.	3% absolute risk	Low quality

Based on the low quantity and heterogeneous nature of the evidence, the GDG was not able to formulate a recommendation addressing sleep disturbance due to wind turbine noise at night time.

The GDG also looked for evidence about the effectiveness of interventions for wind turbine noise exposure. Owing to a lack of research, however, no studies were available on existing interventions and associated costs to reduce wind turbine noise.

Based on this assessment, the GDG therefore provided a conditional recommendation for average noise exposure (L_{den}) to wind turbines and a conditional recommendation for the implementation of suitable measures to reduce noise exposure. No recommendation about a preferred type of intervention could be formulated; nor could a recommendation be made for an exposure level for night noise exposure (L_{night}), as studies were not consistent and in general did not provide evidence for an effect on sleep.

3.4.1.1 Other factors influencing the strength of recommendation

Other factors considered in the context of recommendations on wind turbine noise included those related to values and preferences, benefits and harms, resource implications, equity, acceptability and feasibility. Ultimately, the assessment of all these factors did not lead to a change in the strength of recommendation, although it informed the development of a conditional recommendation on the intervention measures. Further details are provided in section 3.4.2.3.

3.4.2 Detailed overview of the evidence

The following sections provide a detailed overview of the evidence constituting the basis for setting the recommendations on wind turbine noise. It is presented and summarized separately for each of the critical health outcomes, and the GDG's judgement of the quality of evidence is indicated (for a detailed overview of the evidence on important health outcomes, see Annex 4). Research into health outcomes and effectiveness of intervention is addressed consecutively.

A comprehensive summary of all evidence considered for each of the critical and important health outcomes can be found in the eight systematic reviews published in the *International Journal of Environmental Research and Public Health* (see section 2.3.2 and Annex 2).

It should be noted that, due to the time stamp of the systematic reviews, some more recent studies were not included in the analysis. This relates in particular to several findings of the Wind Turbine Noise and Health Study conducted by Health Canada (Michaud, 2015). Further, some studies were omitted, as they did not meet the inclusion criteria, including, for instance, studies using distance to the wind turbine instead of noise exposure to investigate health effects. The justification for including and excluding studies is given in the systematic reviews (Basner & McGuire, 2018; Brown et al., 2017; Clark & Paunovic, 2018; in press; Guski et al., 2017; Niewenhuijsen et al.,2017; Śliwińska-Kowalska & Zaborowski, 2017; van Kempen et al., 2018; see Annex 2 for further details).

3.4.2.1 Evidence on health outcomes

The key question posed was: in the general population exposed to wind turbine noise, what is the exposure–response relationship between exposure to wind turbine noise (reported as various noise indicators) and the proportion of people with a validated measure of health outcome, when adjusted for main confounders? A summary of the PICOS/PECCOS scheme applied and the main findings is set out in Tables 38 and 39.

Table 38. PICOS/PECCOS scheme of critical health outcomes for exposure to wind turbine noise

PECO	Description	
Population	General population	
Exposure	Exposure to high levels of noise produced by wind turbines (average/night time)	
Comparison	Exposure to lower levels of noise produced by wind turbines (average/night time)	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

Table 39. Summary of findings for health effects from exposure to wind turbine noise (L_{den})

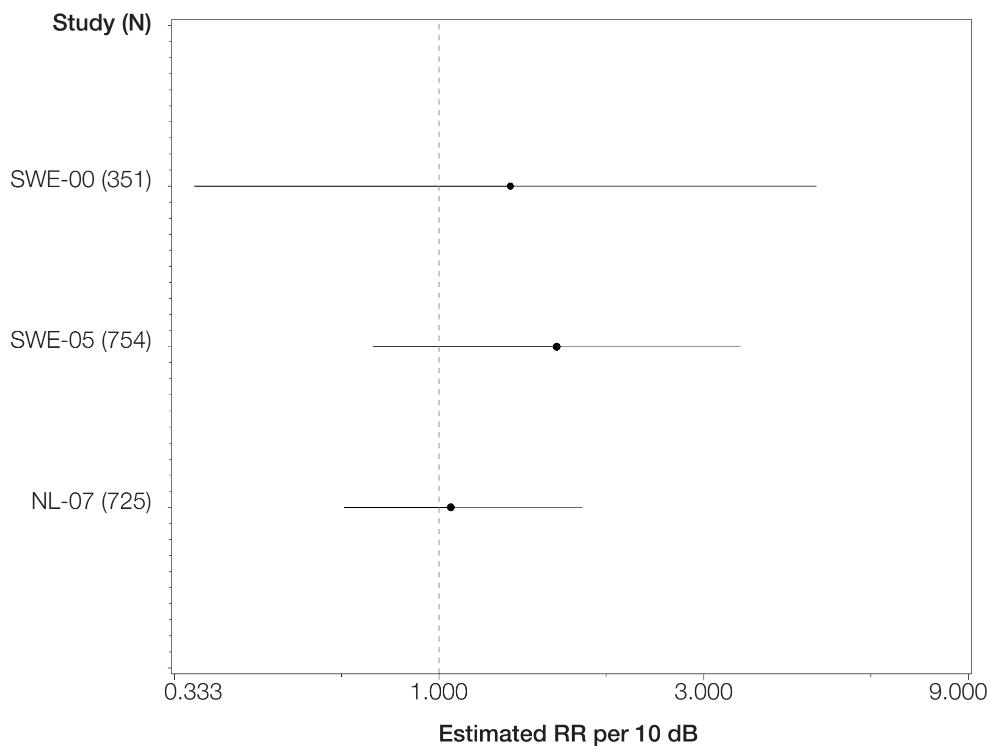
Noise metric	Priority health outcome measure	Quantitative risk for adverse health	Lowest level of exposure across studies	Number of participants (studies)	Quality of evidence
Cardiovascular disease					
L_{den}	Incidence of IHD	–	–	–	–
L_{den}	Incidence of hypertension	–	–	–	–
Annoyance					
L_{den}	%HA	Not able to pool because of heterogeneity	30 dB	2481 (4)	Low (downgraded for inconsistency and imprecision)
Cognitive impairment					
L_{den}	Reading and oral comprehension	–	–	–	–
Hearing impairment and tinnitus					
L_{den}	Permanent hearing impairment	–	–	–	–

Cardiovascular disease

For the relationship between wind turbine noise and prevalence of hypertension, three cross-sectional studies were identified, with a total of 1830 participants (van den Berg et al., 2008; Pedersen, 2011; Pedersen & Larsman, 2008; Pedersen & Persson Waye, 2004; 2007). The number of cases was not reported. All studies found a positive association between exposure to wind turbine noise and the prevalence of hypertension, but none was statistically significant. The lowest levels in studies were either <30 or <32.5 L_{den}. No meta-analysis was performed, since too many parameters were unknown and/or unclear. Due to very serious risk of bias and imprecision in the results, this evidence was rated very low quality (see Fig. 14).

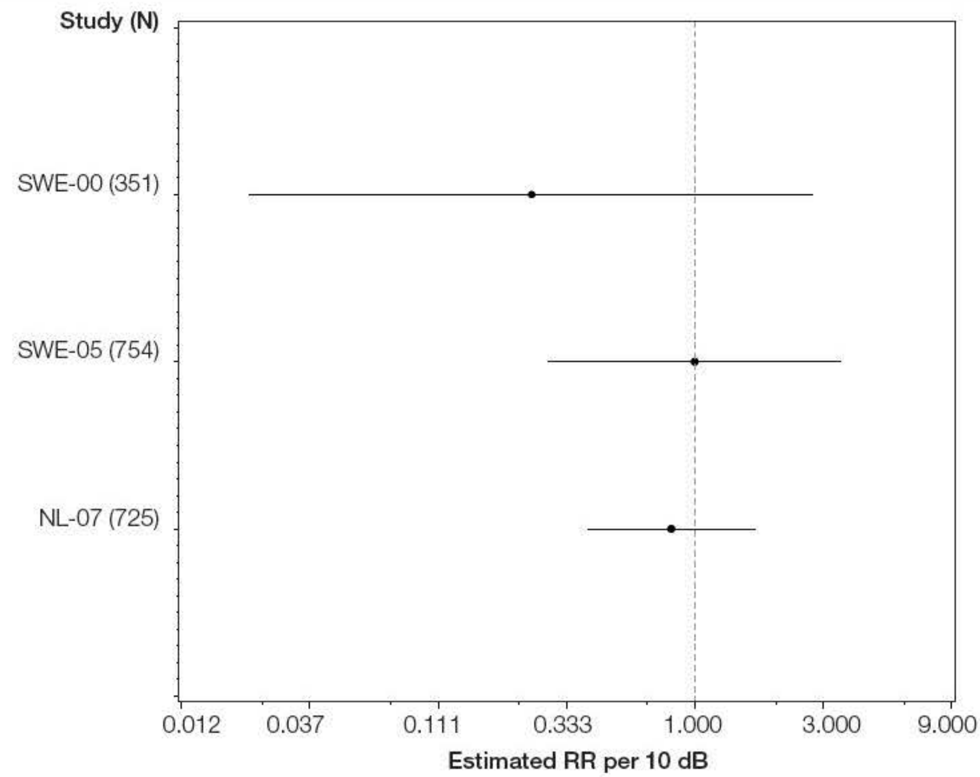
The same studies also looked at exposure to wind turbine noise and self-reported cardiovascular disease, but none found an association. No evidence was available for other measures of cardiovascular disease. As a result, only evidence rated very low quality was available for no considerable effect of audible noise (greater than 20 Hz) from wind turbines or wind farms on self-reported cardiovascular disease (see Fig. 15).

Fig. 14. The association between exposure to wind turbine noise (sound pressure level in dB) and hypertension



Notes: The dotted vertical line corresponds to no effect of exposure to wind turbine noise. The black dots correspond to the estimated RR per 10 dB and 95% CI. For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

Fig. 15. The association between exposure to wind turbine noise (sound pressure level) and self-reported cardiovascular disease



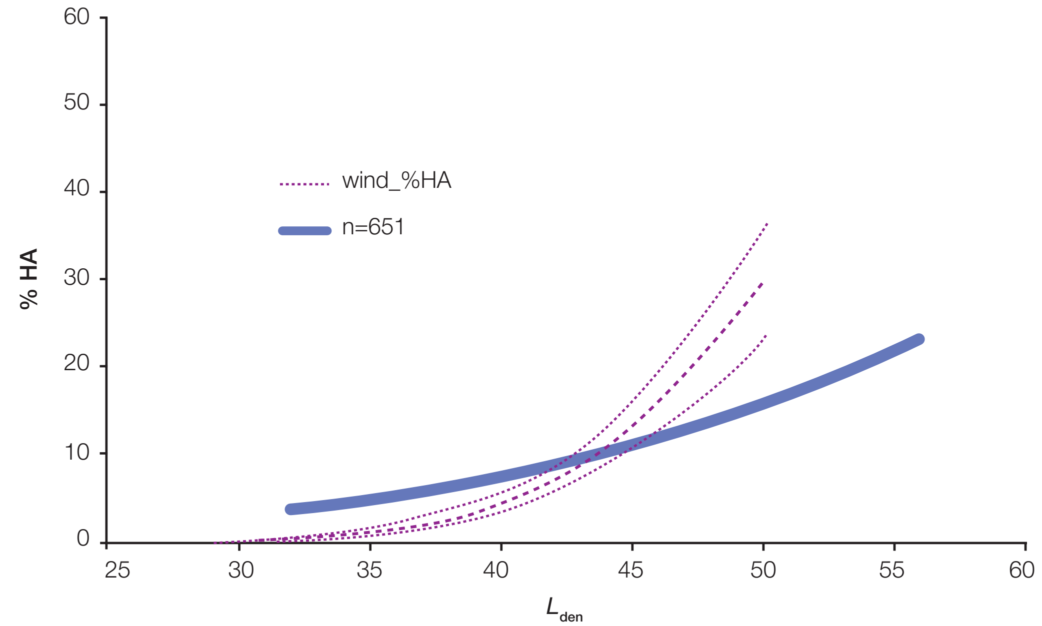
Notes: The dotted vertical line corresponds to no effect of exposure to wind turbine noise. The black circles correspond to the estimated RR per 10 dB (sound pressure level) and 95% CI. For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

Annoyance

Two publications containing descriptions of four individual studies were retrieved (Janssen et al., 2011; Kuwano et al., 2014). All four studies used measurements in the vicinity of the respondents' addresses; the noise exposure metrics used in the three original studies (Pedersen, 2011; Pedersen & Persson Waye, 2004; 2007) included in Janssen et al. (2011) were recalculated into L_{den}. The noise levels in the studies ranged from 29 dB to 56 dB. Different scales were used to assess annoyance, with slightly different definitions of "highly annoyed" and explicit reference to outdoor annoyance in the data used for the Janssen et al. (2011) curve. Construction of the ERFs provided in the two publications differed and they were therefore not further combined in a meta-analysis. Fig. 16 shows the %HA from the two publications. The 10% criterion for %HA is reached at around 45 dB L_{den} (where the two curves coincide). There was a wide variability in %HA between studies, with a range of 3–13%HA at 42.5 dB and 0–32%HA at 47.5 dB. The %HA in the sample is comparatively high, given the relatively low noise levels. There is evidence rated low quality for an association between wind turbine noise and annoyance, but this mainly applies to the association between wind turbine noise and annoyance and not to the shape of the quantitative relationship.

Further statistical analyses of annoyance yield evidence rated low quality for an association between wind turbine noise and %HA when comparing an exposure at 42.5 dB and 47.5 dB, with a mean difference in %HA of 4.5 (indoors) and 6.4 (outdoors). There is also evidence rated moderate quality for a correlation between individual noise exposure and annoyance raw scores (r = 0.28).

Fig. 16. Overlay of the two wind turbine annoyance graphs



Notes: Overlay of the two wind turbine outdoor annoyance graphs adapted from Janssen et al. (2011, red) and Kuwano et al. (2014, blue). The Kuwano et al. curve is based on L_{dn}; no correction for L_{den} has been applied.[18]
For further details on the studies included in the figure please refer to the systematic review on environmental noise and annoyance (Guski et al., 2017).

Cognitive impairment, hearing impairment and tinnitus, adverse birth outcomes

No studies were found, and therefore no evidence was available on the relationship between wind turbine noise and measures of cognitive impairment; hearing impairment and tinnitus; and adverse birth outcomes.

Sleep disturbance

Six cross-sectional studies on wind turbine noise and self-reported sleep disturbance were identified (Bakker et al., 2012; Kuwano et al., 2014; Michaud, 2015; Pawlaczyk-Luszczynska et al., 2014; Pedersen & Persson Waye, 2004; 2007). Noise levels were calculated using different methods, and different noise metrics were reported. Three of the studies asked how noise affects sleep; the other three evaluated the effect of wind turbine noise on sleep using questions that explicitly referred to noise (Table 40).

[18] L_{dn} is the day-night-weighted sound pressure level as defined in section 3.6.4 of ISO 1996-1:2016.

Table 40. Summary of findings for health effects from exposure to wind turbine noise (L_{night})

Noise metric	Priority health outcome measure	Quantitative risk for adverse health	Lowest level of effects in studies	Number of participants (studies)	Quality of evidence
Effects on sleep					
L_{night}	%HSD	1.60 (95% CI: 0.86–2.94) per 10 dB increase	31 dB	3971 (6)	Low (downgraded for study limitations, inconsistency, precision)

The risk of bias was assessed as high for all six studies, as effects on sleep were measured by self-reported data. There were a limited number of subjects at higher exposure levels. A meta-analysis was conducted for five of the six studies, based on the OR for high sleep disturbance for a 10 dB increase in outdoor predicted sound pressure level. The pooled OR was 1.60 (95% CI: 0.86–2.94). The evidence was rated low quality.

3.4.2.2 Evidence on interventions

This section summarizes the evidence underlying the recommendation on the effectiveness of interventions for wind turbine noise exposure. The key question posed was: in the general population exposed to wind turbine noise, are interventions effective in reducing exposure to and/or health outcomes from wind turbine noise? A summary of the PICOS/PECCOS scheme applied is set out in Table 41.

Table 41. PICOS/PECCOS scheme of the effectiveness of interventions for exposure to wind turbine noise

PICO	Description	
Population	**General population**	
Intervention(s)	The interventions can be defined as: (a) a measure that aims to change noise exposure and associated health effects; (b) a measure that aims to change noise exposure, with no particular evaluation of the impact on health; or (c) a measure designed to reduce health effects, but that may not include a reduction in noise exposure.	
Comparison	**No intervention**	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

No studies were found, and therefore no evidence was available on the effectiveness of interventions to reduce noise exposure from wind turbines.

3.4.2.3 Consideration of additional contextual factors

As the foregoing overview has shown, very little evidence is available about the adverse health effects of continuous exposure to wind turbine noise. Based on the quality of evidence available, the GDG set the strength of the recommendation on wind turbine noise to conditional. As a second step, it qualitatively assessed contextual factors to explore whether other considerations could have a relevant impact on the recommendation strength. These considerations mainly concerned the balance of harms and benefits, values and preferences, and resource use and implementation.

Regarding the balance of harms and benefits, the GDG would expect a general health benefit from a marked reduction in any kind of long-term environmental noise exposure. Health effects of individuals living in the vicinity of wind turbines can theoretically be related not only to long-term noise exposure from the wind turbines but also to disruption caused during the construction phase. The GDG pointed out, however, that evidence on health effects from wind turbine noise (apart from annoyance) is either absent or rated low/very low quality (McCunney et al., 2014). Moreover, effects related to attitudes towards wind turbines are hard to discern from those related to noise and may be partly responsible for the associations (Knopper & Ollson, 2011). Furthermore, the number of people exposed is far lower than for many other sources of noise (such as road traffic). Therefore, the GDG estimated the burden on health from exposure to wind turbine noise at the population level to be low, concluding that any benefit from specifically reducing population exposure to wind turbine noise in all situations remains unclear. Nevertheless, proper public involvement, communication and consultation of affected citizens living in the vicinity of wind turbines during the planning stage of future installations is expected to be beneficial as part of health and environmental impact assessments. In relation to possible harms associated with the implementation of the recommendation, the GDG underlined the importance of wind energy for the development of renewable energy policies.

The GDG noticed that the values and preferences of the population towards reducing long-term noise exposure to wind turbine noise vary. Whereas the general population tends to value wind energy as an alternative, environmentally sustainable and low-carbon energy source, people living in the vicinity of wind turbines may evaluate them negatively. Wind turbines are not a recent phenomenon, but their quantity, size and type have increased significantly over recent years. As they are often built in the middle of otherwise quiet and natural areas, they can adversely affect the integrity of a site. Furthermore, residents living in these areas may have greater expectations of the quietness of their surroundings and therefore be more aware of noise disturbance. Negative attitudes especially occur in individuals who can see wind turbines from their houses but do not gain economically from the installations (Kuwano et al., 2014; Pedersen & Persson Waye, 2007; van den Berg et al., 2008). These situational variables and the values and preferences of the population may differ between wind turbines and other noise sources, as well as between wind turbine installations, which makes assessment of the relationship between wind turbine noise exposure and health outcomes particularly challenging.

Assessing resource use and implementation considerations, the GDG noted that reduction of noise exposure from environmental sources is generally possible through simple measures like insulating windows or building barriers. With wind turbines, however, noise reduction interventions are more complicated than for other noise sources due to the height of the source and because outdoor disturbance is a particularly large factor. As generally fewer people are affected (compared to transportation noise), the expected costs are lower than for other environmental sources of noise. The GDG was not aware of any existing interventions (and associated costs) to reduce harms from wind turbine noise, or specific consequences of having regulations on wind turbine noise. Therefore, it could not assess feasibility, or discern whether any beneficial effects of noise reduction would outweigh the costs of intervention. In particular, there is no clear evidence on an acceptable and uniform distance between wind turbines and residential areas, as the sound propagation depends on many aspects of the wind turbine construction and installation.

In light of the assessment of the contextual factors in addition to the quality of evidence, the recommendation for wind turbine noise exposure remains conditional.

Additional considerations or uncertainties

Assessment of population exposure to noise from a particular source is essential for setting health-based guideline values. Wind turbine noise is characterized by a variety of potential moderators, which can be challenging to assess and have not necessarily been addressed in detail in health studies. As a result, there are serious issues with noise exposure assessment related to wind turbines.

Noise levels from outdoor sources are generally lower indoors because of noise attenuation from the building structure, closing of windows and similar. Nevertheless, noise exposure is generally estimated outside, at the most exposed façade. As levels of wind turbine noise are generally much lower than those of transportation noise, the audibility of wind turbines in bedrooms, particularly when windows are closed, is unknown.

In many instances, the distance from a wind farm has been used as a proxy to determine audible noise exposure. However, in addition to the distance, other variables – such as type, size and number of wind turbines, wind direction and speed, location of the residence up- or downwind from wind farms and so on – can contribute to the resulting noise level assessed at a residence. Thus, using distance to a wind farm as a proxy for noise from wind turbines in health studies is associated with high uncertainty.

Wind turbines can generate infrasound or lower frequencies of sound than traffic sources. However, few studies relating exposure to such noise from wind turbines to health effects are available. It is also unknown whether lower frequencies of sound generated outdoors are audible indoors, particularly when windows are closed.

The noise emitted from wind turbines has other characteristics, including the repetitive nature of the sound of the rotating blades and atmospheric influence leading to a variability of amplitude modulation, which can be a source of above average annoyance (Schäffer et al., 2016). This differentiates it from noise from other sources and has not always been properly characterized. Standard methods of measuring sound, most commonly including A-weighting, may not capture the low-frequency sound and amplitude modulation characteristic of wind turbine noise (Council of Canadian Academies, 2015).

Even though correlations between noise indicators tend to be high (especially between L_{Aeq}-like indicators) and conversions between indicators do not normally influence the correlations between the noise indicator and a particular health effect, important assumptions remain when exposure to wind turbine noise in L_{den} is converted from original sound pressure level values. The conversion requires, as variable, the statistical distribution of annual wind speed at a particular height, which depends on the type of wind turbine and meteorological conditions at a particular geographical location. Such input variables may not be directly applicable for use in other sites. They are sometimes used without specific validation for a particular area, however, because of practical limitations or lack of data and resources. This can lead to increased uncertainty in the assessment of the relationship between wind turbine noise exposure and health outcomes.

Based on all these factors, it may be concluded that the acoustical description of wind turbine noise by means of L_{den} or L_{night} may be a poor characterization of wind turbine noise and may limit the ability to observe associations between wind turbine noise and health outcomes.

3.4.3 Summary of the assessment of the strength of recommendations

Table 42 provides a comprehensive summary of the different dimensions for the assessment of the strength of the wind turbine recommendations.

Table 42. Summary of the assessment of the strength of the recommendation

Factors influencing the strength of recommendation	Decision
Quality of evidence	**Average exposure (L_{den})** *Health effects* • Evidence for a relevant absolute risk of annoyance at **45 dB L_{den}** was rated **low quality.** *Interventions* • No evidence was available on the effectiveness of interventions to reduce noise exposure and/or health outcomes from wind turbines. **Night-time exposure (L_{night})** *Health effects* • No statistically significant evidence was available for sleep disturbance related to exposure from wind turbine noise at night. *Interventions* • No evidence was available on the effectiveness of interventions to reduce noise exposure and/or sleep disturbance from wind turbines.
Balance of benefits versus harms and burdens	Further work is required to assess fully the benefits and harms of exposure to environmental noise from wind turbines and to clarify whether the potential benefits associated with reducing exposure to environmental noise for individuals living in the vicinity of wind turbines outweigh the impact on the development of renewable energy policies in the WHO European Region.
Values and preferences	There is wide variability in the values and preferences of the population, with particularly strong negative attitudes in populations living in the vicinity of wind turbines.
Resource implications	Information on existing interventions (and associated costs) to reduce harms from wind turbine noise is not available.
Additional considerations or uncertainties	There are serious issues with noise exposure assessment related to wind turbines.
Decisions on recommendation strength	• **Conditional** for guideline value for average noise exposure (L_{den}) • **Conditional** for the effectiveness of interventions (L_{night})

3.5 Leisure noise

Recommendations

For average noise exposure, the GDG **conditionally** recommends reducing the yearly average from all leisure noise sources combined to **70 dB** $L_{Aeq,24h}$, as leisure noise above this level is associated with adverse health effects. The equal energy principle[19] can be used to derive exposure limits for other time averages, which might be more practical in regulatory processes.

For single-event and impulse noise exposures, the GDG **conditionally** recommends following existing guidelines and legal regulations to limit the risk of increases in hearing impairment from leisure noise in both children and adults.

Following a precautionary approach, to reduce possible health effects, the GDG **strongly** recommends that policy-makers take action to prevent exposure above the guideline values for average noise and single-event and impulse noise exposures. This is particularly relevant as a large number of people may be exposed to and at risk of hearing impairment through the use of personal listening devices (PLDs). There is insufficient evidence, however, to recommend one type of intervention over another.

3.5.1 Rationale for the guideline levels for leisure noise

As specific evidence for the relationship between leisure noise and hearing loss is of insufficient quality, the GDG decided to follow a different approach for this noise source, based on knowledge regarding prevention of hearing loss in the workplace and on the CNG (WHO, 1999). There is sufficient evidence that the nature of the noise matters little in causing hearing loss, so using the existing guidelines is a justified step to prevent permanent hearing loss from leisure noise.

In accordance with the procedures for the other noise sources, the GDG would have considered evidence on exposure–response relationships for the prioritized health outcomes. However, no such ERFs could be established in the systematic reviews for any of the health outcomes (Table 43).

Table 43. Average exposure levels ($L_{Aeq,24h}$) for priority health outcomes from leisure noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Incidence of IHD **Incidence of hypertension** **Prevalence of highly annoyed population** **Reading skills and oral comprehension in children**		No evidence was available
Permanent hearing impairment There is an indication that PLDs have an effect on hearing impairment and tinnitus. There was no evidence (because no studies were found) for an effect of other sources of leisure noise on hearing impairment or tinnitus. The results of the studies could not be synthesized because of heterogeneity of outcome measurement.	No increase	Very low quality/no evidence

[19] The equal energy principle states that the total effect of sound is proportional to the total amount of sound energy received by the ear, irrespective of the distribution of that energy in time (WHO, 1999).

In accordance with the evidence on the effects of PLDs on permanent hearing loss from leisure noise, the GDG recommended a guideline exposure level of 70 dB $L_{Aeq,24h}$ yearly average from all leisure noise sources combined. It was confident that there was no relevant risk increase for permanent hearing impairment below this exposure level of average leisure noise. The GDG recognized that a conversion to alternative time averages for exposure to leisure noise might be helpful for regulatory purposes; thus, a detailed table converting hourly and weekly exposure into yearly averages is provided in the subsection on additional considerations or uncertainties in section 3.5.2.3, Table 49. Furthermore, the GDG recommended sticking to the CNG recommendations for single events to limit the risk of hearing impairment from leisure noise increases for both children and adults (WHO, 1999).[20] Due to the nature and limited amount of available evidence, the GDG made the recommendation conditional.

Next, the GDG assessed the evidence for night noise exposure and its effect on sleep disturbance (Table 44).

Table 44. Night-time exposure levels (L_{night}) for priority health outcomes from leisure noise

Summary of priority health outcome evidence	Benchmark level	Evidence quality
Sleep disturbance	3% absolute risk	No evidence was available

Because of a lack of evidence, the GDG was not able to formulate a recommendation addressing sleep disturbance due to leisure noise at night time.

The GDG also looked for evidence about the effectiveness of interventions for leisure noise exposure. Owing to a lack of research, however, no studies were available on existing interventions and associated costs to reduce leisure noise. As no evidence was available, it was not possible to develop a recommendation on any specific type of intervention measure. However, following a precautionary approach, to reduce possible health effects, the GDG made a strong recommendation that policy-makers take action to prevent exposures above the guideline values for average noise and single-event and impulse noise exposures. This is particularly relevant as a large number of people may be exposed to and at risk of hearing impairment through the use of PLDs. There is insufficient evidence, however, to recommend one type of intervention over another.

3.5. 1.1 Other factors influencing the strength of recommendations

Other factors considered in the context of recommendations on leisure noise included those related to values and preferences, benefits and harms, resource implications, equity, acceptability and feasibility; moreover, nonpriority health outcomes were considered. Ultimately, the assessment of all these factors did not lead to a change in the strength of recommendation. Further details are provided in section 3.5.2.3.

[20] The GDG acknowledged the scarcity of cohort study-based evidence to define a threshold for hearing damage due to single loud exposures. It initially decided to propose $L_{AF,max}$ = 110, but after much discussion it appeared that the conversion of relevant standing limits (expressed in $L_{peak,C}$ and others) lacked sufficient basis.

3.5.2 Detailed overview of the evidence

The following sections provide a detailed overview of the evidence constituting the basis for setting the recommendations on leisure noise. As noted above, however, only limited evidence was available for several of the prioritized health outcomes, so it is presented and summarized for all critical and important health outcomes where possible, along with indications of the GDG's judgement of the quality of evidence. Research into health outcomes and effectiveness of interventions is addressed consecutively.

A comprehensive summary of all evidence considered for each of the critical and important health outcomes can be found in the eight systematic reviews published in the *International Journal of Environmental Research and Public Health* (see section 2.3.2 and Annex 2).

3.5.2.1 Evidence on health outcomes

The key question posed was: in the general population exposed to leisure noise, what is the exposure–response relationship between exposure to leisure noise (reported as various noise indicators) and the proportion of people with a validated measure of health outcome, when adjusted for main confounders? A summary of the PICOS/PECCOS scheme applied and the main findings is set out in Tables 45 and 46.

Table 45. PICOS/PECCOS scheme of critical health outcomes for exposure to leisure noise

PECO	Description	
Population	General population	
Exposure	Exposure to high levels of noise produced by leisure activities (average/night time)	
Comparison	Exposure to lower levels of noise produced by leisure activities (average/night time)	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

Table 46. Summary of findings for health effects from exposure to leisure noise ($L_{Aeq,24h}$)

Noise metric	Priority health outcome measure	Quantitative risk for adverse health	Lowest level of exposure across studies[a]	Number of participants (studies)	Quality of evidence
Cardiovascular disease					
$L_{Aeq,24}$	Incidence of IHD	–	–	–	–
$L_{Aeq,24}$	Incidence of hypertension	–	–	–	–
Annoyance					
$L_{Aeq,24}$	%HA	–	–	–	–
Cognitive impairment					
$L_{Aeq,24}$	Reading and oral comprehension	–	–	–	–
Hearing impairment and tinnitus					
$L_{Aeq,24}$	Permanent hearing impairment	Not estimated	–	484 (3)	Very low (downgraded for study limitations, precision)

Hearing impairment and tinnitus

Several types of leisure activity are accompanied by loud sounds, such as attending nightclubs, pubs and fitness classes; live sporting events; concerts or live music venues; listening to loud music through PLDs. This recommendation is informed by a systematic review that assessed the evidence on permanent hearing loss and tinnitus due to exposure to leisure noise (Śliwińska-Kowalska & Zaborowski, 2017). The review identified two existing systematic reviews that summarized recent estimates of the risk of developing permanent hearing loss from the use of PLDs. It did not identify any studies with objective measurement of exposure to any other type of leisure noise.

The Scientific Committee on Emerging and Newly Identified Hazards and Risk (SCENIHR) (EC, 2008b) report concluded that prolonged exposure to sounds from PLDs may result in temporary hearing threshold shift, permanent hearing threshold shift and tinnitus, as well as poor speech communication in noisy conditions. However, based on the data available, there was no direct evidence for an effect of repeated, regular daily exposure to music through PLDs on development of permanent noise-induced hearing loss. Data on tinnitus were inadequate and therefore inconclusive. No meta-analysis was provided for any of the hearing effects; nor were the exposure–effect curves reported. The SCENIHR report was based on a narrative review of 30 original papers with over 2000 participants and exposure to music sounds that covered a range of 60–120 dB. Studies included in the review were carried out between 1982 and 2007.

In 2014 a second systematic review was published by Vasconcellos et al. (2014). Although the objective of this publication was to determine threshold levels of personally modifiable risk factors for hearing loss in the paediatric population, specific thresholds analyses were limited. Based on the descriptive overview of original papers, the authors identified exposure to loud music (including use of PLDs) and working on a mechanized farm as the main risk factors for hearing loss in children and teenagers. Thresholds of exposure to music, significantly associated with hearing loss in youth, were:

- more than four hours per week or more than five years of personal headphone usage;
- more than four visits per month to a discotheque.

The evidence review identified five new cross-sectional studies on noise from PLDs since the publication of the SCENIHR report (Feder et al., 2013; Levesque et al., 2010; Sulaiman et al., 2013; 2014; Vogel et al., 2014). Direct measurement of hearing thresholds with pure tone audiometry was performed only in three studies – by Feder et al. (2013) and Sulaiman et al. (2013 and 2014). In total, audiometric data from 484 subjects were analysed; among them, 449 were exposed and 35 were not exposed to PLD music. Two other studies by Levesque et al. (2010) and Vogel et al. (2014) did not perform audiometric measurement but reported on tinnitus in a total of 1067 participants.

Noise from PLDs was estimated based on direct measurement of equivalent sound pressure levels (in dB) in four studies (Feder, 2013; Levesque et al., 2010; Sulaiman et al., 2013; 2014) and based on converting volume-control setting levels of PLD into dB levels in one study (Vogel et al., 2014). The resulting exposure levels (L_{Aeq} values) had a mean of between 72 dB and 91 dB, although in two studies these data were not provided. In all studies, individual $L_{Aeq,8h}$ value was calculated based on an estimated level of music and the number of hours a day listening to the music through the PLD declared by an individual in the questionnaire. Resulting $L_{Aeq,8h}$ mean values were between 62 dB and 83 dB when provided.

Potential confounding was controlled by excluding the subjects with exposure to other sources of high-level noise or prior ear problems (Sulaiman et al., 2013), by excluding those with these factors and ototoxic drug intake (Sulaiman et al., 2014) or by controlling for these confounders by accounting for them in the statistical models. The confounders comprised socioeconomic status, demographic factors, tubes in the ear and leisure exposures in one study (Feder, 2013), and age and sex in one study (Vogel et al., 2014). One of the studies did not adjust for confounding factors (Levesque et al., 2010).

Data on permanent hearing loss were taken from audiometric measurements (Feder, 2013; Sulaiman et al., 2013; 2014), while data about permanent tinnitus were taken from self-reported responses to questionnaires (Levesque et al., 2010; Vogel et al., 2014). In one case, the outcome was defined as "permanent hearing-related symptoms", but it is not clear what proportion of subjects experienced permanent tinnitus (Vogel et al., 2014).

For permanent hearing loss, there is no pooled effect size, because the authors of the original studies either did not report data or reported in different formats. However, these studies indicate a harmful effect of listening to PLDs. For permanent tinnitus, there is no pooled effect size because the effects of noise from PLDs on permanent tinnitus were contradictory. These results are generally consistent with previous reviews by SCENIHR (EC, 2008b) and Vasconcellos et al. (2014).

The risk of bias was assessed as high for all five studies. The overall evidence for an effect of PLDs on hearing impairment and tinnitus was rated very low quality.

3.5.2.2 Evidence on interventions

The following section summarizes the evidence underlying the recommendation on the effectiveness of interventions for leisure noise exposure. The key question posed was: in the general population exposed to leisure noise, are interventions effective in reducing exposure to and/or health outcomes from leisure noise? A summary of the PICOS/PECCOS scheme applied and the main findings is set out in Tables 47 and 48.

Table 47. PICOS/PECCOS scheme of the effectiveness of interventions for exposure to leisure noise

PICO	Description	
Population	General population	
Intervention(s)	The interventions can be defined as: (a) a measure that aims to change noise exposure and associated health effects; (b) a measure that aims to change noise exposure, with no particular evaluation of the impact on health; or (c) a measure designed to reduce health effects, but that may not include a reduction in noise exposure.	
Comparison	No intervention	
Outcome(s)	For average noise exposure: 1. cardiovascular disease 2. annoyance 3. cognitive impairment 4. hearing impairment and tinnitus 5. adverse birth outcomes 6. quality of life, well-being and mental health 7. metabolic outcomes	For night noise exposure: 1. effects on sleep

Table 48. Summary of findings for interventions for leisure noise

Type of intervention	Number of participants (studies)	Effect of intervention	Quality of evidence
Hearing impairment			
Type E – behaviour change interventions (education programme/campaign)	4151 (7)	None of the studies involved measurement or estimation of exposure levels or health outcomes. Most studies found a significant effect of change in knowledge or behaviour.	–

Seven individual studies on PLDs, attendance at music venues and participation in other recreational activities where there was risk of hearing damage and/or tinnitus were included in the systematic review (Dell & Holmes, 2012; Gilles & Van de Heyning, 2014; Kotowski et al., 2011; Martin et al., 2013; Taljaard et al., 2013; Weichbold & Zorowka, 2003; 2007). All studies examined interventions directed at changes in knowledge or behaviour and hearing impairment.

The studies all sought evidence on the effectiveness of some form of educational programme or campaign aimed at children, adolescents or college students. These addressed perceptions and knowledge of the risk of high levels of noise – generally, but not exclusively, from PLD sources or from attendance at music events – and actual or intended changes to hearing damage risk behaviours, including avoidance, frequency or duration of exposure, regeneration periods when in high noise, or playback levels.

The outcome assessed in all intervention studies was the change in knowledge and behaviours towards hearing damage risk. The health outcome measures varied widely and included measurements on the youth attitude towards noise scale, participants' knowledge about hearing damage, participants' PLD usage patterns, participants' attitudes to wearing hearing protection (some in general; some at discotheques) and frequency of discotheque attendance. A majority of the studies found a significant effect of change in knowledge or behaviour. No indication on the persistence of knowledge and behavioural change was given, though.

None of the studies included objectively measured outcomes or a measured change in noise level exposure; thus, the effectiveness of the interventions could not be assessed, and the quality of the evidence was not rated according to GRADE.

3.5.2.3 Consideration of additional contextual factors

Based on the quality of the available evidence discussed in the foregoing overview, the GDG set the strength of recommendation of leisure noise to conditional. As a second step, it qualitatively assessed contextual factors to explore whether other considerations could have a relevant impact on the recommendation strength. These considerations mainly concerned the balance of harms and benefits, values and preferences, and resource use and implementation.

When assessing the balance of benefits and harms, the GDG recognized that exposure to leisure noise is widespread and frequent. In particular, as many as 88–90% of teenagers and young adults report listening to music through PLDs earphones (Pellegrino et al., 2013; Vogel et al., 2011). In 2015 WHO estimated that 1.1 billion young people worldwide could be at risk of hearing loss due to unsafe listening practices (WHO, 2015a). Furthermore, among young people aged 12–35 years in middle- and high-income countries, nearly 50% listen to unsafe levels of sound through personal audio devices (mp3 players, smartphones and others), and around 40% are exposed to potentially damaging levels of sound at nightclubs, bars and sporting events. Noise-induced hearing loss can be prevented by following safe listening practices, so the GDG concluded that health benefits can be gained from markedly reducing population exposure to leisure noise, including through actions to promote safe listening practices. A reduction of leisure noise is also assumed to reduce nuisance that can be caused to other people than those who enjoy leisure activities, such as neighbours. Furthermore, specifically for PLDs, it can reasonably be expected that a reduction of noise exposure could also lead to a reduction in accidents, injuries and other potential safety risks. In relation to possible harms and burdens, the GDG could not identify any harms (except economic costs, which are addressed in the paragraph on resource use and implementation) arising from implementation of the recommended guideline values.

Considering values and preferences, the GDG recognized that listening to music with the help of a PLD, going to concerts and attending sport events are activities regarded as enjoyable and therefore assumed to be valued by the overall population. Furthermore, it is expected that values and preferences might vary in particular with respect to the use of PLDs and embracing leisure activities involving loud noise, like concerts, and that some population groups – especially younger individuals – might voluntarily expose themselves to high levels of sound during these activities. Despite this, the GDG was confident that recommendations to lower noise levels for the prevention of hearing damage from leisure noise would be welcome by a majority of the population. Recommendations are expected to be particularly welcome when it comes to protecting the hearing of young children and teenagers, as these vulnerable groups often do not have control over their environment and the noise levels to which they are exposed, such as from noisy toys or at school.

With resource use and implementation, the GDG noted that interventions exist to reduce exposure to leisure noise from PLDs, attendance at music venues and participation in recreational activities, as aggregated by the systematic review on environmental noise interventions and their associated impacts (Brown & van Kamp, 2017). As most of these relate to implementation of a behaviour change, the reduction of exposure to leisure noise is expected to be technically feasible and cheap. None of the empirical investigations objectively measured outcomes or a measured change in noise level exposure, so the effectiveness of such measures cannot be assessed. Nevertheless, it is important to note that there is ample evidence from the occupational health field that high noise levels cause hearing damage, and that occupational interventions to reduce noise exposure are effective at lowering the risk of hearing problems or hearing damage (EC, 2003; Garcia et al., 2018; ISO, 2013; Maassen et al., 2001). In conclusion, resources needed to reduce exposure to leisure noise are not expected to be intensive, but implementation and long-term success of measures might be challenging, owing to cultural factors, as changes in behaviour are expected to be tricky to implement.

In light of the assessment of the contextual factors in addition to the quality of evidence, the recommendation remains conditional.

Additional considerations or uncertainties

The GDG considers the noise levels selected for this recommendation to be reasonable precautionary measures, in view of the rating of very low quality for the available evidence on an effect of leisure noise on permanent hearing impairment and tinnitus identified in the systematic review.

Extensive literature shows hearing impairment in populations exposed to specific types of nonoccupational environments, although these exposures are generally not well characterized. There are no studies with objective measurement of exposure to any other type of leisure noise (except PLDs) and permanent hearing impairment or tinnitus. Nevertheless, this recommendation generally applies to all leisure noise exposures, such as events in public venues (concerts halls, sports events, bars and discotheques) and educational facilities, and use of PLDs. The recommendation also applies to exposure to impulse sounds, such as those in shooting facilities or from the use of toys and firecrackers.

Hearing loss is the resultant value of combined exposures to different sources of leisure noise including, but not limited to, PLDs. Therefore, the recommendations apply to the combined noise levels from all sources.

Noise-induced hearing loss develops very slowly over years of exposure, giving rise to challenges in the assessment of the health impacts from prolonged use of PLDs and exposure to leisure noise. The induction period for the development of hearing impairment and tinnitus is long, and varying exposure conditions and changing lifestyle habits (including confounding noise sources), particularly among young people, will have an impact. Therefore, recommendations regarding leisure noise have often been inferred from the occupational field, where exposure conditions are more stable over time.

Indeed, long-term exposure to noise, objectively assessed and at levels measured in occupational settings for various professions, can lead to permanent hearing loss and tinnitus. This evidence, while not reviewed systematically as part of the work related to these guidelines, can be used as supportive evidence and justification for the need to develop a recommendation for leisure noise, given that many people could be at risk of developing hearing loss and/or tinnitus from exposure to lower levels of environmental noise. Similar otobiological mechanisms must also be considered for environmental noise.

To date, no commonly accepted method for assessing the risk of hearing loss due to environmental exposure to noise has been developed. One of the main challenges is to conduct a long-term objective exposure assessment of environmental noise and relate this to the development of permanent hearing impairment and tinnitus. The GDG underlined the strong need for research to develop a comprehensive methodology. In the absence of a method, and as long as no other tools are available, the equal energy principle outlined in the ISO standard for the estimation of noise-induced hearing loss (WHO, 1999) can be used as a practical tool for protecting public health from exposure to leisure noise. As a result, the relationship between leisure noise exposure and auditory effects can be quantified for a variety of exposure levels, duration and frequency.

Several organizations have established regulations for the protection of workers from risks to their health and safety arising from exposure to noise, and in particular risk to hearing. Of particular relevance is EU Directive 2003/10/EC on the minimum health and safety requirements regarding the exposure of workers to the risks arising from physical agents (noise) (EC, 2003). Based on the ISO 1999 standard (ISO, 2013), the Directive sets limits of exposure depending on equivalent noise level for an eight-hour working day and obliges the employer to take suitable steps if the limits are exceeded. It recommends three action levels for occupational settings, setting the lowest, most conservative value at $L_{ex,8hr}$ = 80 dB. According to the Directive, no consequences of exposure to occupational noise are expected at this level. While exposure patterns and certain characteristics of occupational and leisure noise exist, knowledge of the hearing impairment risks and preventive interventions can be used to assess health risks associated with leisure noise (Neitzel & Fligor, 2017).

The CNG recommend a limit of $L_{Aeq,24h}$ = 70 dB(A) for preventing hearing loss from industrial, commercial shopping and traffic areas, indoors and outdoors (WHO, 1999). Health and safety regulations are usually based on an exposure profile of a typical worker (eight hours per day, five days per week). Using the existing knowledge from the ISO standard and established health and safety regulations, it is possible to use the equal energy principle to derive the resulting noise exposure level for an exposure profile more appropriately suited for leisure noise. Converting 40 hours at 80 dB to a continuous exposure to noise (24 hours per day, seven days per week), this leads to a yearly average exposure of 71 dB for lifelong exposure.[21] This is the same value as the WHO recommendation of

[21] 71 dB = 80 dB (derived from ISO standard) – 6.2 dB (conversion of yearly average of 40 working hours divided by continuous exposure to noise: (10 log (2080hrs/8760 hrs)) – 3 dB (extrapolation of 40 working years to lifelong exposure).

70 dB (WHO, 1999). Table 49 presents the noise levels per hour for various time averages in order to keep within the recommended yearly average exposure, and assuming that exposure to other noise sources generally does not contribute significantly. For example, for specific events taking place for one-, two- or four-hour averages, once a week (such as visiting a discotheque or watching a loud movie), an hourly noise level of 85 dB would lead to an average yearly exposure of 63 dB, 66 dB and 69 dB, respectively. However, the same hourly exposure of 85 dB for an activity taking place for 14 hours per week (two hours per day, seven days a week) would lead to a yearly exposure of 74 dB, which exceeds the recommendations.

Table 49. Combination of hourly exposure and number of hours per week to arrive at a yearly average L_{Aeq}

Hours of exposure per week	One-hour exposure level (L_{Aeq})						
	70	75	80	85	90	95	100
1	48	53	58	63	68	73	78
2	51	56	61	66	71	76	81
4	54	59	64	69	74	79	84
14 (2 hours per day, 7 days per week)	59	64	69	74	79	84	89
28 (4 hours per day, 7 days per week)	62	67	72	77	82	87	92
40 (8 hours per day, 5 days per week)	64	69	74	79	84	89	94
168 (24 hours per day, 7 days per week)	70	75	80	85	90	95	100

Note: green = combinations of exposure/duration below current guideline level; red = combinations of exposure/duration above current guideline level; blue = input parameters.

The equal energy principle cannot be used to derive single-event limits because at high levels the ear starts to respond with nonlinear behaviour. The CNG provides several values, in different units: $L_{AF,max}$ = 110 dB for industrial noises (no distance stated), $L_{peak,lin}$ = 140 dB for adults and $L_{peak,lin}$ = 120 dB for children (measured at 100 mm) (WHO, 1999). EU Directive 2003/10/EC on the minimum health and safety requirements regarding the exposure of workers recommends a lower action level of $L_{peak,C}$ = 135 dB (at 100 mm). In a recent overview Hohmann (2015) provided an ERF for hearing damage caused by shooting noise, from which it appears that a safe level of L_E = 120 dB can be derived.

Although it is clear that high noise levels cause acute hearing damage, there is no agreement on a safe level. Further research is highly recommended. In the mean time, existing guidelines should be applied.

3.5.3 Summary of the assessment of the strength of recommendation

Table 50 provides a comprehensive summary of the different dimensions for the assessment of the strength of the leisure noise recommendations.

Table 50. Summary of the assessment of the strength of the recommendation

Factors influencing the strength of recommendation	Decision
Quality of evidence	**Average exposure ($L_{Aeq,24h}$)** *Health effects* • Evidence of an effect from PLDs on hearing impairment and tinnitus, in the absence of evidence for other health outcomes and absence of evidence on hearing impairment and tinnitus from other types of leisure noise besides PLDs, was rated **very low quality.** *Interventions* • No evidence was available on the effectiveness of interventions to reduce noise exposure and/or health outcomes from leisure noise.
Balance of benefits versus harms and burdens	The general benefit from reduction of leisure noise outweighs any potential harms.
Values and preferences	There is variability in the values and preferences of the general population.
Resource implications	The resources needed to reduce exposure to leisure noise are not expected to be intensive, but implementation and the long-term success of measures may be challenging, mainly due to cultural factors.
Decision on strength of recommendation	• **Conditional** for guideline level for average noise exposure ($L_{Aeq,24h}$) • **Conditional** for single-event and impulse noise • **Strong** for interventions to reduce noise exposure

3.6 Interim targets

An interim target was proposed in the NNG (WHO Regional Office for Europe, 2009), "recommended in situations where the achievement of NNG is not feasible in the short run for various reasons". The NNG emphasized that an interim target is "not a health-based limit value by itself. Vulnerable groups cannot be protected at this level".

The GDG discussed whether to propose interim targets as part of the current guidelines, and if so, what process would be needed to derive those values. The current recommendations are health-based and already provide guideline values per noise source (for both L_{den} and L_{night}). They also include information on exposure–response relationships for various health outcomes, which can be used by policy-makers or other stakeholders to inform the selection of different values, if needed. Further, interim targets may work differently in different countries and for different noise sources, and it may not be optimal to propose them Europe-wide. As a result, there was consensus among members of the GDG not to provide interim targets.

4. Implications for research

The development of these environmental noise guidelines for the WHO European Region has made evident some key knowledge gaps and research needs. The main ones specific to the guideline recommendations are presented as implications for research in the sections that follow.

4.1 Implications for research on health impacts from transportation noise

For the assessment of health effects from the main sources of transportation noise (road traffic, railways and aircraft), the various evidence reviews show the following knowledge gap: there is a need for longitudinal studies on the health impacts from exposure to environmental noise, to inform future recommendations properly (Table 51).

Table 51. Implications for research on health impacts from transportation noise (air, rail, road)

Current state of the evidence	Limited evidence is available on health impacts from transportation noise from large-scale cohort and case-control studies, with objective measurement of both noise exposure and health outcomes.
Population of interest	Research is needed into effects of exposure on children and adults exposed to environmental noise from transportation sources.
Exposure of interest	Objective measurement or calculation of transportation noise exposure is required; in particular, from studies of health effects related to combined exposure to different noise sources.
Comparison of interest	The data should be compared to the effects of lower levels of transportation noise.
Outcomes of interest	Measures of the following health outcomes is required, assessed objectively and harmonized where possible – for example, according to common protocols: • annoyance • effects on sleep • cardiovascular and metabolic effects • adverse birth outcomes • cognitive impairment • mental health, quality of life and well-being • hearing impairment and tinnitus • any other relevant health outcome.
Time stamp	The systematic review included studies between October 2014 and December 2016.

4.1.1 Specific implications for annoyance

To predict absolute %HA at the full range of levels (and the corresponding CIs), an integrated analysis of the original raw data from all of individual studies would be necessary. The evidence review conducted as part of the guidelines focused only on secondary data handling and therefore does not replace a full meta-analysis of all individual data. The development of a generic exposure–response relationship (from a full meta-analysis based on all individual data) is suggested as a priority research recommendation (see Table 52).

Table 52. Recommendation for research addressing the exposure–response relationship

Current state of the evidence	The evidence review on annoyance conducted as part of the guidelines does not provide a generalized ERF but points to significant differences compared to the curves used in the past. It shows that the available generalized ERFs are in need of adjustment, preferably as a result of undertaking a full meta-analysis. This is especially the case for the sources aircraft and railway noise, which new data show are more annoying than previously documented.
Population of interest	Research is needed into effects of exposure on children and adults exposed to air, rail and/or road traffic noise.
Exposure of interest	Objective measurement of transportation noise exposure is required.
Comparison of interest	The data should be compared to the effects of lower levels of transportation noise.
Outcomes of interest	Measures of health outcomes are required, assessed objectively according to common protocols (such as the International Commission on Biological Effects of Noise (ICBEN) scale for annoyance).
Time stamp	The systematic review included studies up to October 2014.

4.2 Implications for research on health impacts from wind turbine noise

Further research into the health impacts from wind turbine noise is needed so that better-quality evidence can inform any future public health recommendations properly. For the assessment of health effects from wind turbines, the evidence was either unavailable or rated low/very low quality. Recommendations for research addressing this priority are proposed in Table 53.

Table 53. Implications for research on health impacts from wind turbine noise

Current state of the evidence	The current evidence on health outcomes related to wind turbine noise is unavailable or of low/very low quality and mainly comes from cross-sectional studies. Methodologically robust longitudinal studies with large samples investigating the quantitative relationship between noise from wind turbines and health effects are needed.
Population of interest	Research is needed into effects of exposure on children and adults exposed and living near sources of wind turbine noise. Studies should assess subgroup differences in effects for vulnerable groups such as children, elderly people and those with existing poor physical and mental health.
Exposure of interest	Exposure to noise at a wide range of levels and frequencies (including low-frequency noise), with information on noise levels measured outdoors and indoors (particularly relevant for effects on sleep) at the residence is needed. The noise exposure should be measured objectively and common protocols for exposure to wind turbine noise should be established, considering a variety of noise characteristics specific to wind turbine noise.
Comparison of interest	The data should be compared to the effects in similar areas without wind turbines. Pre/post studies of new wind turbine installations are needed, especially if “before measures” unbiased by the stress and knowledge of potential wind turbine farm development need to be developed.
Outcomes of interest	Measures of health outcomes are required, assessed objectively – for example, according to common protocols (ICBEN scale for annoyance and self-reported sleep disturbance). The studies should include the most important situational and personal confounding variables, such as negative attitudes towards wind turbines, visual impact, economic gain and other socioeconomic factors.
Time stamp	The systematic review included studies between October 2014 (review on annoyance) and December 2016 (review on cardiovascular disease).

Alongside the defined needs for research on wind turbine noise it should be noted that research regarding industrial noise in general is required. More specifically, there is a need to investigate stationary sources (including heat, ventilation and acclimatization devices) and their impacts on health. Studies on hearing disorders from impulse and/or intermittent sounds are also needed; these would enable assessment of adverse effects created by one or several sounds of short duration with a high maximum sound level or impulse sound level.

4.3 Implications for research on health impacts from leisure noise

For the assessment of effects from leisure noise, the evidence to make a recommendation on the ERF to use for health risk assessment, or of a threshold for effects, was either unavailable or rated very low quality. This is a research gap: longitudinal studies with longer follow-up are needed; these should measure noise objectively, not only from PLDs but also from other types of leisure noise.

There is uncertainty in the measurement of early hearing disorders among young people using the tonal audiometry commonly applied. Precise methods to identify early hearing impairment and other hearing disorders are needed. Owing to long induction periods, however, adequate research may be difficult to perform, particularly among young people who change their exposure in terms of sound level and frequency as they age (for example, changing their music listening habits and venue visits). As a result, the recommendations refer to the results derived from stationary noise sources in the occupational field, in conjunction with the equal energy principle (see Table 54).

Table 54. Implications for research on health impacts from leisure noise

Current state of the evidence	Currently, no evidence is available on hearing impairment and tinnitus from large-scale cohort and case-control studies, with objective measurement of noise exposure and using a suitable method to assess hearing impairment in young people.
Population of interest	Research is needed into effects of exposure on children and adults exposed to environmental noise from different sources and in different settings.
Exposure of interest	Objective measurement of leisure noise exposure is required.
Comparison of interest	The data should be compared to the effects of no leisure noise exposure from these sources.
Outcomes of interest	The primary outcomes identified are: • hearing loss measured by audiometry; • specific threshold analyses focused on stratifying the risk of permanent hearing loss according to clearly defined levels of exposure to leisure noise, such as music through PLDs; • concise methods to identify early hearing impairment and other hearing disorders; • temporary threshold shift after exposure to leisure noise, as it may be reasonably predictive of future permanent threshold shift; • age-related hearing loss progression depending on early-age exposure to leisure noise, such as to loud music; and • tinnitus, measured objectively and subjectively.
Time stamp	The systematic review included studies up to June 2015.

4.4 Implications for research on effectiveness of interventions to reduce exposure and/or improve public health

The quality of the evidence on the effectiveness of interventions to reduce exposure to and health outcomes from environmental noise was variable. Further studies directly linking noise interventions to health outcomes are required, particularly for sources other than road traffic noise, and for human health outcomes other than annoyance.

Most studies involved road traffic noise (63%), followed by aircraft noise (13%) and railway noise (6%). The remaining interventions were for leisure noise (13%) and noise in hospital settings (4%). No interventions were identified that either addressed wind turbine noise or focused on educational settings.

Exposure-related interventions were mainly associated with a reduction in environmental noise exposure. However, in five studies (four road traffic noise studies and one aircraft noise study) some or all of the participants experienced noise exposure increases.

There is no clear evidence with respect to thresholds, which are defined as:

- the smallest change in exposure levels that results in a change in outcome; and
- the minimum before-level, regarding changes in health outcomes as a result of interventions.

The limited evidence base on the health effects of environmental noise interventions is thinly spread across different noise source types, outcomes and intervention types. Diversity exists between studies even within intervention types in terms of study designs, methods of analysis, exposure levels and changes in exposure experienced as a result of the interventions. For these reasons, carrying out a meta-analysis across studies examining the association between changes in level and changes in outcome was not possible.

To remedy this main research gap, longitudinal studies assessing noise exposure and health outcomes objectively should be developed, taking into account the most relevant confounders. The establishment of common protocols for future research is warranted (see Table 55).

Authorities should include significant funding for the design and implementation of studies to evaluate the effectiveness of interventions to reduce noise and their impact on health.

Table 55. Implications for research on effectiveness of interventions to reduce exposure and/or improve public health

Current state of the evidence	The current evidence on effectiveness of interventions to reduce health outcomes is limited and of varying quality. Few longitudinal studies have been done that take into account the most relevant confounders and measure the noise exposure and the outcomes objectively.
Population of interest	Research is needed into effects of interventions on defined populations exposed to and/or living near sources of environmental noise.
Intervention of interest	Research into any noise intervention at various points along the system pathway between source and outcome, for a variety of noise sources, is required.
Comparison of interest	The data should be compared to: • a steady-state control group, in similar areas with various exposure gradients from environmental noise sources; • the noise exposure in the same population, through a series of sequential measurements assessing the change before and after the intervention, preferably with multiple after measurements.
Outcomes of interest	Future intervention studies should use validated and, where possible, harmonized measures of exposure and outcome, as well as of moderators and confounders. The studies should use measures of exposure including noise exposure at a wide range of levels and frequencies (including low-frequency noise), with information on noise levels outdoors and indoors (particularly relevant for effects on sleep). They should also use measures of health outcomes, including the following outcomes assessed objectively – for example, according to common protocols (ICBEN scale for annoyance) – with consideration that the change in human response for some health outcomes from a step change in exposure may have a different time course to that of the change in exposure: • annoyance • effects on sleep • cardiovascular and metabolic diseases • adverse birth outcomes • cognitive impairment • mental health, quality of life and well-being • hearing impairment and tinnitus • any other relevant health outcome. Further, they should use measures of moderators and confounders, including repeated measurements of situational and personal variables such as activity interference, potential confounders such as noise sensitivity, coping strategies and a range of other attitudinal variables.
Time stamp	The systematic review included studies up to October 2014.

5. Implementation of the guidelines

5.1 Introduction

These guidelines focus on the WHO European Region and provide guidance to Member States that is compatible with the noise indicators used in the EU's END (EC, 2002a). They provide information on the exposure–response relationships between exposure to environmental noise from different noise sources and the proportion of people affected by certain health outcomes, as well as interventions that are considered efficient in reducing exposure to environmental noise and related health outcomes.

The WHO guideline values are evidence-based public health-oriented recommendations. As such, they are recommended to serve as the basis for a policy-making process in which policy options are considered. In the policy decisions on reference values, such as noise limits for a possible standard or legislation, additional considerations – such as feasibility, costs, preferences and so on – feature in and can influence the ultimate value chosen as a noise limit. WHO acknowledges that implementing the guideline recommendations will require coordinated effort from ministries, public and private sectors and nongovernmental organizations, as well as possible input from international development and finance organizations. WHO will work with Member States and support the implementation process through its regional and country offices.

5.2 Guiding principles

Four guiding principles provide generic advice and support when incorporating the recommendations into a policy framework, and apply to the implementation of all the recommendations.

The **first principle** is to reduce exposure to noise, while conserving quiet areas. The recommendations focus on reduction of population exposure to environmental noise from a variety of sources, in different settings. The general population can be exposed regularly to more than one source of noise simultaneously (including, in some cases, occupational noise), as well as to other nonacoustic factors that can modify the response to noise (such as vibration from railways, air pollution from traffic or visual aspects of wind turbines). Thus, overall reduction of exposure from all sources should be promoted. Furthermore, noise exposure reduction in one area should not come at the expense of an increase in noise elsewhere; existing large quiet outdoor areas should be preserved.

The **second principle** is to promote interventions to reduce exposure to noise and improve health. The evidence from epidemiological studies on adverse health effects at certain noise levels, used as a basis to derive the guideline values proposed in the recommendations, supports the promotion of noise interventions. The potential health impacts from environmental noise are significant, especially when considering the widespread exposure to environmental noise across the population and the high baseline rates for various health outcomes associated with environmental noise.

There are challenges in assessment of the effectiveness of interventions to reduce noise exposure and/or improve health, as there is often a significant time lag between the intervention and a measurable change in exposure and related health benefits. The lack of – or limited direct evidence for – quantifiable health benefits of some specific interventions does not imply that measures to achieve population exposure according to the proposed guidelines should be ignored.

Given the different factors that determine noise exposure, a single measure alone may not be sufficient to reduce exposure and/or improve health significantly, and a combination of methods may be warranted. Nevertheless, it is widely acknowledged that the most effective actions to reduce exposure tend to be those that reduce noise at the source. Such actions have the biggest potential, whereas other measures can be less effective or sustained over time, especially when they depend on behaviour change or noise reductions inside houses.

The **third principle** is to coordinate approaches to control noise sources and other environmental health risks. Considering the common transport-related sources of environmental noise and air pollution, and in particular the evidence of independent effects on the cardiovascular system, a coordinated approach to policy development in the sectors related to urban planning, transport, climate and energy should be adopted for policies with an impact on environmental noise, air quality and/or climate. Such an approach should yield multiple benefits through increased commitment and financial resources; increased attention to securing health considerations in all policies; and use of policy to control noise and other environmental risks such as air pollutants, including short-lived climate pollutants. There is wide consensus on the value of pursuing coordinated policies that can deliver health and other benefits, such as those associated with the local environment and economic development. Furthermore, coordinated policy-making is potentially cost-saving.

The **fourth principle** is to inform and involve communities that may be affected by a change in noise exposure. In planning new urban and/or rural developments (transport schemes, new infrastructures in less densely populated areas, noise abatement and mitigation strategies), bringing together planners, environmental professionals and public health experts with policy-makers and citizens is key to public acceptability and involvement and to the successful guidance of the decision-making proces. Potential health effects from environmental noise should be included as part of health impact assessments of future policies, plans and projects, and the communities potentially affected by a positive or negative change in noise exposure should be well informed and engaged from the outset to maximize potential benefits to health. Introducing measures incrementally may help with acceptance.

5.3 Assessment of national needs and capacity-building

National needs, including the need for capacity-building, differ between Member States in the WHO European Region. They depend on the existence and level of implementation of national and/or European and international noise policies; these are more likely to be implemented fully in EU countries thanks to the legally binding provisions of the EU's END (EC, 2002a). In most countries in the Region noise is perceived as a major and growing environmental health and public health problem. Noise mapping and action plans are carried out in accordance with the END in EU Member States, and in south-eastern European countries noise legislation has mainly been harmonized with the END. Nevertheless, significant differences still exist in the completeness and regular updating of noise exposure assessment between countries. Noise exposure assessment is a required input for noise health impact assessments, along with exposure–response relationships and population baseline data.

WHO has identified some common needs for knowledge transfer and capacity-building for health risk assessment of environment noise in the Member States that joined the EU after 2003, the newly independent states and south-eastern European countries (WHO Regional Office for Europe, 2012):

- implementation of the END and its annexes, especially in the preparation of strategic noise mapping and action plans;
- human resources development through education and training in health risk assessment and burden of diseases stemming from environmental noise;
- methodological guidance for health risk assessment of environmental noise.

These guidelines mostly recommend exposure–response relationships related to the exposure indicators L_{den} and L_{night}. They are therefore of particular relevance to EU countries and those applying the END. In countries that do not use these indicators, users of the guidelines need to convert their noise indicators into L_{den} and L_{night} before being able to apply the recommendations. Conversion between indicators is possible, using a certain set of assumptions (Brink et al., 2018).

5.4 Usefulness of guidelines for target audiences

The provision of guideline values as a practical tool for guiding exposure reduction and the design of effective measures and policies is widely seen as useful. The WHO guidelines equip policy-makers and other end-users with a range of different needs with the necessary evidence base to inform their decisions. As indicated in section 1.4, these guidelines serve as a reference for several target audiences, and for each group they can be useful in different ways.

- For technical experts and decision-makers, the guidelines can be used to provide exposure–response relationships that give insight into the consequences of certain regulations or standards on the associated health effects. They also can be useful at the national and international level when developing noise limits or standards, as they provide the scientific basis to identify the levels at which environmental noise causes a significant health impact. Based on these recommendations, national governments and international organizations can be better informed when introducing noise limits, to ensure protection of people's health.
- For health impact assessment and environmental impact assessment practitioners and researchers, these guidelines provide exposure–response relationships that give insight into the expected health effects at observed or expected noise exposure levels. They offer recommendations on the maximum admissible noise levels for some sources and provide important input to assit in deriving the health burden from noise; in that sense, they can be used when producing studies such as noise maps and action plans to obtain an evaluation of the magnitude of the health problem. The systematic reviews developed in support of these guidelines allow practitioners to raise awareness of the credibility of the issue of noise as a public health problem and to use the recommended exposure–response relationships uniformly. Researchers will also benefit from the guidelines as they clearly identify critical data gaps that need to be filled in the future to better protect the population from the harmful effects of noise.
- The guideline recommendations provide a useful tool for national and local authorities when deciding about noise reduction measures, as they provide data to estimate the health burden on the population and therefore allow comparison among different policy options. These options

can include measures to reduce the noise emitted by the sources, measures aimed at impeding the transmission of noise from the sources to people and measures aimed at better planning the location of houses (urban planning).

- The guideline recommendations can also be used by civil society, patients and other advocacy groups to raise awareness and encourage actions to protect the population, including vulnerable groups, from exposure to noise.

Regarding noise abatement and mitigation of noise sources, practical exposure–response relationships for various noise sources are useful quantitative input to determine the impact of noise on health. They can be valuable information to use in cost–effectiveness and cost–benefit analyses of various policies for noise abatement. In this respect, the guideline recommendations can be an integral part of the policy process for noise reduction by various institutions; they are of great value for communicating the health risks and potential cost-effective solutions to reduce noise.

National and local authorities and nongovernmental organizations responsible for risk communication and general awareness-raising can use these guidelines for promotion campaigns and appropriate risk communication. The guidelines provide scientific evidence on a range of health effects associated with noise and facilitate appropriate risk communication to specific vulnerable groups. They therefore need to be promoted broadly to citizens, national and local authorities and nongovernmental organizations responsible for risk communication.

5.5 Methodological guidance for health risk assessment of environmental noise

A health risk assessment is the scientific evaluation of potential adverse health effects resulting from human exposure to a particular hazard – in this case, environmental noise. The main purpose of the assessment is to estimate and communicate the health impact of exposure to noise or changes in noise in different socioeconomic, environmental and policy circumstances.

The guideline recommendations, along with the detailed information contained in the systematic evidence reviews, can be used to assess health impacts in order to answer a variety of policy questions on:

- the public health burden associated with current or projected levels of noise;
- the human health benefits associated with changing a noise policy or applying a more stringent noise standard;
- the impacts on human health of emissions from specific sources of noise for selected economic sectors (and the benefits of policies related to them); and
- the human health impacts of current policy or implemented action.

The results from a health risk assessment are usually reported as the number of attributable deaths, number of cases, years of life lost, years lost due to disability or DALYs.

The quantification of the impacts for one combination of noise source, noise exposure indicator and health outcome may to some extent include effects attributable to another. Consequently, for any particular set of combinations, consideration should be given to potential double counting.

It is also important to note the uncertainties in quantification of the health impacts. One set of uncertainties relates to the CIs associated with the recommended ERFs; these quantify the random error and variability attributed to heterogeneity in the epidemiological studies used for health risk assessment. Other types of uncertainty include modelling/calculation of noise exposure, estimates of population background rates for morbidity and mortality, and transferability of ERFs from locations where studies were carried out or data were otherwise gathered to another location. This is especially true for noise annoyance, for which there is often considerable heterogeneity in effect sizes of studies because estimates vary between noise sources and are to some degree dependent on the situation and context. Furthermore, cultural differences around what is considered annoying are significant, even within Europe. It is therefore not possible to determine the "exact value" of %HA for each exposure level in any generalized situation. Instead, data and exposure–response curves derived in a local context should be applied whenever possible to assess the specific relationship between noise and annoyance in a given situation. If, however, local data are not available, general exposure–response relationships can be applied, assuming that the local annoyance follows the generalized average annoyance. Despite the challenges in applying a "generalized" ERF to specific local situations, the GDG believes that the percentage of high annoyance defined in section 2.4.3 is an acceptable estimate of the "average" %HA at a certain noise level – for example, in Europe.

When performing a health risk assessment of environmental noise, it is important to note several considerations. The selection of particular noise source(s), noise exposure indicator(s) and health outcome combinations to be used for estimation of the health impacts depends on the particular policies and/or measures being assessed. These guidelines propose recommendations for four types of noise source using noise indicators L_{den} and/or L_{night} (road traffic, railway noise, aircraft noise and wind turbine noise) and one recommendation using $L_{Aeq,24h}$ (leisure noise). Any population may be exposed to different noise sources associated with the same health outcome. Estimated impacts should not be added together without recognizing that addition will, in most practical circumstances, lead to some overestimation of the true impact. Impacts estimated for only one combination will, on the other hand, underestimate the true impact of the noise mixture, if other sources of noise also affect that same health outcome.

The scientific evidence reviewed and summarized in these guidelines implies that the following health outcomes can be quantified in a health risk assessment, and that their effects are cumulative:

- from road traffic noise – incidence of IHD, annoyance and sleep disturbance, and potentially incidence of stroke and diabetes;
- from railway noise – annoyance and sleep disturbance;
- from aircraft noise – annoyance, reading and oral comprehension in children, sleep disturbance and potentially change in waist circumference and incidence of IHD;
- from wind turbine noise: annoyance.

The DWs suggested in section 2.4.3 can be used to calculate DALYs.

Data on incidence and prevalence of some health outcomes related to noise (mainly cardiovascular disease) can be found at a national level in online databases available on the WHO Regional Office for Europe website (WHO Regional Office for Europe, 2017).

General principles of relevance for environmental factors when conducting health risk assessments and quantifying the burden of disease can be found elsewhere (European Centre for Health Policy, 1999; Murray, 1994; Murray & Acharya, 1997; Murray & Lopez, 2013; Quigley et al., 2006; WHO, 2014a; 2014b; WHO Regional Office for Europe, 2016). In particular, the WHO Regional Office for Europe and JRC jointly published the first estimates of the burden of disease from environmental noise in 2011 (WHO Regional Office for Europe & JRC, 2011). The publication includes guidance on the procedure for the health risk assessment of environmental noise, exemplary estimates of the burden of the health impacts of environmental noise and a discussion of the uncertainties and limitations of the procedure to calculate the environmental burden of disease. The reader is referred to this publication for more detailed explanations on quantitative risk assessment methods for environmental noise.

5.6 Route to implementation: policy, collaboration and the role of the health sector

Preventing noise and related health impacts relies on effective action across different sectors: health, environment, transport, urban planning and so on. The health sector needs to be engaged effectively in different sectors' policy processes at national, regional and international levels. It needs to provide authoritative advice about the health impacts of noise and policy options that will bring the greatest benefits to health.

In most countries in the WHO European Region, the commitment of the health sector to engage in action to address environmental noise issues needs to be improved and better coordinated. A more coherent overall response is needed, taking into account relevant linkages with existing health priorities and concerns. Thus, some actions can be seen as aspects of the role of the health sector:

- engaging in proper communication with relevant sectors about noise exposure from different sectors and sources (environmental, urban development, transport and so on) to ensure that health issues are adequately addressed as part of international, regional, national and/or local efforts to address environmental noise – the implementation approach may differ across sectors, depending on the level of awareness of noise as a public health problem;
- promoting the guideline recommendations to policy-makers from different sectors and organizing information campaigns and awareness-raising activities in collaboration with national health authorities and WHO country offices to inform citizens and health practitioners about the health risks of environmental noise;
- using decision support instruments such as health impact and health risk assessments to quantify health risks and potential benefits associated with policies and interventions aimed at addressing environmental noise, including presenting information about the severity of the health effects (for example, with cardiovascular disease) to convey the serious impacts of noise and to try to change attitudes and behaviours of policy-makers and the general public;
- promoting the guidelines to health practitioners and physicians, especially at the community level (through associations of physicians, cardiologists and so on as part of the stakeholder group);
- supporting the establishment of national health institutions capable of initiating and developing health promotion measures, and conducting research, monitoring and reporting on health impacts from environmental noise and its different sources;

- organizing capacity-building workshops and training to increase knowledge of the guidelines as well as creating tools, skills and resources for health risk assessment and developing intersectoral collaboration, particularly in non-EU countries;
- promoting relevant research initiatives and shaping the research agenda, in part based on critical research recommendations and gaps identified in the guidelines, as well as on the impact and effectiveness of interventions and experience with their implementation;
- developing and updating guidelines and policies that influence national, regional and international benchmarks and targets related to environmental noise, as well as advocating the inclusion of the guidelines in development and shaping of national, regional and international noise policies and standards;
- working with other sectors to strengthen noise level monitoring and evaluation, particularly in non-EU countries, to ensure proper conducting of health risk assessments of environmental noise.

5.7 Monitoring and evaluation: assessing the impact of the guidelines

Exposure–response relationships and other recommendations provided by these guidelines should be incorporated into national health policies and the main related policy documents. They should be used for health impact and health risk assessments to identify health risks and potential benefits associated with policies and interventions related to environmental noise.

Population noise exposure should be monitored and assessed at a national scale, at least in urban areas. Furthermore, information on trends in occurrence of noise-related health outcomes considered in these guidelines, such as annoyance or sleep disturbance, should be gathered. These monitoring activities should be performed on a regular basis to ensure proper health risk assessments of noise.

5.8 Updating the guidelines

The progress and pace of noise and health research has intensified over the last 10 years, including new studies published after the completion of the systematic reviews done for these guidelines. This is partly related to the growing car fleet and resulting traffic, the density of urbanization, demographic changes and shifts towards renewable energy, including wind turbines, which have caused an increase in public perception and political awareness of the environmental noise problem. Noise exposure assessment has also improved, due partly to European legislation, and this has provided useful data for epidemiological studies on the health effects of environmental noise. Considering this, the recommendations proposed in these guidelines are expected to remain valid for a period of about 10 years. WHO will monitor the development of the scientific advancements on noise and health research in order to inform any updated guidance on environmental noise.

Annexes

Annex 1. Steering, advisory and external review groups

Tables A1.1–A1.5 give details of the various teams involved in the development of the WHO environmental noise guidelines for the European Region.

Table A1.1 WHO Steering Group

Name	Role	Affiliation
Shelly Chadha	Technical Officer, Office for Hearing Impairment	WHO headquarters, Geneva, Switzerland
Carlos Dora	Coordinator	WHO headquarters, Department of Public Health and Environment, Geneva, Switzerland
Marie-Eve Héroux	Technical Officer, Air Quality and Noise	WHO Regional Office for Europe, European Centre for Environment and Health, Bonn, Germany
Dorota Jarosinska	Programme Manager, Living and Working Environments	WHO Regional Office for Europe, European Centre for Environment and Health, Bonn, Germany
Rokho Kim	Environmental Health Specialist, Team Leader	WHO Regional Office for the Western Pacific, Division of Noncommunicable Diseases and Health through the Life-Course, Manila, Philippines
Jurgita Lekaviciute	Consultant, Noise	WHO Regional Office for Europe, European Centre for Environment and Health, Bonn, Germany
Srdan Matic	Coordinator, Environment and Health	WHO Regional Office for Europe, Copenhagen, Denmark
Julia Nowacki	Technical Officer, Health Impact Assessment	WHO Regional Office for Europe, European Centre for Environment and Health, Bonn, Germany
Elizabet Paunovic	Head of Office	WHO Regional Office for Europe, European Centre for Environment and Health, Bonn, Germany
Poonum Wilkhu	Consultant, Noise	WHO Regional Office for Europe, European Centre for Environment and Health, Bonn, Germany
Jördis Wothge	Consultant, Noise	WHO Regional Office for Europe, European Centre for Environment and Health, Bonn, Germany

Table A1.2. Guideline Development Group

Area of expertise	Reference	Area of expertise	Reference
Noise sources and their measurement	1	Annoyance	6
Biological mechanisms of effects	2	Cognitive impairment, quality of life, mental health and well-being	7
Cardiovascular and metabolic diseases	3	Adverse birth outcomes	8
Sleep disturbance	4	Environmental noise interventions	9
Hearing impairment/tinnitus	5	Methodology and guideline development	10

Name	Position and affiliation	Area of expertise sought for guideline development (see reference numbers above)									
		1	2	3	4	5	6	7	8	9	10
Wolfgang Babisch	Senior Scientific Officer (retired) Federal Environment Agency Germany		X	X		X					
Goran Belojevic	Professor Institute of Hygiene and Medical Ecology Faculty of Medicine University of Belgrade Serbia			X			X				
Mark Brink	Senior Scientist Federal Office for the Environment Switzerland	X			X		X				
Sabine Janssen	Senior Scientist Department of Sustainable Urban Mobility and Safety Netherlands Organisation for Applied Scientific Research (TNO) Netherlands				X		X				
Peter Lercher (2013–2014)	Professor Medical University of Innsbruck Austria							X	X		
Marco Paviotti	Policy Officer Directorate-General for Environment European Commission Belgium	X								X	
Göran Pershagen	Professor Institute of Environmental Medicine Karolinska Institute Sweden		X	X					X		

Table A1.2. contd

Area of expertise	Reference	Area of expertise	Reference
Noise sources and their measurement	1	Annoyance	6
Biological mechanisms of effects	2	Cognitive impairment, quality of life, mental health and well-being	7
Cardiovascular and metabolic diseases	3	Adverse birth outcomes	8
Sleep disturbance	4	Environmental noise interventions	9
Hearing impairment/tinnitus	5	Methodology and guideline development	10

Name	Position and affiliation	Area of expertise sought for guideline development (see reference numbers above)									
		1	2	3	4	5	6	7	8	9	10
Kerstin Persson Waye	Professor Occupational and Environmental Medicine The Sahlgrenska Academy University of Gothenburg Sweden	X			X		X				
Anna Preis	Professor Institute of Acoustics Adam Michiewicz University Poland					X	X				
Stephen Stansfeld (Chair)	Professor/Head of the Centre for Psychiatry Barts and Queen Mary University of London United Kingdom							X			
Martin van den Berg	Senior Noise Expert Ministry of Infrastructure and Environment Netherlands	X									
GRADE methodologist											
Jos Verbeek	Senior Researcher Finnish Institute of Occupational Health Finland	X									

Table A1.3. Systematic Review Team

Systematic review topics	Experts involved	Affiliation
Cardiovascular and metabolic diseases	Elise van Kempen	National Institute of Public Health and the Environment (RIVM), Netherlands
	Göran Pershagen	Institute of Environmental Medicine, Karolinska Institute, Sweden
	Maribel Casas Sanahuja	Institute for Global Health (ISGlobal), Spain
	Maria Foraster	Barcelona Institute for Global Health (ISGlobal), Spain and Swiss Tropical and Public Health Institute, Switzerland
Sleep disturbance	Mathias Basner	Department of Psychiatry, Perelman School of Medicine at the University of Pennsylvania, United States of America
	Sarah McGuire	Department of Psychiatry, Perelman School of Medicine at the University of Pennsylvania, United States of America
Hearing impairment and tinnitus	Mariola Sliwinska-Kowalska	Nofer Institute of Occupational Medicine, Poland
	Kamil Rafal Zaborowski	Nofer Institute of Occupational Medicine, Poland
Annoyance	Rainer Guski	Department of Psychology, Ruhr-University, Germany
	Dirk Schreckenberg	ZEUS GmbH, Centre for Applied Psychology, Environmental and Social Research, Germany
	Rudolf Schuemer	Consultant for ZEUS GmbH, Centre for Applied Psychology, Environmental and Social Research, Germany
Cognitive impairment, mental health and well-being	Charlotte Clark	Ove Arup & Partners, United Kingdom
	Katarina Paunovic	Institute of Hygiene and Medical Ecology, Faculty of Medicine, University of Belgrade, Serbia
Adverse birth outcomes	Mark Nieuwenhuijsen	Institute for Global Health (ISGlobal), Spain
	Gordana Ristovska	Institute of Public Health of Republic of Macedonia, the former Yugoslav Republic of Macedonia
	Payam Dadvand	Institute for Global Health (ISGlobal), Spain
Interventions	Lex Brown	Griffith School of Environment/Urban Research Program, Griffith University, Australia
	Irene Van Kamp	National Institute of Public Health and the Environment (RIVM), Netherlands

Table A1.4. External Review Group

Area of expertise	Reference	Area of expertise	Reference
Cardiovascular and metabolic diseases	1	Cognitive impairment, mental health and well-being	5
Sleep disturbance	2	Adverse birth outcomes	6
Hearing impairment/ Tinnitus	3	Environmental noise interventions	7
Annoyance	4	Recommendations and implementation guidance	8

Name	Affiliation	Area of expertise sought for guideline development (see reference numbers above)							
		1	2	3	4	5	6	7	8

Annex 3. Summary of conflict of interest management

All external contributors to the guidelines, including members of the GDG, Systematic Review Team and External Review Group, completed WHO declaration of interest forms in accordance with WHO's policy for experts. Further, at the initial stage of the project WHO technical staff reviewed and accepted *curricula vitae* of the candidates for the GDG.

At the beginning of the GDG meetings, the participants declared any conflict of interest by submitting declaration of interest forms. Updated declarations of interest were also collected from the members of the GDG, Systematic Review Team and External Review Group at the final stage of the project.

The conflict of interest assessment was done according to WHO procedures. If a conflict was declared, an initial review was undertaken by the WHO Secretariat to assess its relevance and significance. A declared conflict of interest is insignificant or minimal if it is unlikely to affect or to be reasonably perceived to affect the expert's judgment. Insignificant or minimal interests are: unrelated or only tangentially related to the subject of the activity or work and its outcome; nominal in amount or inconsequential in importance; or expired and unlikely to affect current behaviour.

The WHO Secretariat reviewed and assessed the declarations. In one case the legal unit was consulted for advice; in another the potential conflict was reported in the updated declaration of interest at the final stage of the process and assessed unlikely to affect expert's performance; in a further case a member of the GDG was also a co-author of a systematic review owing to the need to support systematic review authors with additional expertise, but there was no remuneration for this activity.

No member of the GDG or the Systematic Review Team was excluded from his or her role in the guideline development process. The declared conflicts of interest of the External Review Group members were considered when interpreting comments during the external review process.

Annex 4. Detailed overview of the evidence of important health outcomes

As a first step of the evidence retrieval process, the GDG defined two categories of health outcome associated with environmental noise: those considered (i) critical or (ii) important, but not critical for decision-making in the guideline development process.

The GDG relied on the critical health outcomes to inform its decisions on priority health outcomes, so only these were used to inform the recommendations. Nevertheless, as the relevance of some of important health outcomes was difficult to estimate *a priori,* systematic reviews were conducted for both critical and important health outcomes.

This annex provides a detailed overview of the evidence of the important health outcomes – namely adverse birth outcomes, quality of life, well-being and mental health and metabolic outcomes – for each of the noise sources. A comprehensive discussion of all the evidence considered (both critical and important) is available in the published systematic reviews (see section 2.3.2 and Annex 2 for details).

1. Road traffic noise

1.1 Adverse birth outcomes

In total, the systematic review found five studies (two with more or less the same population) on road traffic noise and birth outcomes and three related studies on total ambient noise, likely to be mostly road traffic noise. Too few studies for each of the various measures related to adverse birth outcomes were available to undertake a quantitative meta-analysis. There was evidence rated low quality for a relationship between road traffic noise and low birth weight (Dadvand et al., 2014; Gehring et al., 2014; Hjortebjerg et al., 2016; Wu et al., 1996); however, the estimates were imprecise and in some cases not statistically significant. Further, there was no clear relation between exposure to road traffic noise and pre-term delivery, but there was a positive association between road traffic noise and small for gestational age (OR = 1.09; 95% CI: 1.06–1.12 per 6 dB increase). The evidence for both measures of adverse birth outcomes comes from the same publications and this evidence was rated low quality (Gehring et al., 2014; Hystad et al., 2014).

This evidence was supported by one ecological time-series study published recently looking at total ambient noise and various measures related to adverse birth outcomes (Arroyo et al., 2016a; 2016b; Diaz et al., 2016).

1.2 Quality of life, well-being and mental health

Evidence rated moderate quality was found for an effect of road traffic noise on emotional and conduct disorders in childhood (Belojevic et al., 2012; Crombie et al., 2011; Hjortebjerg et al., 2015; Ristovska et al., 2004; Stansfeld et al., 2005; 2009a; Tiesler et al., 2013) and evidence rated moderate quality for an association of road traffic noise with hyperactivity in children (Hjortebjerg et al., 2015; Tiesler et al., 2013).

There was no clear relationship, however, between road traffic noise exposure and self-reported quality of life (evidence rated low quality) (Barcelo Perez & Piñeiro, 2008; Brink, 2011; Clark et al., 2012; Honold et al., 2012; Roswall et al., 2015; Schreckenberg et al., 2010b; Stansfeld et al., 2005; 2009b; van Kempen et al., 2010); medication intake for depression and anxiety (evidence rated very low quality) (Floud et al., 2011; Halonen et al., 2014); depression, anxiety and psychological distress (evidence rated very low quality) (Honold et al., 2012; Stansfeld et al., 2009b); and interview measures of depression and anxiety (evidence rated very low quality) (Stansfeld et al., 2009b).

1.3 Metabolic outcomes

1.3.1 Diabetes

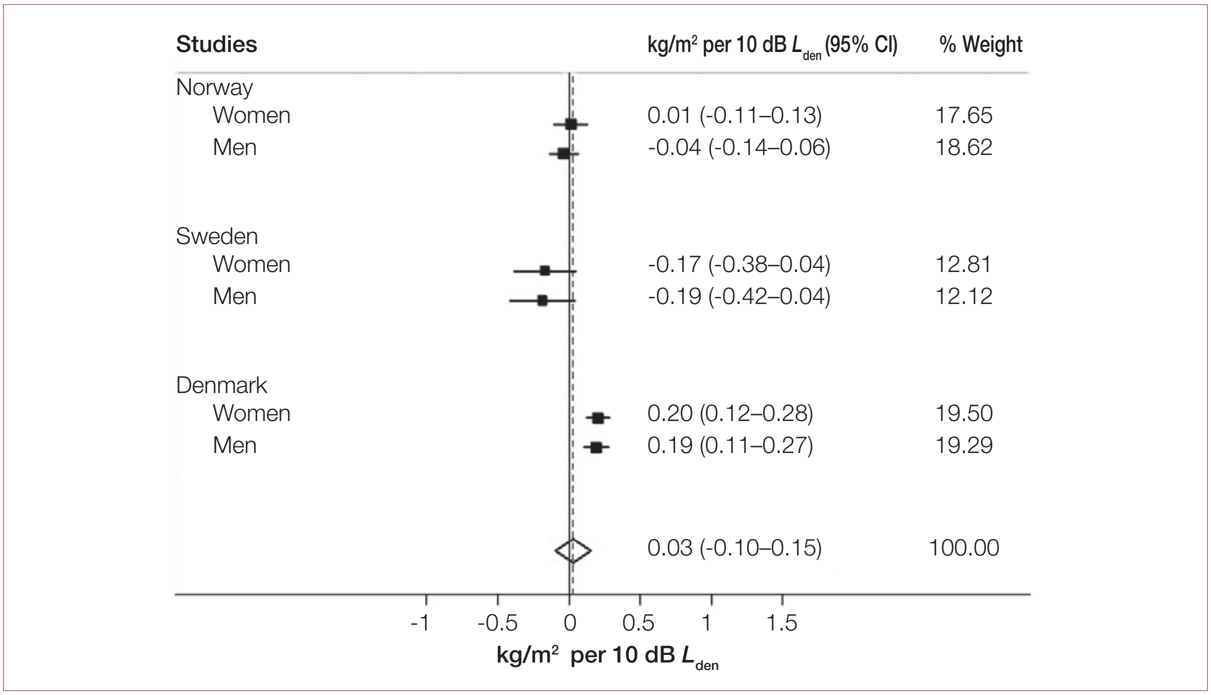
For the relationship between road traffic noise and the incidence of diabetes, one cohort study was identified, which included 57 053 participants and 2752 cases (Sörensen et al., 2013). The estimate of the effect was RR = 1.08 (95% CI: 1.02–1.14) per 10 dB L_{den} increase in noise across the range of 50–70 dB, and therefore the evidence was rated moderate quality.

Furthermore, two cross-sectional studies were identified that looked at the prevalence of diabetes (Selander et al., 2009; van Poll et al., 2014). The studies included 11 460 participants and 242 cases. Both studies reported a harmful effect of noise, and one showed a statistically significant association. However, the results were imprecise and with serious risk of bias, so the evidence was rated very low quality.

1.3.2 Obesity

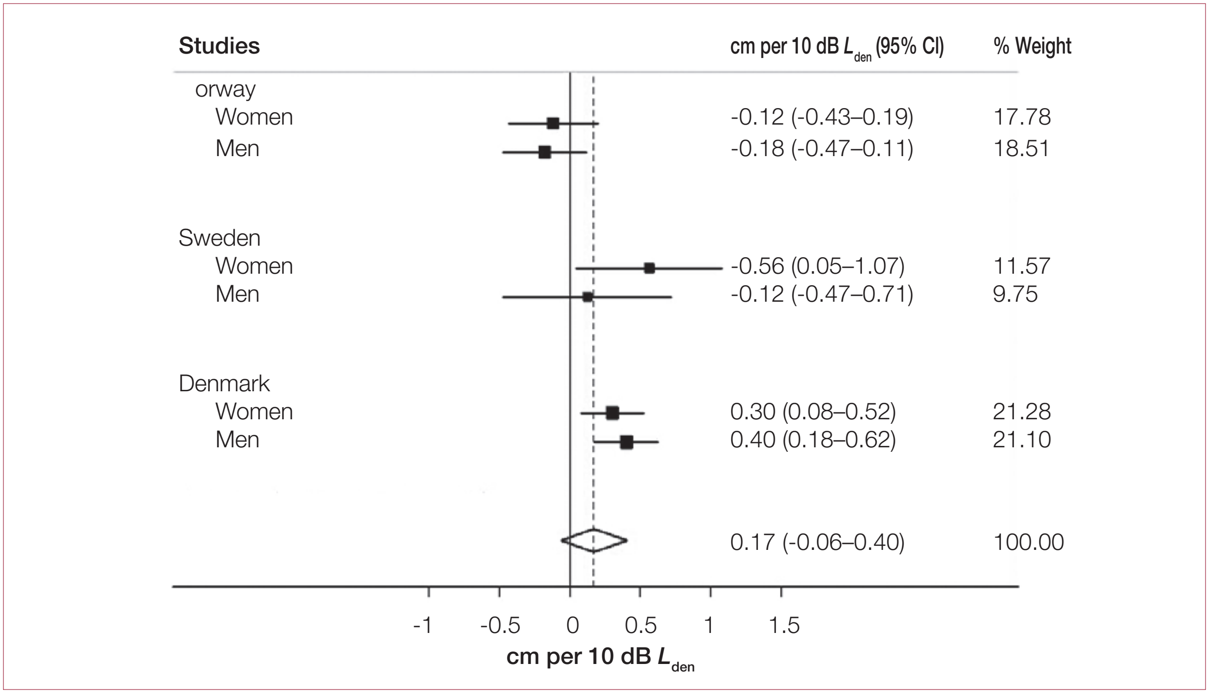
With regard to the association between road traffic noise and change in body mass index (BMI) and waist circumference, three cross-sectional studies were identified, with 71 431 participants (Christensen et al., 2016; Oftedal et al., 2014; 2015; Pyko et al., 2015). For each 10 dB increase in road traffic noise, there was a statistically nonsignificant increase in BMI of 0.03 kg/m^2 (95% CI: –0.10–0.15 kg/m^2) and in waist circumference of 0.17 cm (95% CI: –0.06–0.40 cm). There was inconsistency in the results between the studies; therefore, for both associations, the evidence was rated very low quality (Fig. A4.1 and Fig. A4.2).

Fig. A4.1 The association between exposure to road traffic noise (L_{den}) and BMI in three Nordic studies



Notes: The black vertical line corresponds to no effect of noise exposure. The black dots correspond to the estimated slope coefficients per 10 dB for each sex in each study, with 95% CIs. The diamond designates summary estimates and 95% CIs based on random effects models. The dashed red line corresponds to these summary estimates. Heterogeneity between studies: p = 0.000; heterogeneity between genders: p = 0.360; overall (I-squared = 84.4%, p = 0.000). Weights are from random effect analysis.

Fig. A4.2 The association between exposure to road traffic noise (L_{den}) and waist circumference in three Nordic studies



Notes: The black vertical line corresponds to no effect of noise exposure. The black dots correspond to the estimated slope coefficients per 10 dB for each sex in each study, with 95% CIs. The diamond designates summary estimates and 95% CIs based on random effects models. The dashed red line corresponds to these summary estimates. Heterogeneity between studies: p = 0.001; heterogeneity between genders: p = 0.842; overall (I-squared = 69.0%, p = 0.007). Weights are from random effect analysis.

2. Railway noise

2.1 Adverse birth outcomes

No studies were found, and therefore no evidence was available on the association between railway noise and adverse birth outcomes.

2.2 Quality of life, well-being and mental health

Evidence rated very low quality was found for a weak effect of railway noise exposure on self-reported quality of life or health, albeit from a limited number of studies (Roswall et al., 2015; Torre et al., 2007). There was evidence rated moderate quality for an effect of railway noise on emotional and conduct disorders in childhood (Hjortebjerg et al., 2015), but no clear relationship between railway noise and children’s hyperactivity (Hjortebjerg et al., 2015); this evidence was rated moderate quality.

2.3 Metabolic outcomes

2.3.1 Diabetes

One cohort study was identified that looked at the relationship between railway noise and the incidence of diabetes (Sörensen et al., 2013). The cohort study of 57 053 participants, including 2752 cases, found evidence rated moderate quality that there was no considerable effect of railway noise on diabetes, with an RR of 0.97 (95% CI: 0.89–1.05) per 10 dB L_{den} increase in noise.

Furthermore, one cross-sectional study was identified that looked at the relationship between railway noise and the prevalence of diabetes (van Poll et al., 2014), including 9365 participants and 89 cases. An RR of 0.21 (95% CI: 0.05–0.82) per 10 dB L_{den} increase in noise was found, but the reasons for the beneficial effect were not immediately apparent. The evidence in the study was rated very low quality.

2.3.2 Obesity

Regarding the association between railway noise and change in BMI and waist circumference, two cross-sectional studies were identified, with 57 531 participants (Christensen et al., 2016; Pyko et al., 2015). Christensen and colleagues observed a statistically significant increase of 0.18 kg/m^2 (95% CI: 0.00–0.36 kg/m^2) per 10 dB for BMI and 0.62 cm (95% CI: 0.14–1.09 cm) per 10 dB for waist circumference in those exposed to railway noise, at levels above 60 dB L_{den}. Pyko and colleagues found a statistically significant increase in waist circumference of 0.92 cm (95% CI: 0.06–1.78 cm) per 10 dB L_{den}. The corresponding estimate for BMI was statistically nonsignificant, at 0.06 kg/m^2 (95% CI: –0.02–0.16 kg/m^2). The evidence was rated low/very low quality.

3. Aircraft noise

3.1 Adverse birth outcomes

Evidence rated very low quality was available for an association between aircraft noise and pre-term delivery, low birth weight and congenital anomalies, as evidenced by six studies included in the systematic review (Ando & Hattori, 1973; Edmonds et al., 1979; Jones & Tauscher, 1978; Knipschild et al., 1981; Matsui et al., 2003; Schell, 1981). The potential for risk of bias in these was high and the results tended to be inconsistent.

3.2 Quality of life, well-being and mental health

Evidence rated very low quality was available for an effect of aircraft noise on medication intake for depression and anxiety (Floud et al., 2011). There was evidence rated very low quality for an effect of aircraft noise exposure on interview measures of depression and anxiety (Hardoy et al., 2005) and rated low quality for an association of aircraft noise with hyperactivity in children (Clark et al., 2013; Crombie et al., 2011; Stansfeld et al., 2009a).

The evidence showed, however, no substantial effect of aircraft noise on self-reported quality of life or health (Clark et al., 2012; Schreckenberg et al., 2010a; 2010b; Stansfeld et al., 2005; van Kempen et al., 2010) or on emotional and conduct disorders in childhood (Clark et al., 2012; 2013; Crombie et al., 2011; Stansfeld et al., 2005; 2009a). This evidence was rated very low quality.

3.3 Metabolic outcomes

3.3.1 Diabetes

For the relationship between aircraft noise and incidence of diabetes one cohort study was identified, including 5156 participants and 1346 cases (Eriksson et al., 2014). The estimate of the effect was imprecise, with an RR of 0.99 (95% CI: 0.47–2.09) per 10 dB L_{den} increase in noise; the evidence was therefore rated very low quality.

Furthermore, one cross-sectional study was identified that looked at the prevalence of diabetes (van Poll et al., 2014), including 9365 participants and 89 cases. The RR was 1.01 (95% CI: 0.78–1.31) per 10 dB increase in aircraft noise. The evidence was rated very low quality.

3.3.2 Obesity

For the association between aircraft noise and change in BMI and waist circumference, one cohort study was identified, with 5156 participants (Eriksson et al., 2014). For each 10 dB increase in aircraft noise level, the increase in BMI was 0.14 kg/m^2 (95% CI: −0.18–0.45) (evidence rated low quality), and the increase in waist circumference was 3.46 cm (95% CI: 2.13–4.77) (evidence rated moderate quality). The range of noise levels in the study was 48–65 dB L_{den}. In the case of BMI, the change over the whole range in noise values was not statistically significant and was less than what could be considered clinically relevant (3–5% change in BMI); however, for waist circumference, the change was equivalent to an increase of 5.8 cm.

4. Wind turbine noise

4.1 Quality of life, well-being and mental health

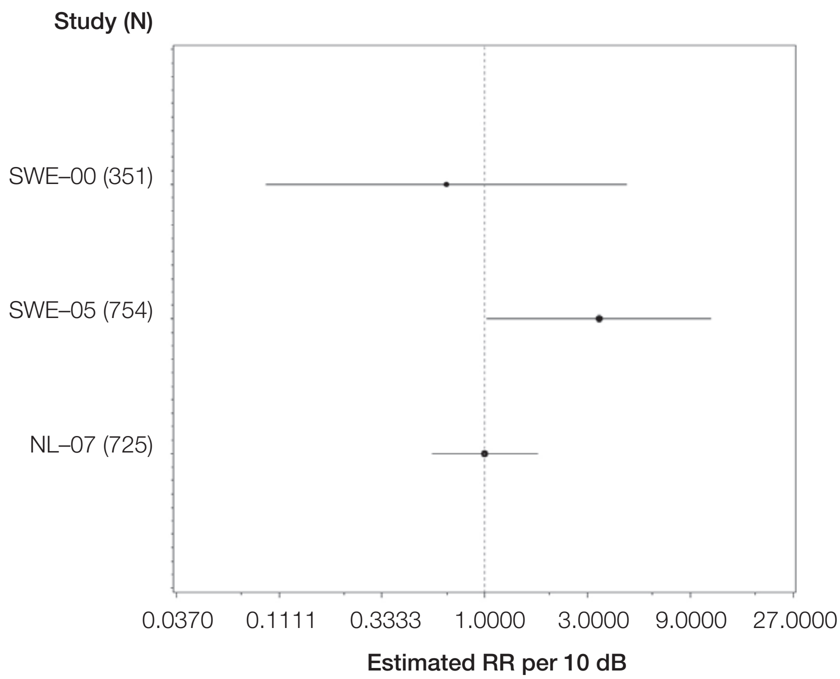
Five low-quality systematic reviews of wind turbine noise effects on mental health and well-being have been carried out (Ellenbogen et al., 2012; Kurpas et al., 2013; Merlin et al., 2013; Onakpoya et al., 2015; Schmidt & Klokker, 2014). These reviews differed in their conclusions and delivered inconsistent evidence that wind turbine noise exposure is associated with poorer quality of life, well-being and mental health. Therefore, the evidence for no substantial effect of wind turbine noise on quality of life, well-being or mental health was rated very low quality.

4.2 Metabolic outcomes

4.2.1 Diabetes

For the relationship between wind turbine noise and prevalence of diabetes, three cross-sectional studies were identified, with a total of 1830 participants (Bakker et al., 2012; Pedersen, 2011; Pedersen & Larsman, 2008; Pedersen & Persson Waye, 2004; 2007; Pedersen et al., 2009; van den Berg et al., 2008). The number of cases was not reported. The effect sizes varied across studies, and only one study found a positive association between exposure to wind turbine noise and the prevalence of diabetes; therefore, no meta-analysis was performed. Due to very serious risk of bias and imprecision in the results, this evidence was rated very low quality. As a result, there is no clear relationship between audible noise (greater than 20 Hz) from wind turbines or wind farms and prevalence of diabetes (Fig. A4.3).

Fig. A4.3 The association between exposure to wind turbine noise (sound pressure level) and self-reported diabetes



Note: The dotted vertical line corresponds to no effect of exposure to wind turbine noise. The black circles correspond to the estimated RR per 10 dB (sound pressure level) and 95% CI.
For further details on the studies included in the figure please refer to the systematic review on environmental noise and cardiovascular and metabolic effects (van Kempen et al., 2018).

5. Leisure noise

Owing to a lack of evidence meeting the critieria for systematic reviewing, no results for any of the important health outcomes can be given for exposure to leisure noise.

Noise is an important public health issue. It has negative impacts on human health and well-being and is a growing concern. The WHO Regional Office for Europe has developed these guidelines, based on the growing understanding of these health impacts of exposure to environmental noise. The main purpose of these guidelines is to provide recommendations for protecting human health from exposure to environmental noise originating from various sources: transportation (road traffic, railway and aircraft) noise, wind turbine noise and leisure noise. They provide robust public health advice underpinned by evidence, which is essential to drive policy action that will protect communities from the adverse effects of noise. The guidelines are published by the WHO Regional Office for Europe. In terms of their health implications, the recommended exposure levels can be considered applicable in other regions and suitable for a global audience.

Walkup, J. T. et al., Cognitive Behavioral Therapy, Sertraline, or a
Combination in Childhood Anxiety (2008)

February 22, 2023

The NEW ENGLAND JOURNAL of MEDICINE

ESTABLISHED IN 1812 DECEMBER 25, 2008 VOL. 359 NO. 26

Cognitive Behavioral Therapy, Sertraline, or a Combination in Childhood Anxiety

John T. Walkup, M.D., Anne Marie Albano, Ph.D., John Piacentini, Ph.D., Boris Birmaher, M.D., Scott N. Compton, Ph.D., Joel T. Sherrill, Ph.D., Golda S. Ginsburg, Ph.D., Moira A. Rynn, M.D., James McCracken, M.D., Bruce Waslick, M.D., Satish Iyengar, Ph.D., John S. March, M.D., M.P.H., and Philip C. Kendall, Ph.D.*

ABSTRACT

BACKGROUND

Anxiety disorders are common psychiatric conditions affecting children and adolescents. Although cognitive behavioral therapy and selective serotonin-reuptake inhibitors have shown efficacy in treating these disorders, little is known about their relative or combined efficacy.

METHODS

In this randomized, controlled trial, we assigned 488 children between the ages of 7 and 17 years who had a primary diagnosis of separation anxiety disorder, generalized anxiety disorder, or social phobia to receive 14 sessions of cognitive behavioral therapy, sertraline (at a dose of up to 200 mg per day), a combination of sertraline and cognitive behavioral therapy, or a placebo drug for 12 weeks in a 2:2:2:1 ratio. We administered categorical and dimensional ratings of anxiety severity and impairment at baseline and at weeks 4, 8, and 12.

RESULTS

The percentages of children who were rated as very much or much improved on the Clinician Global Impression–Improvement scale were 80.7% for combination therapy (P<0.001), 59.7% for cognitive behavioral therapy (P<0.001), and 54.9% for sertraline (P<0.001); all therapies were superior to placebo (23.7%). Combination therapy was superior to both monotherapies (P<0.001). Results on the Pediatric Anxiety Rating Scale documented a similar magnitude and pattern of response; combination therapy had a greater response than cognitive behavioral therapy, which was equivalent to sertraline, and all therapies were superior to placebo. Adverse events, including suicidal and homicidal ideation, were no more frequent in the sertraline group than in the placebo group. No child attempted suicide. There was less insomnia, fatigue, sedation, and restlessness associated with cognitive behavioral therapy than with sertraline.

CONCLUSIONS

Both cognitive behavioral therapy and sertraline reduced the severity of anxiety in children with anxiety disorders; a combination of the two therapies had a superior response rate. (ClinicalTrials.gov number, NCT00052078.)

This article (10.1056/NEJMoa0804633) was published on October 30, 2008, and updated on January 17, 2013, at NEJM.org.

N Engl J Med 2008;359:2753-66.

Anxiety disorders are common in children and cause substantial impairment in school, in family relationships, and in social functioning.[1,2] Such disorders also predict adult anxiety disorders and major depression.[3-6] Despite a high prevalence (10 to 20%[3,7,8]) and substantial morbidity, anxiety disorders in childhood remain underrecognized and undertreated.[1,9] An improvement in outcomes for children with anxiety disorders would have important public health implications.

In clinical trials, separation and generalized anxiety disorders and social phobia are often grouped together because of the high degree of overlap in symptoms and the distinction from other anxiety disorders (e.g., obsessive–compulsive disorder). Efficacious treatments for these disorders include cognitive behavioral therapy[10,11] and the use of selective serotonin-reuptake inhibitors (SSRIs).[12,13] However, randomized, controlled trials comparing cognitive behavioral therapy, the use of an SSRI, or the combination of both therapies with a control are lacking. The evaluation of combination therapy is particularly important because approximately 40 to 50% of children with these disorders do not have a response to short-term treatment with either monotherapy.[14,15]

Our study, called the Child–Adolescent Anxiety Multimodal Study, was designed to address the current gaps in the treatment literature by evaluating the relative efficacy of cognitive behavioral therapy, sertraline, a combination of the two therapies, and a placebo drug. This article reports the results of short-term treatment.

METHODS

STUDY DESIGN AND IMPLEMENTATION

This study was designed as a two-phase, multicenter, randomized, controlled trial for children and adolescents between the ages of 7 and 17 years who had separation or generalized anxiety disorder or social phobia. Phase 1 was a 12-week trial of short-term treatment comparing cognitive behavioral therapy, sertraline, and their combination with a placebo drug. Phase 2 is a 6-month open extension for patients who had a response in phase 1.

The authors designed the study, wrote the manuscript, and vouch for the data gathering and analysis. Pfizer provided sertraline and matching placebo free of charge but was not involved in the design or implementation of the study, the analysis or interpretation of data, the preparation or review of the manuscript, or the decision to publish the results of the study.

STUDY SUBJECTS

Children between the ages of 7 and 17 years with a primary diagnosis of separation or generalized anxiety disorder or social phobia (according to the criteria of the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision [DSM-IV-TR][16]), substantial impairment, and an IQ of 80 or more were eligible to participate. Children with coexisting psychiatric diagnoses of lesser severity than the three target disorders were also allowed to participate; such diagnoses included attention deficit–hyperactivity disorder (ADHD) while receiving stable doses of stimulant and obsessive–compulsive, post-traumatic stress, oppositional–defiant, and conduct disorders. Children were excluded if they had an unstable medical condition, were refusing to attend school because of anxiety, or had tried but had not had a response to two adequate trials of SSRIs or an adequate trial of cognitive behavioral therapy. Girls who were pregnant or were sexually active and were not using an effective method of birth control were also excluded. Children who were receiving psychoactive medications other than stable doses of stimulants and who had psychiatric diagnoses that made participation in the study clinically inappropriate (i.e., current major depressive or substance-use disorder; unmedicated ADHD, combined type; or a lifetime history of bipolar, psychotic, or pervasive developmental disorders) or who presented an acute risk to themselves or others were also excluded.

Recruitment occurred from December 2002 through May 2007 at Duke University Medical Center, New York State Psychiatric Institute–Columbia University Medical Center–New York University, Johns Hopkins Medical Institutions, Temple University, University of California, Los Angeles, and Western Psychiatric Institute and Clinic–University of Pittsburgh Medical Center. The protocol was approved and monitored by institutional review boards at each center and by the data and safety monitoring board of the National Institute of Mental Health. Subjects and at least one parent provided written informed consent.

INTERVENTIONS

Cognitive behavioral therapy involved fourteen 60-minute sessions, which included review and ratings of the severity of subjects' anxiety, response to treatment, and adverse events. Therapy was based on the Coping Cat program,[17,18] which was adapted for the subjects' age and the duration of the study.[19] Each subject who was assigned to receive cognitive behavioral therapy received training in anxiety-management skills, followed by behavioral exposure to anxiety-provoking situations. Parents attended weekly check-ins and two parent-only sessions. Experienced psychotherapists, certified in the Coping Cat protocol, received regular site-level and cross-site supervision.

Pharmacotherapy involved eight sessions of 30 to 60 minutes each that included review and ratings of the severity of subjects' anxiety, their response to treatment, and adverse events. Sertraline (Zoloft) and matching placebo were administered on a fixed–flexible schedule beginning with 25 mg per day and adjusted up to 200 mg per day by week 8. Through week 8, subjects who were considered to be mildly ill or worse and who had minimal side effects were eligible for dose increases. Psychiatrists and nurse clinicians with experience in medicating children with anxiety disorders were certified in the study pharmacotherapy protocol and received regular site-level and cross-site supervision. Pill counts and medication diaries were used to facilitate and document adherence.

Combination therapy consisted of the administration of sertraline and cognitive behavioral therapy. Whenever possible, therapy and medication sessions occurred on the same day for the convenience of subjects.

OBJECTIVES

Study objectives were, first, to compare the relative efficacy of the three active treatments with placebo; second, to compare combination therapy with either sertraline or cognitive behavioral therapy alone; and third, to assess the safety and tolerability of sertraline, as compared with placebo. We hypothesized that all three active treatments would be superior to placebo and that combination therapy would be superior to either sertraline or cognitive behavioral therapy alone.

OUTCOME ASSESSMENTS

We obtained demographic information, information on symptoms of anxiety, and data on coexisting disorders and psychosocial functioning using reports from both the subjects and their parents and from interviews of subjects and parents at the time of screening, at baseline, and at weeks 4, 8, and 12. The interviews were administered by independent evaluators who were unaware of study-group assignments.

We used the Anxiety Disorders Interview Schedule for DSM-IV-TR, Child Version,[20] to establish diagnostic eligibility. The categorical primary outcome was the treatment response at week 12, which was defined as a score of 1 (very much improved) or 2 (much improved) on the Clinical Global Impression–Improvement scale,[21] which ranges from 1 to 7, with lower scores indicating more improvement, as compared with baseline. A score of 1 or 2 reflects a substantial, clinically meaningful improvement in anxiety severity. The dimensional primary outcome was anxiety severity as measured on the Pediatric Anxiety Rating Scale, computed by the summation of six items assessing anxiety severity, frequency, distress, avoidance, and interference during the previous week.[22] Total scores on this scale range from 0 to 30, with scores above 13 indicating clinically meaningful anxiety. The Children's Global Assessment Scale[23] was used to rate overall impairment. Scores on this scale range from 1 to 100; scores of 60 or lower are considered to indicate a need for treatment, and a score of 50 corresponds to moderate impairment that affects most life situations and is readily observable. Agreement among the raters was high for anxiety severity ($r=0.85$) and diagnostic status (intraclass correlation coefficient=0.82 to 0.88) on the basis of a videotaped review of 10% of assessments by independent evaluators that were performed at baseline and at week 12.

ADVERSE EVENTS

Adverse events were defined as any unfavorable change in the subjects' pretreatment condition, regardless of its relationship to a particular therapy. Serious adverse events were life-threatening events, hospitalization, or events leading to major incapacity. Harm-related adverse events were defined as thoughts of harm to self or others or related behaviors.

All subjects were interviewed at the start of each visit by the study coordinator with the use of a standardized script. Identified adverse events and harm-related events were then evaluated and rated by each subject's study clinician. This report presents data on all serious adverse events, all harm-related adverse events, and moderate and severe (i.e., functionally impairing) adverse events that occurred in 3% or more of subjects in any study group. The data and safety monitoring board of the National Institute of Mental Health performed a quarterly review of reported adverse events.

Given the greater number of study visits (and hence more reporting opportunities) and the unblinded administration of sertraline in the combination-therapy group, the test of the adverse-event profile of sertraline focused on statistical comparisons between sertraline and placebo and sertraline and cognitive behavioral therapy.

RANDOMIZATION AND MASKING

The randomization sequence in a 2:2:2:1 ratio was determined by a computer-generated algorithm and maintained by the central pharmacy, with stratification according to age, sex, and study center. Subjects were assigned to study groups after being deemed eligible and undergoing verbal reconsent with a study investigator. Subjects in the sertraline and placebo groups did not know whether they were receiving active therapy, nor did their clinicians. However, subjects who received combination therapy knew they were receiving active sertraline. The study protocol called for independent evaluators who completed assessments to be unaware of all treatment assignments.

STATISTICAL ANALYSIS

On the basis of previous studies,[10-15] we hypothesized that 80% of children in the combination-therapy group, 60% in either the sertraline group or the cognitive-behavioral-therapy group, and 30% in the placebo group would be considered to have had a response to treatment at week 12. We determined that we needed to enroll 136 subjects in each active-treatment group and 70 subjects in the placebo group for the study to have a power of 80% to detect a minimum difference of 17% between any two study groups in the rate of response, assuming an alpha of 0.05 and a two-tailed test with no adjustment for multiple comparisons.

Analyses were performed with the use of SAS software, version 9.1.3 (SAS Institute). For categorical outcomes (including data regarding adverse events), treatments were compared with the use of Pearson's chi-square test, Fisher's exact test, or logistic regression, as appropriate. Logistic-regression models included the study center as a covariate. For dimensional outcomes, linear mixed-effects models (implemented with the use of PROC MIXED) were used to determine predicted mean values at each assessment point (weeks 4, 8, and 12) and to test the study hypotheses with respect to between-group differences at week 12. In each linear mixed-effects model, time and study group were included as fixed effects, with linear and quadratic time and time-by-treatment group interaction terms. Each model also began with a limited number of covariates (e.g., age, sex, and race), followed by backward stepping to identify the best-fitting and most parsimonious model. In all models, random effects included intercept and linear slope terms, and an unstructured covariance was used to account for within-subject correlation over time. All comparisons were planned and tests were two-sided. A P value of less than 0.05 was considered to indicate statistical significance. The sequential Dunnett test was used to control the overall (familywise) error rate.[24]

We analyzed data from all subjects according to study group. Sensitivity analyses were performed with the last observation carried forward (LOCF) and multiple imputation assuming missingness at random. Results were similar for the two missing-data methods. We report the results of the LOCF analysis because the response rates were lower and hence provide a more conservative estimate of outcomes.

RESULTS

SUBJECTS

A total of 3066 potentially eligible subjects were screened by telephone (Fig. 1). Of these subjects, 761 signed consent forms and completed the inclusion and exclusion evaluation, 524 were deemed to be eligible and completed the baseline assessment, and 488 underwent randomization. Eleven subjects (2.3%) stopped treatment but were included in the assessment (treatment withdrawals); 46 subjects (9.4%) stopped both treatment and assessment (study withdrawals). On the basis of logistic-regression analyses, pairwise comparisons indicated that subjects in the cognitive-behavioral-therapy group were significantly less likely to withdraw from treatment than were those in the sertraline group (odds ratio, 0.33; 95% confidence interval [CI], 0.13 to 0.87; P=0.03) or the placebo group (odds ratio, 0.24; 95% CI; 0.09 to

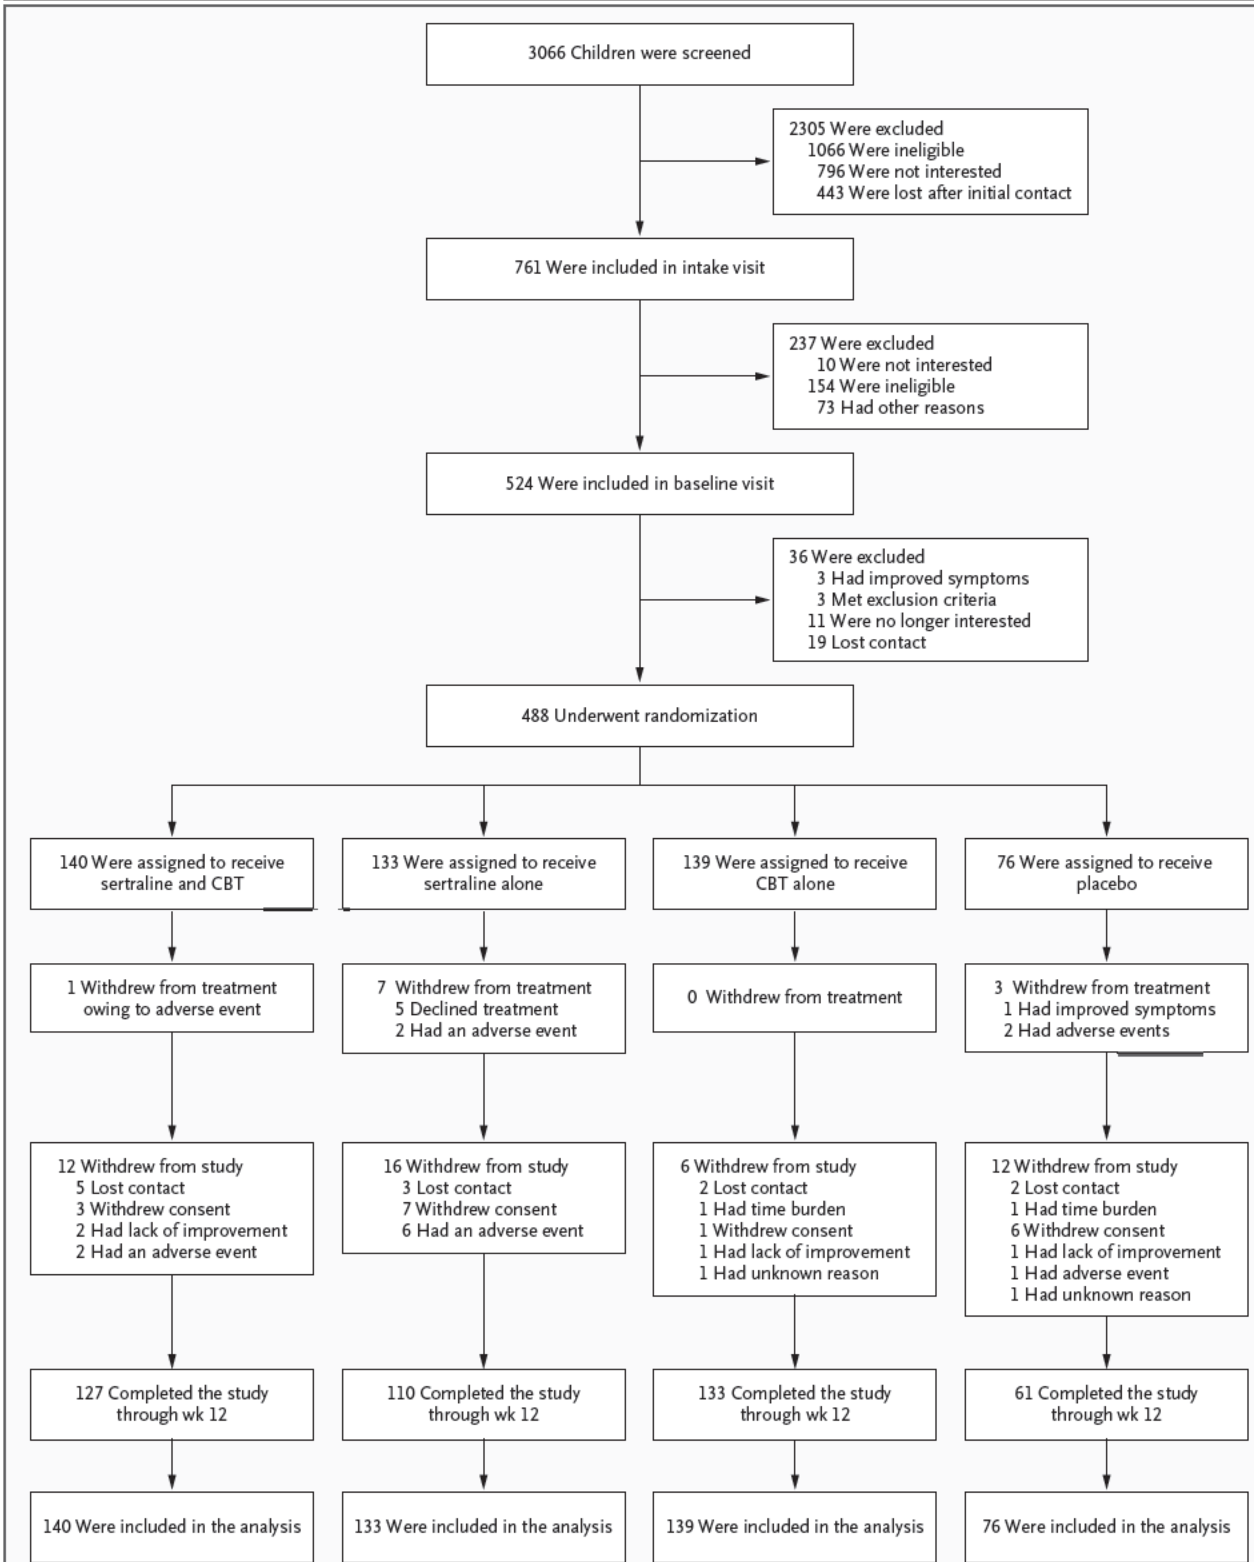

Figure 1. Enrollment and Outcomes.

Subjects who are shown as having withdrawn from treatment discontinued their assigned therapy but continued to undergo study assessment. Subjects who are shown as having withdrawn from the study discontinued both therapy and assessment. CBT denotes cognitive behavioral therapy.

* Plus–minus values are means ±SD. All analyses were performed on data from the intention-to-treat population. Primary outcome variables were scores on the Clinical Global Impression–Improvement scale and the Pediatric Anxiety Rating Scale. NA denotes not applicable.

† Values are the proportion of subjects who had a response to therapy, which was defined as a score of 1 (very much improved) or 2 (much improved) on the Clinical Global Impression–Improvement scale, which ranges from 1 to 7, with lower scores indicating more improvement, as compared with baseline.

‡ Scores on the Pediatric Anxiety Rating Scale range from 0 to 30, with scores higher than 13 consistent with moderate levels of anxiety and a diagnosis of an anxiety disorder.

§ Values are expected mean scores, which were determined by linear mixed-effects model analysis.

¶ Scores on the Clinical Global Impression–Severity scale range from 1 to 7, with higher scores indicating greater severity of the disorder.

‖ Scores on the Children's Global Assessment Scale range from 1 to 100, with lower scores indicating greater impairment. Scores of 60 or lower are considered to indicate a need for treatment, and a score of 50 corresponds to moderate impairment that affects most life situations and is readily observable.

of participants was 10.7±2.8 years, with 74.2% under the age of 13 years. There were nearly equal numbers of male and female subjects. Most subjects were white (78.9%), with other racial and ethnic groups represented. Subjects came from predominantly middle-class and upper-middle-class families (74.6%) and lived with both biologic parents (70.3%). Most subjects had received the diagnosis of two or more primary anxiety disorders (78.7%) and one or more secondary disorders (55.3%). At baseline, subjects had moderate-to-severe anxiety and impairment (Table 2). Given the geographic diversity among study centers, there were significant differences among sites on several baseline demographic variables (e.g., race and socioeconomic status). Overall, these variables were equally distributed among study groups within each center; however, three centers had one instance each of unequal distribution for sex, race, or socioeconomic status.

CLINICAL RESPONSE

In the intention-to-treat analysis, the percentages of children who were rated as 1 (very much improved) or 2 (much improved) on the Clinical Global Impression–Improvement scale at 12 weeks were 80.7% (95% CI, 73.3 to 86.4) in the combination-therapy group, 59.7% (95% CI, 51.4 to 67.5) in the cognitive-behavioral-therapy group, 54.9% (95% CI, 46.4 to 63.1) in the sertraline group, and 23.7% (95% CI, 15.5 to 34.5) in the placebo group (Table 2). With the study center as a covariate, planned pairwise comparisons from a logistic-regression model showed that each active treatment was superior to placebo as follows: combination therapy versus placebo, $P<0.001$ (odds ratio, 13.6; 95% CI, 6.9 to 26.8); cognitive behavioral therapy versus placebo, $P<0.001$ (odds ratio, 4.8; 95% CI, 2.6 to 9.0); and sertraline versus placebo, $P<0.001$ (odds ratio, 3.9; 95% CI, 2.1 to 7.4). Similar pairwise comparisons revealed that combination therapy was superior to either sertraline alone (odds ratio, 3.4; 95% CI, 2.0 to 5.9; $P<0.001$) or cognitive behavioral therapy alone (odds ratio, 2.8; 95% CI, 1.6 to 4.8; $P=0.001$). However, there was no significant difference between sertraline and cognitive behavioral therapy ($P=0.41$).

There was no main effect for center ($P=0.69$); however, a comparison among centers according to study group revealed a significant difference in response to combination therapy but no differences with respect to the response to sertraline alone ($P=0.15$) or cognitive behavioral therapy alone ($P=0.25$). Further evaluation of response rates revealed that the average response rate for combination therapy at one center was significantly lower than at the other centers ($P=0.002$). A sensitivity analysis of site response rates showed that when data from the one site were removed, the average response rate of the other sites was consistent with that of the full sample.

The mixed-effects model for the Pediatric Anxiety Rating Scale revealed a significant quadratic effect for time ($P<0.001$) and a significant quadratic time-by-treatment interaction for cognitive behavioral therapy versus placebo ($P=0.01$) but not for either combination therapy or sertraline versus placebo. In other words, as compared with placebo, cognitive behavioral therapy had a linear mean trajectory (Fig. 2). Planned pairwise comparisons of the expected mean scores on the Pediatric Anxiety Rating Scale at week 12 revealed a similar ordering of outcomes, with all active treatments superior to placebo, according to the following comparisons: combination therapy versus placebo, $t=-5.94$ ($P<0.001$); cogni-

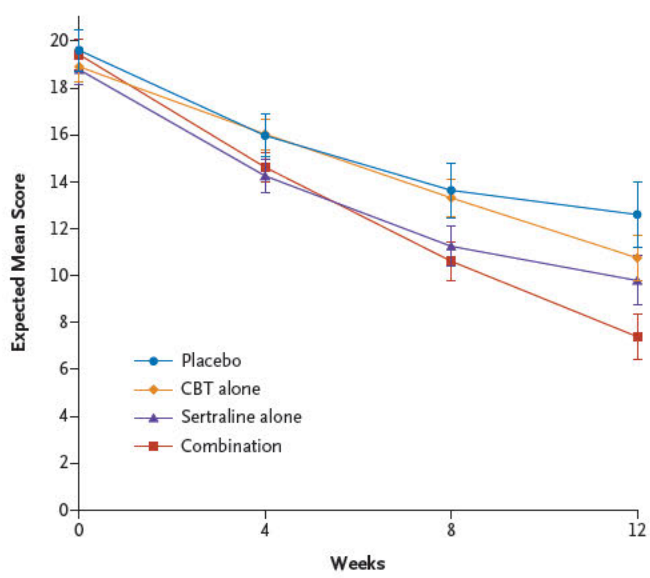

Figure 2. Scores on the Pediatric Anxiety Rating Scale during the 12-Week Study.

Scores on the Pediatric Anxiety Rating Scale range from 0 to 30, with scores higher than 13 consistent with moderate levels of anxiety and a diagnosis of an anxiety disorder. The expected mean score is the mean of the sampling distribution of the mean. The I bars represent standard errors.

tive behavioral therapy versus placebo, t=−2.11 (P=0.04); and sertraline versus placebo, t=−3.15 (P=0.002). In addition, combination therapy was superior to both sertraline alone (t=−3.26, P=0.001) and cognitive behavioral therapy alone (t=−4.73, P<0.001). No significant difference was found between sertraline and cognitive behavioral therapy (t=−1.32, P=0.19). The same magnitude and pattern of outcome were found for the Clinical Global Impression–Severity scale and the Children's Global Assessment Scale.

Estimates of the effect size (Hedges' g) and the number needed to treat between the active-treatment groups and the placebo group were calculated. Effect sizes are based on the expected mean scores on the Pediatric Anxiety Rating Scale, derived from the mixed-effects model. The number needed to treat is based on the dichotomized, end-of-treatment scores on the Clinical Global Impression–Improvement scale with the use of LOCF. The effect size was 0.86 (95% CI, 0.56 to 1.15) for combination therapy, 0.45 (95% CI, 0.17 to 0.74) for sertraline, and 0.31 (95% CI, 0.02 to 0.59) for cognitive behavioral treatment. The number needed to treat was 1.7 (95% CI, 1.7 to 1.9) for combination therapy, 3.2 (95% CI, 3.2 to 3.5) for sertraline, and 2.8 (95% CI, 2.7 to 3.0) for cognitive behavioral therapy.

* Subjects who withdrew from treatment stopped receiving their assigned therapy but continued to undergo assessment; those who withdrew from the study stopped receiving their assigned treatment and did not undergo continued assessment.

TREATMENT AND STUDY WITHDRAWALS

Most treatment and study withdrawals were attributed to reasons other than adverse events (43 of 57, 75.4%) (Table 3). Of the 14 withdrawals that were attributed to an adverse event, 11 (78.6%) were in the groups receiving either sertraline alone or placebo and consisted of 3 physical events (headache, stomach pains, and tremor) and 8 psychiatric adverse events (worsening of symptoms, 3 subjects; agitation or disinhibition, 3; hyperactivity, 1; and nonsuicidal self-harm and homicidal ideation, 1).

* Adverse events that occurred in at least 3% of the patients in any study group are reported, unless otherwise noted. Subjects could have more than one adverse event. Case definitions of psychiatric disorders are from the DSM-IV-TR.[16] CBT denotes cognitive behavioral therapy, and NA not applicable.
† Differences in the number of adverse events in the sertraline group, as compared with the placebo group and the cognitive-behavioral-therapy group, were evaluated with the use of Fisher's exact test, unless otherwise noted.
‡ The reported P value was calculated with the use of Pearson's chi-square statistic.
§ P<0.05 for the comparison between the sertraline group and the cognitive-behavioral-therapy group.
¶ All harm-related adverse events and serious adverse events are reported (i.e., not limited only to those occurring in at least 3% of the subjects).
‖ This event was considered to be possibly related to treatment.

SERIOUS ADVERSE EVENTS

Three subjects had serious adverse events during the study period. One child in the sertraline group had a worsening of behavior that was attributed to the parents' increased limit setting on avoidance behavior; the event was considered to be possibly related to sertraline. A child in the combination-therapy group had a worsening of preexisting oppositional–defiant behavior that resulted in psychiatric hospitalization; this event was considered to be unrelated to a study treatment. The third subject was hospitalized for a tonsillectomy, which was also considered to be unrelated to a study treatment (Table 4).

ADVERSE EVENTS

Subjects in the combination-therapy group had a greater number of study visits and therefore significantly more opportunities for elicitation of adverse events than did those in the other study groups, with a mean of 12.8±4.0 opportunities (range, 1 to 22) in the combination-therapy group, as compared with 9.9±3.6 (range, 1 to 14) in the sertraline group, 10.6±2.0 (range, 1 to 14) in the cognitive-behavioral-therapy group, and 9.7±4.2 (range, 1 to 14) in the placebo group (P<0.001 for all comparisons). Rates of adverse events, including suicidal and homicidal ideation, were not significantly greater in the sertraline group than in the placebo group. No child in the study attempted suicide. Among children in the cognitive-behavioral-therapy group, there were fewer reports of insomnia, fatigue, sedation, and restlessness or fidgeting than in the sertraline group (P<0.05 for all comparisons). For a list of mild adverse events that were not associated with functional impairment, as well as moderate and severe events, see the Supplementary Appendix, available with the full text of this article at www.nejm.org.

DISCUSSION

Our study examined therapies that many clinicians consider to be the most promising treatments for childhood anxiety disorders. Our findings indicate that as compared with placebo, the three active therapies — combination therapy with both cognitive behavioral therapy and sertraline, cognitive behavioral therapy alone, and sertraline alone — are effective short-term treatments for children with separation and generalized anxiety disorders and social phobia, with combination treatment having superior response rates. No physical, psychiatric, or harm-related adverse events were reported more frequently in the sertraline group than in the placebo group, a finding similar to that for SSRIs, as identified in previous studies of anxious children.[12,13,25] Few withdrawals from either treatment or the study were attributed to adverse events. Suicidal ideation and homicidal ideation were uncommon. No child attempted suicide during the study period.

Since they were recruited at multiple centers and locations, the study subjects were racially and ethnically diverse. However, despite intense outreach, the sample did not include the most socioeconomically disadvantaged children. Subjects were predominantly younger children and included those with ADHD and other anxiety disorders, factors that allow for generalization of the results to these populations. Conversely, the exclusion of children and teens with major depression and pervasive developmental disorders may have limited the generalizability of the results to these populations.

The observed advantage of combination therapy over either cognitive behavioral therapy or sertraline alone during short-term treatment (an improvement of 21 to 25%) suggests that among these effective therapies, combination therapy provides the best chance for a positive outcome. The superiority of combination therapy might be due to additive or synergistic effects of the two therapies. However, additional contact time in the combination-therapy group, which was unblinded, and expectancy effects on the part of both subjects and clinicians cannot be ruled out as alternative explanations. Nonetheless, the magnitude of the treatment effect in the combination-therapy group (with two subjects as the number needed to treat to prevent one additional event) suggests that children with anxiety disorders who receive quality combination therapy can consistently expect a substantial reduction in the severity of anxiety. An increased number of visits in the combination-therapy group resulted in increased opportunities for elicitation of adverse events. Consequently, the potential for expectancies among subjects, parents, and clinicians regarding the side effects of medications in the context of more visits may have increased the rate of some adverse events in the combination-therapy group and may limit conclusions that can be drawn regarding the rates of adverse events in combination therapy.

The positive benefit of cognitive behavioral therapy, as compared with placebo, adds new information to the existing literature.[26] The number needed to treat for cognitive behavioral therapy in this study (three subjects) is the same as that identified in a meta-analysis of studies comparing subjects who were assigned to cognitive behavioral therapy with those assigned to a waiting list for therapy or to sessions without active therapy.[14] Our study's test of cognitive behavioral therapy included children with moderate-to-severe anxiety and addresses criticism of previous trials that included children with only mild-to-moderate anxiety.[14] Before our study, cognitive behavioral therapy for childhood anxiety was considered to be "probably efficacious."[26] This evaluation of cognitive behavioral therapy and other recent studies[27,28] suggests that such therapy for childhood anxiety is a well-established, evidenced-based treatment.[29] Given that the risk of some adverse events was lower in the behavioral-therapy group than in the sertraline group, some parents and their children may consider choosing cognitive behavioral therapy as their initial treatment.

The results of our study confirm the short-term efficacy of sertraline for children with generalized anxiety disorder[25] and show that sertraline is effective for children with separation anxiety disorder and social phobia. The number needed to treat for sertraline in our study (three subjects) was the same as that previously identified in a meta-analysis[15] of six randomized, placebo-controlled trials of SSRIs for childhood anxiety disorders.[12,13,25,30,31] These studies and others[27] suggest that SSRIs, as a class, are the medication of choice for these conditions. The titration schedule that we used, which emphasized upward dose adjustment in the absence of response and adverse events, suggests that the average end-point dose of sertraline in this study is the highest dose consistent with good outcome and tolerability. No adverse events were observed more frequently in the sertraline group than in the placebo group. In contrast to the apparent risk of suicidal ideation and behavior in studies of depression in children and adolescents,[15] our study did not demonstrate any increased risk for suicidal behavior in the sertraline group. Given the benefit of sertraline alone or in combination with cognitive behavioral therapy and the limited risk of adverse events associated with the drug in our study, the well-monitored use of sertraline and other SSRIs in the treatment of childhood anxiety disorders is indicated.

Cognitive behavioral therapy and sertraline either in combination or as monotherapies appear to be effective treatments for these commonly occurring childhood anxiety disorders. Results confirm those of previous studies of SSRIs and cognitive behavioral therapy and, most important, show that combination therapy offers children the best chance for a positive outcome. Our findings indicate that all three of the treatment options may be recommended, taking into consideration the family's treatment preferences, treatment availability, cost, and time burden. To inform more prescriptive selection of patients for treatment, further analysis of predictors and moderators of treatment response may identify who is most likely to respond to which[32] of these effective alternatives.

Supported by grants (U01 MH064089, to Dr. Walkup; U01 MH64092, to Dr. Albano; U01 MH64003, to Dr. Birmaher; U01 MH63747, to Dr. Kendall; U01 MH64107, to Dr. March; U01 MH64088, to Dr. Piacentini; and U01 MH064003, to Dr. Compton) from the National Institute of Mental Health (NIMH). Sertraline and matching placebo were supplied free of charge by Pfizer.

Dr. Walkup reports receiving consulting fees from Eli Lilly and Jazz Pharmaceuticals and fees for legal consultation to defense counsel and submission of written reports in litigation involving GlaxoSmithKline, receiving lecture fees from CMP Media, Medical Education Reviews, McMahon Group, and DiMedix, and receiving support in the form of free medication and matching placebo from Eli Lilly and free medication from Abbott for clinical trials funded by the NIMH; Dr. Albano, receiving royalties from Oxford University Press for the Anxiety Disorders Interview Schedule for DSM-IV, Child and Parent Versions, but not for interviews used in this study, and royalties from the Guilford Press; Dr. Piacentini, receiving royalties from Oxford University Press for treatment manuals on childhood obsessive–compulsive disorder and tic disorders and from the Guilford Press and APA Books for other books on child mental health and receiving lecture fees from Janssen-Cilag; Dr. Birmaher, receiving consulting fees from Jazz Pharmaceuticals, Solvay Pharmaceuticals, and Abcomm, lecture fees from Solvay, and royalties from Random House for a book on children with bipolar disorder; Dr. Rynn, receiving grant support from Neuropharm, Boehringer Ingelheim Pharmaceuticals, and Wyeth Pharmaceuticals, consulting fees from Wyeth, and royalties from APPI for a book chapter on pediatric anxiety disorders; Dr. McCracken, receiving consulting fees from Sanofi-Aventis and Wyeth, lecture fees from Shire and UCB, and grant support from Aspect, Johnson & Johnson, Bristol-Myers Squibb, and Eli Lilly; Dr. Waslick, receiving grant support from Baystate Health, Somerset Pharmaceuticals, and GlaxoSmithKline; Dr. Iyengar, receiving consulting fees from Westinghouse for statistical consultation; Dr. March, receiving study medications from Eli Lilly for an NIMH-funded clinical trial and receiving royalties from Pearson for being the author of the Multidimensional Anxiety Scale for Children, receiving consulting fees from Eli Lilly, Pfizer, Wyeth, and GlaxoSmithKline, having an equity interest in MedAvante, and serving on an advisory board for AstraZeneca and Johnson & Johnson; and Dr. Kendall, receiving royalties from Workbook Publishing for anxiety-treatment materials. No other potential conflict of interest relevant to this article was reported.

The views expressed in this article are those of the authors and do not necessarily represent the official views of the NIMH, the National Institutes of Health, or the Department of Health and Human Services.

We thank the children and their families who made this study possible; and J. Chisar, J. Fried, R. Klein, E. Menvielle, S. Olin, J. Severe, D. Almirall, and members of NIMH's data and safety monitoring board.

APPENDIX

The following investigators participated in this study: **Steering Committee:** J. Walkup (chair), A. Albano (cochair), S. Compton (executive secretary); **Statistics–Experimental Design:** S. Compton, S. Iyengar, J. March; **Cognitive Behavioral Therapy:** P. Kendall, G. Ginsburg; **Pharmacotherapy:** M. Rynn, J. McCracken; **Assessment:** J. Piacentini, A. Albano; **Study Coordinators:** C. Keeton, H. Koo, S. Aschenbrand, L. Bardsley, R. Beidas, J. Catena, K. Dever, K. Drake, R. Dublin, E. Fontaine, J. Furr, A. Gonzalez, K. Hedtke, L. Hunt, M. Keller, J. Kingery, A. Krain, K. Miller, J. Podell, P. Rentas, M. Rozenmann, C. Suveg, C. Weiner, M. Wilson, T. Zoulas; **Data Center:** K. Sullivan, M. CHAPTER 3 EFFECTS OF NIGHT-TIME NOISE ON SLEEP

CHAPTER 4 EFFECTS OF NIGHT-TIME NOISE ON HEALTH AND WELL-BEING

CHAPTER 5 GUIDELINES AND RECOMMENDATIONS

ABSTRACT

The WHO Regional Office for Europe set up a working group of experts to provide scientific advice to the Member States for the development of future legislation and policy action in the area of assessment and control of night noise exposure. The working group reviewed available scientific evidence on the health effects of night noise, and derived health-based guideline values. In December 2006, the working group and stakeholders from industry, government and nongovernmental organizations reviewed and reached general agreement on the guideline values and key texts for the final document of the *Night noise guidelines for Europe*.

Considering the scientific evidence on the thresholds of night noise exposure indicated by $L_{night,outside}$ as defined in the Environmental Noise Directive (2002/49/EC), an $L_{night,outside}$ of 40 dB should be the target of the night noise guideline (NNG) to protect the public, including the most vulnerable groups such as children, the chronically ill and the elderly. $L_{night,outside}$ value of 55 dB is recommended as an interim target for the countries where the NNG cannot be achieved in the short term for various reasons, and where policy-makers choose to adopt a stepwise approach. These guidelines are applicable to the Member States of the European Region, and may be considered as an extension to, as well as an update of, the previous WHO *Guidelines for community noise* (1999).

FOREWORD

WHO defines health as a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity, and recognizes the enjoyment of the highest attainable standard of health as one of the fundamental rights of every human being. Environmental noise is a threat to public health, having negative impacts on human health and well-being. In order to support the efforts of the Member States in protecting the population's health from the harmful levels of noise, WHO issued *Guidelines for community noise* in 1999, which includes guideline values for community noise in various settings based on the scientific evidence available. The evidence on health impacts of night noise has been accumulated since then.

In the WHO European Region, environmental noise emerged as the leading environmental nuisance triggering one of the most common public complaints in many Member States. The European Union tackled the problem of environmental noise with an international law on the assessment and management of environmental noise. The WHO Regional Office for Europe developed the *Night noise guidelines for Europe* to provide expertise and scientific advice to the Member States in developing future legislations in the area of night noise exposure control and surveillance, with the support of the European Commission. This guidelines document reviews the health effects of night time noise exposure, examines exposure-effects relations, and presents guideline values of night noise exposure to prevent harmful effects of night noise in Europe. Although these guidelines are neither standards nor legally binding criteria, they are designed to offer guidance in reducing the health impacts of night noise based on expert evaluation of scientific evidence in Europe.

The review of scientific evidence and the derivation of guideline values were conducted by outstanding scientists. The contents of the document were peer reviewed and discussed for a consensus among the experts and the stakeholders from industry, government and nongovernmental organizations. We at WHO are thankful for those who contributed to the development and presentation of this guidelines and believe that this work will contribute to improving the health of the people in the Region.

EXECUTIVE SUMMARY

INTRODUCTION

The aim of this document is to present the conclusions of the WHO working group responsible for preparing guidelines for exposure to noise during sleep. This document can be seen as an extension of the WHO *Guidelines for community noise* (1999). The need for "health-based" guidelines originated in part from the European Union Directive 2002/49/EC relating to the assessment and management of environmental noise (commonly known as the Environmental Noise Directive and abbreviated as END) which compels European Union Member States to produce noise maps and data about night exposure from mid-2007. The work was made possible by a grant from the European Commission and contributions from the Swiss and German governments.

Although a number of countries do have legislation directed at controlling night noise exposure, there is little information on actual exposure and its subsequent effects on the population. Estimates made in some countries of the number of people highly disturbed by noise during sleep (see Fig. 1 for the Netherlands as an example) indicate that a substantial part of the population could be exposed to levels that might risk their health and well-being.

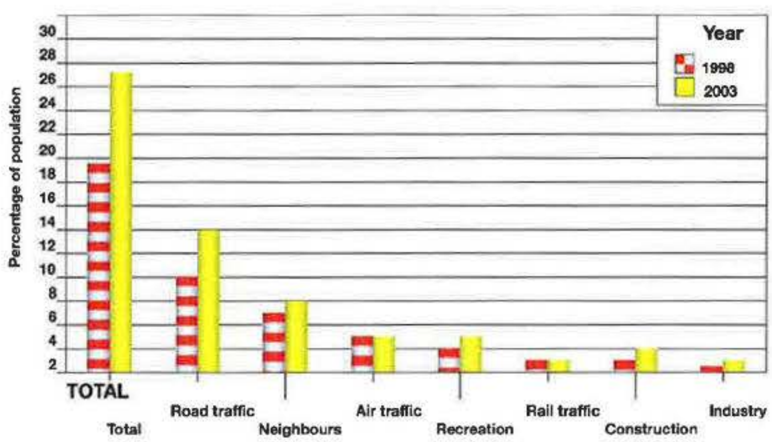

Fig. 1. Percentage of population highly disturbed by noise during sleep in the Netherlands: survey results for 1998 and 2003

As direct evidence concerning the effects of night noise on health is rarely available, these guidelines also use indirect evidence: the effects of noise on sleep and the relations between sleep and health. The advantage of this approach is that a lot of medical evidence is available on the relation between sleep and health, and detailed information also exists on sleep disturbance by noise.

PROCESS OF DEVELOPING GUIDELINES

In 2003, the WHO Regional Office for Europe set up a working group of experts to provide scientific advice to the European Commission and to its Member States for the development of future legislation and policy action in the area of control and surveillance of night noise exposure. The review of available scientific evidence on the health effects of night noise was carried out by an interdisciplinary team who set out to derive health-based guideline values. The contributions from the experts were reviewed by the team and integrated into draft reports following discussion at four technical meetings of the working group. In 2006, all the draft reports were compiled into a draft document on guidelines for exposure to noise at night, which was reviewed and commented on by a number of stakeholders and experts.

At the final conference in Bonn, Germany, on 14 December 2006, representatives from the working group and stakeholders from industry, government and non-governmental organizations reviewed the contents of the draft document chapter by chapter, discussed several fundamental issues and reached general agreement on the guideline values and related texts to be presented as conclusions of the final WHO *Night noise guidelines for Europe.*

NOISE INDICATORS

From the scientific point of view the best criterion for choosing a noise indicator is its ability to predict an effect. Therefore, for different health end points, different indicators could be chosen. Long-term effects such as cardiovascular disorders are more correlated with indicators summarizing the acoustic situation over a long time period, such as yearly average of night noise level outside at the facade ($L_{night,outside}$)[1], while instantaneous effects such as sleep disturbance are better with the maximum level per event (L_{Amax}), such as passage of a lorry, aeroplane or train.

From a practical point of view, indicators should be easy to explain to the public so that they can be understood intuitively. Indicators should be consistent with existing practices in the legislation to enable quick and easy application and enforcement. $L_{night,outside}$, adopted by the END, is an indicator of choice for both scientific and practical use. Among currently used indicators for regulatory purposes, L_{Aeq} (A-weighted equivalent sound pressure level) and L_{Amax} are useful to predict short-term or instantaneous health effects.

SLEEP TIME

Time use studies, such as that undertaken by the Centre for Time Use Research, 2006 (www.timeuse.org/access/), show that the average time adult people are in bed is around 7.5 hours, so the real average sleeping time is somewhat shorter. Due to personal factors like age and genetic make-up there is considerable variation in sleeping time and in beginning and end times. For these reasons, a fixed interval of 8 hours is a minimal choice for night protection.

Though results vary from one country to another, data show (see Fig. 2 as an example) that an 8-hour interval protects around 50% of the population and that it would take a period of 10 hours to protect 80%. On Sundays, sleeping time is consistently 1 hour longer, probably due to people recovering from sleep debt incurred during the week. It should also be borne in mind that (young) children have longer sleeping times.

[1] L_{night} is defined in the END as the outside level. In order to avoid any doubt, the suffix "outside" is added in this document.

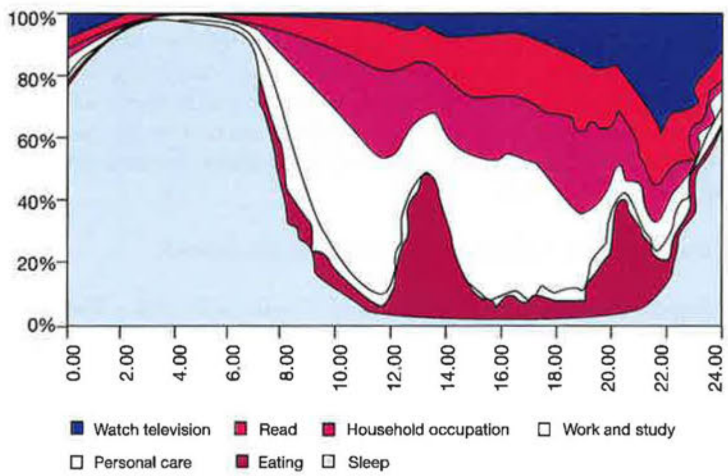

Fig. 2 Percentage of time that the Portuguese population spend asleep or in different activities

NOISE, SLEEP AND HEALTH

There is plenty of evidence that sleep is a biological necessity, and disturbed sleep is associated with a number of health problems. Studies of sleep disturbance in children and in shift workers clearly show the adverse effects.

Noise disturbs sleep by a number of direct and indirect pathways. Even at very low levels physiological reactions (increase in heart rate, body movements and arousals) can be reliably measured. Also, it was shown that awakening reactions are relatively rare, occurring at a much higher level than the physiological reactions.

DEFINITION OF "SUFFICIENT" AND "LIMITED" EVIDENCE

Sufficient evidence: A causal relation has been established between exposure to night noise and a health effect. In studies where coincidence, bias and distortion could reasonably be excluded, the relation could be observed. The biological plausibility of the noise leading to the health effect is also well established.

Limited evidence: A relation between the noise and the health effect has not been observed directly, but there is available evidence of good quality supporting the causal association. Indirect evidence is often abundant, linking noise exposure to an intermediate effect of physiological changes which lead to the adverse health effects.

The working group agreed that there is sufficient evidence that night noise is related to self-reported sleep disturbance, use of pharmaceuticals, self-reported health problems and insomnia-like symptoms. These effects can lead to a considerable burden of disease in the population. For other effects (hypertension, myocardial infarctions, depression and others), limited evidence was found: although the studies were few or not conclusive, a biologically plausible pathway could be constructed from the evidence.

An example of a health effect with limited evidence is myocardial infarction. Although evidence for increased risk of myocardial infarction related to L_{day} is sufficient according to an updated meta-analysis, the evidence in relation to $L_{night,outside}$ was considered limited. This is because $L_{night,outside}$ is a relatively new exposure indicator, and few field studies have focused on night noise when considering cardiovascular outcomes. Nevertheless, there is evidence from animal and human studies supporting a hypothesis that night noise exposure might be more strongly associated with cardiovascular effects than daytime exposure, highlighting the need for future epidemiological studies on this topic.

The review of available evidence leads to the following conclusions.

- Sleep is a biological necessity and disturbed sleep is associated with a number of adverse impacts on health.
- There is sufficient evidence for biological effects of noise during sleep: increase in heart rate, arousals, sleep stage changes and awakening.
- There is sufficient evidence that night noise exposure causes self-reported sleep disturbance, increase in medicine use, increase in body movements and (environmental) insomnia.
- While noise-induced sleep disturbance is viewed as a health problem in itself (environmental insomnia), it also leads to further consequences for health and well-being.
- There is limited evidence that disturbed sleep causes fatigue, accidents and reduced performance.
- There is limited evidence that noise at night causes hormone level changes and clinical conditions such as cardiovascular illness, depression and other mental illness. It should be stressed that a plausible biological model is available with sufficient evidence for the elements of the causal chain.

VULNERABLE GROUPS

Children have a higher awakening threshold than adults and therefore are often seen to be less sensitive to night noise. For other effects, however, children seem to be equally or more reactive than adults. As children also spend more time in bed they are exposed more to night noise levels. For these reasons children are considered a risk group.

Since with age the sleep structure becomes more fragmented, elderly people are more vulnerable to disturbance. This also happens in pregnant women and people with ill health, so they too are a group at risk.

Finally, shift workers are at risk because their sleep structure is under stress due to the adaptations of their circadian rhythm.

THRESHOLDS FOR OBSERVED EFFECTS

The no observed adverse effect level (NOAEL) is a concept from toxicology, and is defined as the greatest concentration which causes no detectable adverse alteration of morphology, functional capacity, growth, development or lifespan of the target organism. For the topic of night noise (where the adversity of effects is not always clear) this concept is less useful. Instead, the observed effect thresholds are provided: the level above which an effect starts to occur or shows itself to be dependent on the exposure level. It can also be a serious pathological effect, such as myocardial infarctions, or a changed physiological effect, such as increased body movement.

Threshold levels of noise exposure are important milestones in the process of evaluating the health consequences of environmental exposure. The threshold levels also delimit the study area, which may lead to a better insight into overall consequences. In Tables 1 and 2, all effects are summarized for which *sufficient and limited evidence* exists. For these effects, the threshold levels are usually well known, and for some the dose-effect relations over a range of exposures could also be established.

Effect		Indicator	Threshold, dB
Biological effects	Change in cardiovascular activity	*	*
	EEG awakening	$L_{Amax,inside}$	35
	Motility, onset of motility	$L_{Amax,inside}$	32
	Changes in duration of various stages of sleep, in sleep structure and fragmentation of sleep	$L_{Amax,inside}$	35
Sleep quality	Waking up in the night and/or too early in the morning	$L_{Amax,inside}$	42
	Prolongation of the sleep inception period, difficulty getting to sleep	*	*
	Sleep fragmentation, reduced sleeping time	*	*
	Increased average motility when sleeping	$L_{night,outside}$	42
Well-being	Self-reported sleep disturbance	$L_{night,outside}$	42
	Use of somnifacient drugs and sedatives	$L_{night,outside}$	40
Medical conditions	Environmental insomnia**	$L_{night,outside}$	42

Table 1
Summary of effects and threshold levels for effects where *sufficient* evidence is available

* *Although the effect has been shown to occur or a plausible biological pathway could be constructed, indicators or threshold levels could not be determined.*

***Note that "environmental insomnia" is the result of diagnosis by a medical professional whilst "self-reported sleep disturbance" is essentially the same, but reported in the context of a social survey. Number of questions and exact wording may differ.*

Table 2
Summary of effects and threshold levels for effects where *limited* evidence is available**

Effect		Indicator	Estimated threshold, dB
Biological effects	Changes in (stress) hormone levels	*	*
Well-being	Drowsiness/tiredness during the day and evening	*	*
	Increased daytime irritability	*	*
	Impaired social contacts	*	*
	Complaints	$L_{night,outside}$	35
	Impaired cognitive performance	*	*
Medical conditions	Insomnia	*	*
	Hypertension	$L_{night,outside}$	50
	Obesity	*	*
	Depression (in women)	*	*
	Myocardial infarction	$L_{night,outside}$	50
	Reduction in life expectancy (premature mortality)	*	*
	Psychic disorders	$L_{night,outside}$	60
	(Occupational) accidents	*	*

* *Although the effect has been shown to occur or a plausible biological pathway could be constructed, indicators or threshold levels could not be determined.*

** *Note that as the evidence for the effects in this table is limited, the threshold levels also have a limited weight. In general they are based on expert judgement of the evidence.*

RELATIONS WITH $L_{NIGHT, OUTSIDE}$

Over the next few years, the END will require that night 'noise' exposures are reported in $L_{night,outside}$. It is, therefore, interesting to look into the relation between $L_{night,outside}$ and adverse health effects. The relation between the effects and $L_{night,outside}$ is, however, not straightforward. Short-term effects are mainly related to maximum levels per event inside the bedroom: $L_{Amax,inside}$. In order to express the (expected) effects in relation to the single European Union indicator, some calculation needs to be done. The calculation for the total number of effects from reaction data on events (arousals, body movements and awakenings) needs a number of assumptions. The first that needs to be made is independence: although there is evidence that the order of events of different loudness strongly influences the reactions, the calculation is nearly impossible to carry out if this is taken into consideration. Secondly, the reactions per event are known in relation to levels at the ear of the sleeper, so an assumption for an average insulation value must be made. In the report a value of 21 dB has been selected. This value is, however, subject to national and cultural differences. One thing that stands out is the desire of a large part of the population to sleep with windows (slightly) open. The relatively low value of 21 dB takes this into account already. If noise levels increase, people do indeed close their windows, but obviously reluctantly, as complaints about bad air then increase and sleep disturbance remains high. This was already pointed out in the WHO *Guidelines for community noise* (1999).

From source to source the number of separate events varies considerably. Road traffic noise is characterized by relatively low levels per event and high numbers, while air and rail traffic are characterized by high levels per event and low numbers. For two typical situations estimates have been made and presented in graphical form. The first is an average urban road (600 motor vehicles per night, which corresponds roughly to a 24-hour use of 8000 motor vehicles, or 3 million per year, the lower boundary the END sets) and the second case is for an average situation of air traffic exposure (8 flights per night, nearly 3000 per year).

Fig. 3 shows how effects increase with an increase of $L_{night,outside}$ values for the typical road traffic situation (urban road). A large number of events lead to high levels of awakening once the threshold of $L_{Amax,inside}$ is exceeded. To illustrate this in practical terms: values over 60 dB $L_{night,outside}$ occur at less then 5 metres from the centre of the road.

In Fig. 4 the same graph is presented for the typical airport situation. Due to a lower number of events there are fewer awakenings than in the road traffic case (Fig. 3), but the same or more health effects. In these examples the worst case figures can be factors higher: the maximum number of awakenings for an $L_{night,outside}$ of 60–65 dB is around 300 per year.

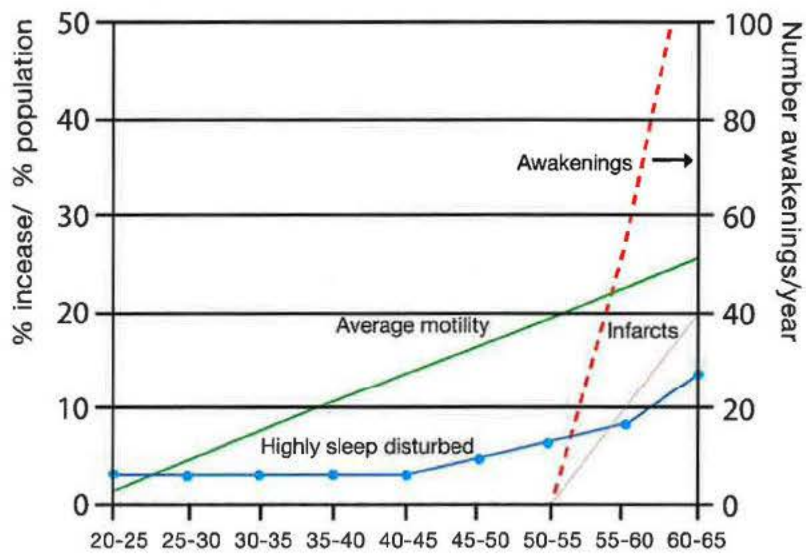

Fig. 3 Effects of road traffic noise at night*

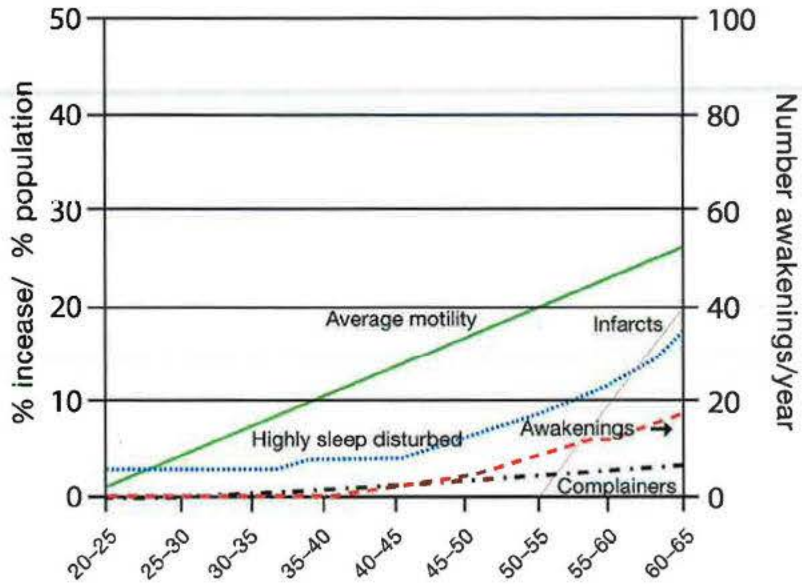
**Average motility and infarcts are expressed in percent increase (compared to baseline number); the number of highly sleep disturbed people is expressed as a percent of the population; awakenings are expressed in number of additional awakenings per year.*

A recent study suggests that high background levels of noise (from motorways) with a low number of separate events can cause high levels of average motility.

Therefore, by using the $L_{night,outside}$ as a single indicator, a relation between effects and indicator can be established. For some effects, however, the relation can be

Fig. 4 Effects of aircraft noise at night*



**Average motility and infarcts are expressed in percent increase (compared to baseline number); the number of highly sleep disturbed people is expressed as a percent of the population; complainers are expressed as a % of the neighbourhood population; awakenings are expressed in number of additional awakenings per year.*

source dependent. Although L_{night} gives a good relation for most effects, there is a difference between sources for some. Train noise gives fewer awakenings, for instance. Once source is accounted for, the relations are reasonably accurate.

RECOMMENDATIONS FOR HEALTH PROTECTION

Based on the systematic review of evidence produced by epidemiological and experimental studies, the relationship between night noise exposure and health effects can be summarized as below. (Table 3)

Below the level of 30 dB $L_{night,outside}$, no effects on sleep are observed except for a slight increase in the frequency of body movements during sleep due to night noise. There is no sufficient evidence that the biological effects observed at the level below 40 dB $L_{night,outside}$ are harmful to health. However, adverse health effects are observed at the level above 40 dB $L_{night,outside}$, such as self-reported sleep disturbance, environmental insomnia, and increased use of somnifacient drugs and sedatives.

Therefore, 40 dB $L_{night,outside}$ is equivalent to the lowest observed adverse effect level (LOAEL) for night noise. Above 55 dB the cardiovascular effects become the major public health concern, which are likely to be less dependent on the nature of the noise. Closer examination of the precise impact will be necessary in the range between 30 dB and 55 dB as much will depend on the detailed circumstances of each case.

Table 3 Effects of different levels of night noise on the population's health

Average night noise level over a year $L_{night,outside}$	Health effects observed in the population
Up to 30 dB	Although individual sensitivities and circumstances may differ, it appears that up to this level no substantial biological effects are observed. $L_{night,outside}$ of 30 dB is equivalent to the no observed effect level (NOEL) for night noise.
30 to 40 dB	A number of effects on sleep are observed from this range: body movements, awakening, self-reported sleep disturbance, arousals. The intensity of the effect depends on the nature of the source and the number of events. Vulnerable groups (for example children, the chronically ill and the elderly) are more susceptible. However, even in the worst cases the effects seem modest. $L_{night,outside}$ of 40 dB is equivalent to the lowest observed adverse effect level (LOAEL) for night noise.
40 to 55 dB	Adverse health effects are observed among the exposed population. Many people have to adapt their lives to cope with the noise at night. Vulnerable groups are more severely affected.
Above 55 dB	The situation is considered increasingly dangerous for public health. Adverse health effects occur frequently, a sizeable proportion of the population is highly annoyed and sleep-disturbed. There is evidence that the risk of cardiovascular disease increases.

A number of instantaneous effects are connected to threshold levels expressed in L_{Amax}. The health relevance of these effects cannot be easily established. It can be safely assumed, however, that an increase in the number of such events over the baseline may constitute a subclinical adverse health effect by itself leading to significant clinical health outcomes.

Based on the exposure-effects relationship summarized in Table 3, the night noise guideline values are recommended for the protection of public health from night noise as below.

Table 4 Recommended night noise guidelines for Europe

Night noise guideline (NNG)	$L_{night,outside}$ = 40 dB
Interim target (IT)	$L_{night,outside}$ = 55 dB

[1] $L_{night,outside}$ is the night-time noise indicator (L_{night}) of Directive 2002/49/EC of 25 June 2002: the A-weighted long-term average sound level as defined in ISO 1996-2: 1987, determined over all the night periods of a year; in which: the night is eight hours (usually 23.00 – 07.00 local time), a year is a relevant year as regards the emission of sound and an average year as regards the meteorological circumstances, the incident sound is considered, the assessment point is the same as for L_{den}. See *Official Journal of the European Communities*, 18.7.2002, for more details.

For the primary prevention of subclinical adverse health effects related to night noise in the population, it is recommended that the population should not be exposed to night noise levels greater than 40 dB of $L_{night,outside}$ during the part of the night when most people are in bed. The LOAEL of night noise, 40 dB $L_{night,outside}$, can be considered a health-based limit value of the night noise guidelines (NNG) necessary to protect the public, including most of the vulnerable groups such as children, the chronically ill and the elderly, from the adverse health effects of night noise.

An interim target (IT) of 55 dB $L_{night,outside}$ is recommended in the situations where the achievement of NNG is not feasible in the short run for various reasons. It should be emphasized that IT is not a health-based limit value by itself. Vulnerable groups cannot be protected at this level. Therefore, IT should be considered only as a feasibility-based intermediate target which can be temporarily considered by policy-makers for exceptional local situations.

RELATION WITH THE GUIDELINES FOR COMMUNITY NOISE (1999)

Impact of night-time exposure to noise and sleep disturbance is indeed covered in the 1999 guidelines, as below (WHO, 1999):

> "If negative effects on sleep are to be avoided the equivalent sound pressure level should not exceed 30 dBA indoors for continuous noise. If the noise is not continuous, sleep disturbance correlates best with L_{Amax} and effects have been observed at 45 dB or less. This is particularly true if the background level is low. Noise events exceeding 45 dBA should therefore be limited if possible. For sensitive people an even lower limit would be preferred. It should be noted that it should be possible to sleep with a bedroom window slightly open (a reduction from outside to inside of 15 dB). To prevent sleep disturbances, one should thus consider the equivalent sound pressure level and the number and level of sound events. Mitigation targeted to the first part of the night is believed to be effective for the ability to fall asleep."

The 1999 guidelines are based on studies carried out up to 1995 (and a few meta-analyses some years later). Important new studies (Passchier-Vermeer et al., 2002; Basner et al., 2004) have become available since then, together with new insights into normal and disturbed sleep. New information has made more precise assessment of exposure-effect relationship. The thresholds are now known to be lower than L_{Amax} of 45 dB for a number of effects. The last three sentences still stand: there are good reasons for people to sleep with their windows open, and to prevent sleep disturbances one should consider the equivalent sound pressure level and the number of sound events. The present guidelines allow responsible authorities and stakeholders to do this. Viewed in this way, the *night noise guidelines for Europe* are complementary to the 1999 guidelines. This means that the recommendations on government policy framework on noise management elaborated in the 1999 guidelines should be considered valid and relevant for the Member States to achieve the guideline values of this document.

CHAPTER 1

INTRODUCTION: METHODS AND CRITERIA

With regard to sleep and waking, we must consider what they are: whether they are peculiar to soul or to body, or common to both; and if common, to what part of soul or body they appertain: further, from what cause it arises that they are attributes of animals, and whether all animals share in them both, or some partake of the one only, others of the other only, or some partake of neither and some of both.

(Aristotle, On sleep and sleeplessness, 350 BC)

1.1 INTRODUCTION

1.1.1 EXISTING POLICY DOCUMENTS FOR NIGHT-TIME NOISE

The aim of this document is to present guidance for exposure to noise during sleep. What is already available?

There are three related documents at the international level:

- *Guidelines for community noise* (WHO, 1999)
- *Directive 2002/49/EC relating to the assessment and management of environmental noise* (European Commission, 2002b)
- *Position Paper on dose-effect relationships for night-time noise* (European Commission, 2004).

In Chapter 5 the relation with the *Guidelines for community noise* (1999) will be explained.

The European Union (EU) Directive relating to the assessment and management of environmental noise (or, as it is commonly known, the Environmental Noise Directive – END), establishes that Member States should create noise maps (2007) and action plans (2008) for parts of their territory. The noise maps should present noise levels expressed in the harmonized indicators L_{den} and L_{night}. Although in the first round only between 20% and 30% of the population will be covered, it is expected that through the use of harmonized methods and indicators a deeper insight will be gained into the exposure of the population to noise. The END does not, however, set any limit values: on the basis of the subsidiarity principle this is left to the Member States. The Directive does, however, require Member States to report on their limit values and express them in the standard indicators. On the CIRCA web site (Communication and Information Resource Centre Administrator, European Commission, 2006) an overview of the data reported to the Commission can be found. Out of the 25 Member States, 10 reported on the L_{night} limits. In Table 1.1 some of these data are summarized.

Due to differences in legal systems it is hard to predict what the actual effect of a certain limit value will be. It could be a relatively high value but rigidly enforced, or a very low value with no legal binding whatsoever.

The *Position Paper* on dose-effect relationships for night-time noise is foreseen in the END (Annex III) and aims to give the competent authorities a tool to evaluate the impact on the population. However, it neither provides limit values nor guidelines. The same information that was used in the *Position Paper* also plays a role in these guidelines.

Table 1.1
Reported L_{night} limit values for road traffic noise in new residential areas

EU Member State	$L_{night,outside}$
France	62
Germany	49
Spain	45
Netherlands	40
Austria	50
Sweden	51 (converted from L_{Aeq} limit 30 dB(A) inside bedroom)
Finland	46
Hungary	55
Latvia	40
Estonia	45
Switzerland	50

1.1.2 GENERAL MODEL

There is no doubt that a relation exists between sleep and health and well-being, as most of us know from personal experience. That does not mean, however, that this relation is simple. People who do not sleep well may not feel well the day after, but the reverse is also true: unfit people may have a disturbed sleep. Untangling the relations between health and disturbed sleep (night-time noise is only one of many causes) proved difficult, and Fig. 2.1 at the end of Chapter 2 shows why.

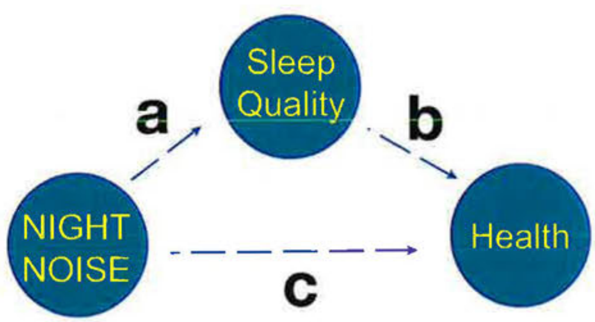

Fig. 1.1.
General structure of the report on the effects of night noise

The general structure of the report is given in Fig. 1.1: evidence for the effects of night-time noise on health (c) is supported by evidence on the indirect route via (a) and (b). In Chapter 2 the relations between sleep and health are examined (relation (b) in Fig. 1.1), and this involves clinical evidence from sleep laboratories, but also evidence from animal experiments. In Chapter 3 it is shown how noise disturbs sleep from the basic, autonomous level up to conscious awakenings: relation (a). Chapter 4 presents the evidence between night-time noise and health and well-being: relation (c) in Fig. 1.1. The last chapter, Chapter 5, then provides guidance on reducing health impacts caused by night-time noise exposure.

1.1.3 PROCESS OF DEVELOPING GUIDELINES

The WHO Regional Office for Europe started the night noise guidelines (NNGL) project with a grant from the European Commission's Directorate-General for Health and Consumer Affairs. In 2003, the WHO Regional Office for Europe set up a working group of experts to provide scientific advice for the development of guidelines for future legislation and policy action in the area of control and surveillance of night noise exposure. The review of available scientific evidence on the health effects of night noise was carried out by the working group to derive health-based guideline values. The contributions,from the experts were reviewed by the team and integrated into draft reports following discussion at four technical meetings of the working group.

The first meeting of the working group was held in Bonn, June 2004. It was agreed that the experts would produce background papers on a number of topics identified and assigned at the meeting.

The second meeting in Geneva, December 2004, concentrated on such technical issues as exposure assessment, metrics, health effects and guideline set-up. The topic-specific experts presented the first drafts for the identified topics for detailed discussions at the meeting. The discussions concentrated on central issues such as exposure assessment and guideline derivation.

The third meeting in Lisbon, April 2005, reviewed the revised background papers, and discussed in detail the overall structure of the guidelines document, and the process of consensus building among the working group and stakeholders.

At the workshop of acoustics experts in The Hague, September 2005, a consensus was made on the use of L_{night} as the single indicator for guideline values as it effectively combines the information on the number of events and the maximum sound levels per event over a year.

In 2006, all the draft reports collected at previous meetings were compiled by Mr. Martin van den Berg into a coherent document on guidelines for exposure to noise at night. The latter was revised according to the comments collected though a peer-review by the working group experts.

At the concluding meeting in Bonn, December 2006, the working group and stakeholders from industry, government and nongovernmental organizations reviewed the contents of the draft document chapter by chapter, discussed several fundamental issues and reached general consensus on the guideline values. The final implementation report of NNGL project was submitted to the EU in early 2007.

The following countries and institutes contributed to the development of *Night noise guidelines for Europe* as project partners.

AUSTRIA:	Institute of Hygiene and Social Medicine, University of Innsbruck
CZECH REPUBLIC:	Charles University in Prague
DENMARK:	National Institute of Public Health
FRANCE:	INRETS/LTE–Laboratoire Transports et Environnement CNRS–Centre National de Recherche Scientifique
GERMANY:	Umweltbundesamt–Federal Environmental Agency Landesgesundheitsamt Baden-Württemberg

ITALY:	ARPAT–Environmental Protection Agency, Tuscany Region
	University of Rome "La Sapienza"– Center for Pediatric Sleep Disorders
NETHERLANDS:	TNO–Netherlands Organisation for Applied Scientific Research
	RIVM–National Institute of Public Health and the Environment
POLAND:	University of Warsaw, Clinic of Psychiatry of the Medical Academy
PORTUGAL:	IST–Instituto Superior Técnico
SLOVENIA:	Institute of Public Health of the Republic of Slovenia
SWEDEN:	University of Gävle, Centre for Built Environment
UNITED KINGDOM:	Queen Mary and Westfield College, University of London

In addition, WHO received advice and support from a number of national experts who participated in the working group. The affiliations of these additional expert advisers include:

CANADA:	Health Canada
GERMANY:	Forschungs- und Beratungsbüro Maschke
SWITZERLAND:	Bundesamt für Umwelt, Wald und Landschaft
	Universität St. Gallen, Institut für Wirtschaft und Ökologie
NETHERLANDS:	Ministry of Housing, Spatial Planning and Environment
UNITED KINGDOM:	Casella Stanger Environmental Consultants

Since the project report was published on the EU web site, various comments were received from experts who have not participated in the working group. The most critical points were regarding the achievability of guideline values in practice. Responding to these feedbacks, the WHO Regional Office for Europe, prepared a revision of guidelines and recommendations, and consulted with international experts and stakeholders including the EU. As of late 2008, it was agreed that the guideline should be based on the lowest observed adverse effects level (LOAEL) rather than the no observed effects level (NOEL). Interim target was also introduced as a feasibility-based level.

1.2 STRENGTH OF EVIDENCE

1.2.1 BASIC CONCEPTS

This document uşes well-established practices from other disciplines and policy fields. Of main interest here are evidence-based medicine, the use of epidemiological evidence for environmental risk assessment and experiences with – principally– air quality guidelines.

The concept of "evidence" is further formalized, as variations in wording and scope are currently in use.

1.2.2 RISK ASSESSMENT AND RISK CONTROL

Fig. 1.2
Elements of risk control

Source:
Health Council of the Netherlands, 2004.

Fig. 1.2 outlines a general approach for risk assessment and control. This approach consists of the following steps:

1. problem description: assessing the impact on the population
2. risk analysis: evaluation of impact
3. risk evaluation: assessing impact considered undesirable
4. assessment of options to avoid or reduce impact
5. cost–benefit analysis of the options or of the mix of options
6. assessment of the preferred option
7. implementation and control.

It is important to observe that guideline values can be an input to, as well as an output of this process. At lower levels of decision (a particular infrastructure project, for instance) a preset guideline value reduces – intentionally – the degrees of freedom in the process. At the highest national or international level a guideline value is the outcome. As the scope of this document is to present the health consequences of night-time noise exposure (and not so much the economic outcomes of the choice of a certain value) it concentrates on the first three elements in the risk assessment block.

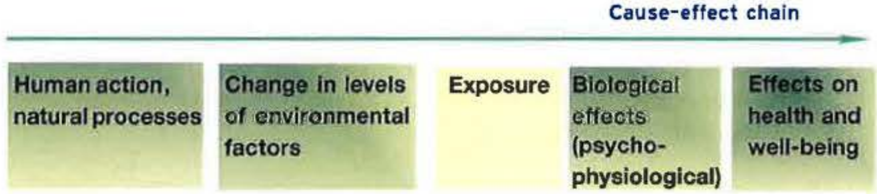
The following questions need to be addressed.

- What is the strength of the available evidence – what are the uncertainties?
- What is the health significance for the effects found?
- How serious is the impact on health?
- Does every instance of exposure lead to an effect and how are they related?
- How can the number of affected people be established?

1.2.3 CAUSE–EFFECT CHAIN

Underlying this approach is the notion of a cause–effect chain between environmental factors and health, symbolically simplified in Fig. 1.3.

Fig. 1.3
Cause-effect chain



Source: Health Council of the Netherlands, 2004.

There are important questions that need to be asked.

- Is there a causal relation between one link in the chain and the next?
- What are the intervening factors in that relation?
- How strong is the evidence for the relations?

The last question is the hardest to answer, as "strength of evidence" is not easy to express in simple numbers or labels. There are two forms of uncertainty: uncertainty because of variability of outcomes and uncertainty due to a lack of knowledge.

For the purpose of this document the following classification will be used, largely based on the IARC (International Agency for Research on Cancer) criteria accessible at http://monographs.iarc.fr/ENG/Preamble/currentb6evalrationale0706.php (see Table 1.2).

Table 1.2 Classification of evidence

Grade of evidence	Criteria
Sufficient evidence	A causal relation has been established between exposure to night-time noise and an effect. In studies where coincidence, bias and distortion could reasonably be excluded, the relation could be observed and it is plausible that the effect is (also) caused by the exposure.
Limited evidence	A relation was observed between exposure to night-time noise and an effect in studies where coincidence, bias and distortion could not reasonably be excluded. The relation is, however, plausible. A direct relation between cause and effect has not been observed, but there is indirect evidence of good quality and the relation is plausible. Indirect evidence is assumed if exposure leads to an intermediate effect and other studies prove that the intermediate effect leads to the effect.
Insufficient evidence	Available studies are of low quality and lack significance to allow conclusions about causality of the relation between exposure and effect. Plausibility of the relation is limited or absent.

1.2.4 PROCEDURE FOR DERIVING GUIDELINES

The following procedure was followed in order to derive an ordering of guideline values:

1. collection of relevant data
2. evaluation of data in terms of strength of evidence
3. evaluation of data in terms of biological effects, health and well-being
4. ranking of guideline values.

This procedure is essentially the same as in other guideline documents, although steps are more explicitly formalized. A major difference is that sound is a natural environmental quality, which makes defining a no-effect level a futile exercise. Therefore the choice was made for a series of levels with increasing severity of effects.

1.3 CONSIDERATIONS WITH REGARD TO NIGHT-TIME NOISE INDICATORS

Briefly, the fundamental choices of night-time noise indicators with respect to length of night, use of single event descriptors and long-term average are commented on to assist the reader in understanding the relations presented in later chapters.

1.3.1 LENGTH OF NIGHT

Time use studies (Centre for Time Use Research, 2006) show that the average time adult people are in bed is around 7.5 hours, so the real average sleeping time is somewhat shorter. Due to personal factors such as age and genetic factors there is considerable variation in sleeping time and in beginning and end times. For these reasons, a fixed interval of 8 hours is a minimal choice for night-time protection. From Fig. 1.4 it can be noted that around 50% of the population is protected with an interval of 8 hours and it would take a period of 10 hours to protect 80%. On Sundays, sleeping time is consistently one hour longer, probably due to people recovering from sleep debt incurred during the week. Data for other countries are readily available but this is the only study covering a long period in a consistent way. Fig. 1.5 (from a time use study in Portugal) shows that the stable pattern found in the Netherlands (Fig. 1.4) is not only typical for northern Europe, but also for the southern part. The pattern, however, seems to have shifted slightly. These figures stress that sleep times might be biologically fixed in humans, and culture has almost no influence.

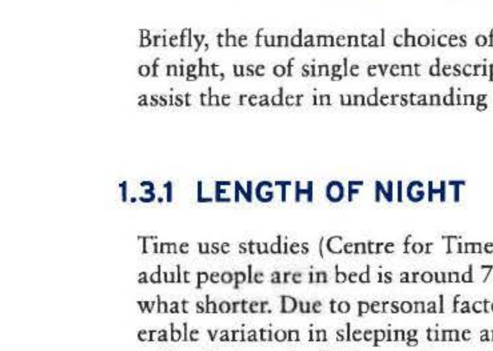


Fig. 1.4

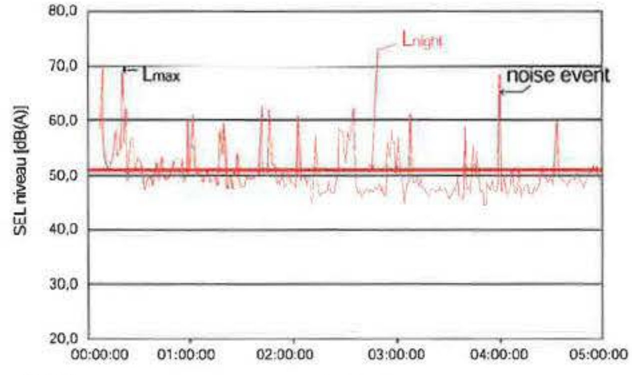
1.3.2 EVENT OR LONG-TERM DESCRIPTOR

Much attention has been paid to the use of single event descriptors such as L_{Amax} (maximum outdoor sound pressure level) and SEL (sound exposure level). As the *Position Paper* on EU noise indicators (European Commission, 2000) points out, this is an important laboratory tool to describe instantaneous reactions to noise. But when it comes to long-term protection, the number of events is equally important. The possibility of predicting after-effects like sleepiness, reaction time, sleeping pill use and health complaints, in particular, requires a combination of a number of events and their level instead of just the average L_{Amax} or average SEL. For events with a similar time pattern there is a relatively simple relation between L_{Amax} and SEL, and therefore between L_{Amax} and L_{night} (night-time noise indicator as defined

Fig. 1.6
Relation between L_{night}, L_{Amax} and SEL



Source: European Commission, 2000

by the END – see paragraph 1.3.4 below). Appendix 2 describes this in detail. For now let it suffice to say that a choice for an L_{night} level ties the L_{Amax} related effects to a maximum and therefore allows for a protective/conservative approach.

Fig. 1.6 is based on a sound recording in a bedroom for one night. The top of the peaks are the L_{Amax} levels, the total energy is the L_{night} (thick horizontal line). The sound energy in one event is the SEL (not represented). In reality the L_{night} is the average over all nights in one year. This reasoning applies also to the issue of long-term average. A value for an arbitrary single night will, except in extreme cases, bear no relationship to an individual's long-term health status, whereas a sustained sufficiently high level over a long period may.

1.3.3 NUMBER OF EVENTS

There is no generally accepted way to count the number of (relevant) noise events. Proposals range from the number of measured L_{Amax}, the number of units (vehicles, aeroplanes, trains) passing by, to the number exceeding a certain L_{Amax} level (commonly indicated by NAxx; NA70 is the number of events higher than 70 dB).

1.3.4 CONVERSION BETWEEN INDICATORS

1.3.4.1 Introduction

L_{night} is defined as the 1 year L_{Aeq} (exposure to noise) over 8 hours outside at the most exposed facade. For the purpose of strategic noise mapping and reporting the height is fixed at 4 metres. As L_{night} is a relatively new definition and because the studies rarely cover such a long period, the research data are rarely expressed in L_{night}. The most frequently used noise descriptor in sleep research is the L_{Amax} or SEL near the sleeper. This means that a considerable amount of conversion work needs to be done if relations are to be expressed in L_{night}. There are four issues:

- conversion between SEL and L_{Amax}
- conversion from instantaneous to long-term
- conversion from inside to outside
- conversion from (outside) bedroom level to most exposed façade.

Further background information on these issues is provided in section 1.3.5. This section details the conversions that are actually carried out.

1.3.4.2 *SEL to L_{Amax}*

SEL is only used for aircraft noise in this report and, according to Ollerhead et al. (1992) from ground-based measurements, the following relation was found:

$$SEL = 23.9+0.81*L_{Amax} \qquad [1].$$

A more general approach can be used to estimate SEL for transportation noise.

If the shape of the time pattern of the sound level can be approximated by a block form, then $SEL \approx L_{Amax} + 10lg\ t$, where t (in seconds) is the duration of the noise event. This rule can be used, inter alia, for a long freight train that passes at a short distance. When t is in the range from 3 to 30 seconds, then SEL is 5–15 dB higher than L_{Amax}. For most passages of aircraft, road vehicles or trains, the shape of the time pattern of the sound level can be better approximated with a triangle. If the sound level increases with rate a (in dB per second), and thereafter is at its maximum for a short duration before it decreases with rate -a, then $SEL \approx L_{Amax} - 10lg(a) + 9.4$. Depending on the distance to the source, for most dwellings near transportation sources the rate of increase is in the order of a few dB per second up to 5 dB per second. When (a) is in the range from 9 dB to 1 dB per second, then SEL is 0–9 dB higher than L_{Amax}.

1.3.4.3 *Events to long-term*

When the SEL values are known (if necessary after converting from L_{Amax}) they can be converted to L_{night}. In general terms, the relation between L_{night} and SEL is:
$L_{night} = 10*lg\ \Sigma_i\ 10^{SEL_i/10} - 10*lg\ (T)$.

If all (N) events have approximately the same SEL level, this may be reduced to:

$$L_{night} = SEL + 10*lg(N) - 70.2 \qquad [2],$$

in which:
N = the number of events occurring in period T;
T = time during which the events occur in seconds. For a (night) year 10lg(T) is 70.2.

The notation adheres to the END where the L_{night} is defined as a year average at the most exposed facade. Any reference to an inside level is noted as such, that is, as $L_{night,inside}$. In order to avoid any doubt the notation $L_{night,outside}$ may be used, for instance in tables where both occur.

1.3.4.4 *Inside to outside*

As the L_{night} is a year value, the insulation value is also to be expressed as such. This means that if the insulation value is 30 dB with windows closed and 15 dB with windows open, the resulting value is 18 dB if the window is open 50% of the time. If these windows are closed only 10% of the time, the result is little more than 15 dB. The issue is complicated by the fact that closing behaviour is, to a certain extent, dependent on noise level. When results about effects are expressed with indoor (that is, inside bedrooms) exposure levels, they need to be converted to L_{night}, in accordance with the END definition. The most important assumption is the correction for inside levels to outside levels. An average level difference of 21 dB has been chosen, as this takes into account that even in well-insulated houses windows may be open a large part of the year. In general:

$$L_{night} = L_{night,inside} + Y \text{ dB} \qquad [3].$$

Y is the year average insulation value of the (bedroom) facade. In this report a default value of 21 dB is used (see also section 1.3.5). It should be stressed that this conversion is thought to be highly dependent on local building habits, climate and window opening behaviour.

1.3.4.5 Most exposed facade

If an inside level is converted to an outside level with [3], it is assumed that this is equivalent to an L_{night} value on the most exposed facade. No information is available on bedroom position and use, so no explicit conversion factor can be given in this report.

This means that the effect estimated on the basis of L_{night} corresponds to an upper limit, because part of the bedrooms will be on a less exposed facade. If an estimate of the exposed population is based on a relation derived with [3], the actual prevalence will be less. From a practical point of view the most exposed facade safeguards protection in cases where there is a possibility that rooms can be swapped.

It should be pointed out that the above does not apply if a relation is based on L_{night} values which are directly measured or computed. These relations will show a large variation because of a misclassification effect, but they give a "correct" estimate of the prevalence of effects in the population. In other words, in some cases a low effect may be attributed to a high L_{night} because the bedroom is on the quiet side.

1.3.5 INSIDE/OUTSIDE DIFFERENCES

Night-time environmental noise affects residents mainly inside their homes. In order to protect residents inside their homes from noise from outside sources, attention should be focused on windows since they are generally the weakest points in the sound propagation path. Roofs must also be considered with regard to aircraft noise.

There are many types of window in the EU, varying from single thin panes within frames without additional insulation, to four-pane windows within insulated frames. The simplest types of facade have a sound reduction (from outside to inside) of usually less than 24 dB, and the most elaborate facades (built to cope with cold climates, for example), have sound reductions of more than 45 dB. In central Europe, most windows are double-glazed, mounted in a rigid and well-insulated frame. Their range of sound reduction is between 30 dB and 35 dB when closed.

When night-time environmental noise reaches high levels, residents tend to close their bedroom windows (cf. Langdon and Buller, 1977; Scharnberg et al., 1982; Schreckenberg et al., 1999; Diaz et al., 2001). The studies by Scharnberg et al. and Schreckenberg et al. found that more than 50% of bedroom windows are closed when outside road traffic noise levels exceed 55 dB (L_{Aeq}). These findings have been replicated in Sweden, according to recent results from the Swedish soundscape research programme on road traffic noise (Fig. 1.7). Nevertheless, while residents with closed windows reported a reduction of sleep disturbances due to noise, they also reported an increase in sleep disturbances due to poor ventilation. Schreckenberg et al. (1999) report a much steeper increase in the incidence of closed windows when road traffic noise reaches high levels than is the case with increased levels of railway noise. Even when night-time noise levels reach 55 B, only 35% of the residents exposed to railway noise reported that they closed their windows at night.

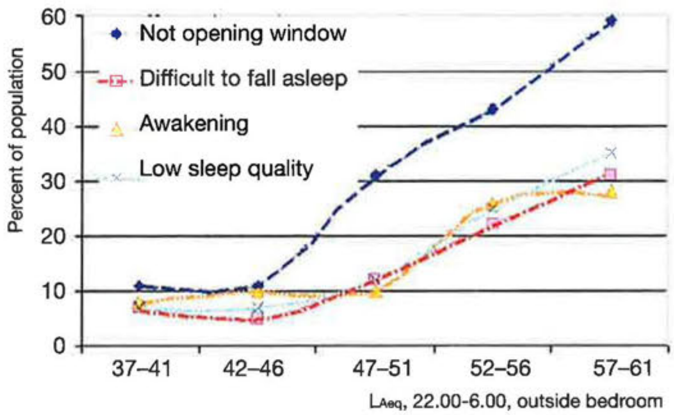


Fig. 1.7
Results from Swedish soundscape research programme on road traffic noise

Source: Öhrström, in European Commission, 2002a.

When windows are slightly open, outside sound levels are usually reduced by 10–15 dB. It should be kept in mind that most European residents want to keep their bedroom windows slightly open at night in order to provide proper ventilation (Scharnberg et al., 1982; Lambert and Plouhinec, 1985; Lambert and Vallet, 1994), and the WHO paper on community noise (WHO, 1999) also recommends that people should be able to sleep with their bedroom windows open.

Passchier-Vermeer et al. (2002) carried out detailed noise measurements inside and outside the bedroom and at the same time measured window position with sensors. The results (Table 1.3) showed that windows are fully closed only in 25% of the nights.

Window position	% nights
Closed	25
Slightly open	43
Hand width	23
Half open	5
Fully open	4

Table 1.3
Window positions during research period (April–November)

This results in average inside/outside differences of around 21 dB, with there being only a slight difference between single- and double-glazed windows (Table 1.4). The survey did not include dwellings which had been specifically insulated against noise. Nevertheless, there was a large variation in insulation values.

	Single-glazed window	Double-glazed window
Average difference at night	21.3	22.2

Table 1.4
Average inside/outside differences in dB

It should be stressed that this figure only applies to facades that have not been fitted with special appliances to reduce noise impact. To give an extreme example of where this general finding does not apply, rooms may be equipped with air conditioning so that windows can stay closed or could even be sealed. Less drastic provisions are sound-attenuated ventilation openings. Little is known, however, about the inhabitants' experiences (long-term use, appreciation) of these and other solutions. For example, sound-attenuated ventilation openings are sometimes blocked in order to cut out draughts.

1.3.6 BACKGROUND LEVEL

A simple definition of background level or "ambient noise" level is the noise that is not targeted for measurement or calculation. Background noise can interfere with the target noise in a number of ways. It can:

- mask the signal
- interact physically
- interact psychologically.

As this report is often dealing with low-level target noise, masking is an important issue. The other two interactions are more important in the domain of annoyance. Masking, however, is a complex process. The human auditory system is uncannily good at separating signals from "background". Microphones (and the software behind them) have been slow to catch up, as the unsatisfactory results show when it comes to automatically recognizing aircraft in long-term unmanned measuring stations.

The rule of thumb that a noise can be considered masked if the signal is 10 dB below the background is only valid if the noises have the same frequency composition and if they actually occur at the same time. This is particularly important to stress where L_{Aeq} levels are compared: even a relatively continuous motorway of 50 dB cannot mask aircraft noise of 30 dB, because this may be composed of five aircraft arriving at an L_{Amax} of 57 dB. Neither can birdsong, because the frequency domains do not overlap.

Another factor relevant for this report is that background levels are lower at night-time than they are in the daytime. This is true for most man-made noises, but also for the natural background levels as wind speeds at night slow down.

Most levels mentioned in this report do not take background levels into account – explicitly. Where long-term L_{Aeq} levels are related to effects like hypertension and self-reported sleep disturbance, background levels are ignored, but they could obscure the effect at the lower end of the scale. This then influences the lowest level where an effect starts to occur.

In sleep laboratory studies the background level is kept as low as possible, around 30 dB. The background of the instrumentation is 20 dB.

In semi-field experiments it has been found that background noise levels inside bedrooms are very low, partly because people tend to choose their bedrooms on the quiet side of the building. This may have the side-effect of exposing children to higher levels.

1.3.7 CHOICE OF INDICATORS FOR REGULATORY PURPOSES

From the scientific point of view the correct choice for a noise indicator is its performance in predicting the effect. There are, however, a number of additional criteria which may influence the choice. Firstly, for different health end points different indicators could be suitable. Further considerations are of a more political nature, as mentioned in the *Position Paper* on EU noise indicators (European Commission, 2000). Indicators should also be easy to explain to the public – intuitively understandable, avoiding unnecessary breaks with current practice and enforceable. This is probably why in many countries L_{Amax} is a popular indicator: it has undeniable qualities in these areas.

This is also the case for L_{Aeq} indicators for short periods of, for example, one or a few hours in the middle of the night. Other fashionable indicators are those looking at numbers above a threshold.

For these indicators the relation between health end points and their values is either not well established, or the correlation between them and current indicators is high, or the correlation between the indicator and an effect is low.

1.4 EXPOSURE IN THE POPULATION

1.4.1 NOISE LEVELS

Surprisingly little information is available on the exposure of houses to night-time noise. It is possible that, in a few years time, the END will lead to the creation of a substantial database on these levels, but up till now only two countries have detailed data available (Table 1.5).

	L_{night} in dB				
Country	**40–45**	**46–50**	**51–55**	**56–60**	**61–65+**
Switzerland (Müller-Wenk, 2002)	–	24%	14%	7%	2%
Netherlands (Nijland and Jabben, 2004)	25%	31%	19%	6%	1%

Table 1.5
Percentage of dwellings per noise class of L_{night} in dB

Notwithstanding the obvious differences between these two countries, the data show a remarkable similarity.

A first result of the END (see Table 1.6) comes from a study into night regulations for (large) airports (Wubben and Busink, 2004).

Airport	Number of inhabitants	Number of night operations per year	Night operations as percentage of daytime operations
Amsterdam	21 863	23 462	5.8%
Frankfurt	134 651	46 662	10.1%
London	477 289	26 465	5.7%
Paris	180 184	51 683	10.3%

Table 1.6
Number of inhabitants within 45 L_{night} contour

1.4.2 REPORTED NIGHT-TIME NOISE DISTURBANCE

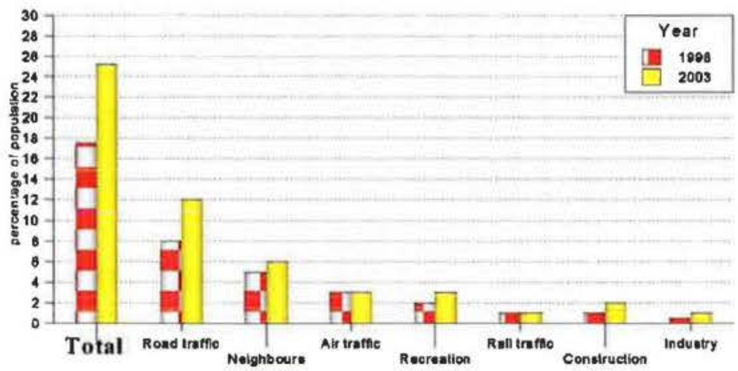
Complaints about night-time exposure to noise are widespread and not exactly new: Roman writers used to complain about the racket in the streets at night (Juvenal, 160). Surprisingly, little detailed information is available today.

Nevertheless, data collected from a few Member States can help to give an impression of the order of magnitude of effects.

Fig. 1.8 shows the relative contributions to overall sleep disturbance caused by noise from different sources in the Netherlands. These data were derived from surveys in 1998 and 2003 (van Dongen et al., 2004) in which 4000 and 2000 people, randomly selected, were asked: "To what extent is your sleep disturbed by noise from [source mentioned]..." on a scale from 1 to 10. People recording the three highest points in the scale were considered "highly disturbed", according to an international convention. The totals are calculated from the number of people reporting serious sleep disturbance from one or more sources.

Unfortunately, comparable research data from other countries or regions is not available, and there is reason to believe that there may be considerable differences in the figures. Since this study is based on a survey conducted in the Netherlands, it is not representative for other Member States in the EU. General (not specific for night-time) annoyance data from Germany and the United Kingdom give an indication that similar numbers of people are affected.

Fig. 1.8 Percentage of population highly disturbed by noise during sleep in the Netherlands



However, the fact that other noise nuisances may contribute significantly to overall sleep disturbance should not be overlooked. Further research on this topic is needed in order to gain an insight into the contribution of various noise sources to sleep disturbance.

1.5 CONCLUSIONS

The methods and criteria for deriving guidelines rest on well-established procedures from epidemiology. To relate the effects to the dose, standard metrics will be used wherever available. If possible, the values found in literature will be converted to avoid confusion. Most of the conversions are relatively straightforward and depend on physical laws; others, in particular the conversion between outside and inside levels, depend on local factors and should be used only if no other information is available.

Information about night-time noise exposure is relatively scarce, despite 10 EU Member States having limit values for night-time noise. The END could substantially increase this information (large-scale noise mapping is foreseen in 2007), increasing the demand for guidance.

CHAPTER 2

THE RELATION BETWEEN SLEEP AND HEALTH

A night of quiet and repose in the profound silence of Dingley Dell, and an hour's breathing of its fresh and fragrant air on the ensuing morning, completely recovered Mr Pickwick from the effects of his late fatigue of body and anxiety of mind.

(Charles Dickens, The Pickwick Papers, 1836)

2.1 SLEEP, NORMAL SLEEP, DEFINITIONS OF SLEEP DISTURBANCE, CHARACTERISTICS MECHANISMS, THE INSOMNIA MODEL

2.1.1 NORMAL SLEEP (OBJECTIVE MEASUREMENTS)

Sleep is part of living and, along with being awake, forms an inherent biological rhythm (Cooper, 1994). Normal sleep can be defined in an objective or subjective manner. The objective criteria are defined using a polysomnographic recording (PSG) of sleep, the method that measures different physiological functions during sleep. Minimal polygraphic requirements to measure sleep adequately include two channels of electroencephalography (EEG), one channel for the electrooculogram (EOG), and one channel for the submental electromyography (EMG). In routine PSG, additional channels are used to assess respiration, leg movements, oxygenation and cardiac rhythm (Ebersole and Pedley, 2003).

Scoring of sleep stages is usually done on an epoch-by-epoch basis, with a 30-second length used as a standard. Epochs are scored according to the guidelines of Rechtschaffen and Kales (1968). Each epoch is scored as the stage that occupies more than 50% of that epoch. Sleep can be divided into the following stages.

- **Arousal** is not a uniform concept and has been defined differently by different researchers. Commonly, the occurrence of alpha rhythms is required for EEG arousal. Depending on the additional requirements and on the length of time that the slower cortical rhythms are interrupted, arousals have been called, for instance, micro-arousal, minor arousal, EEG awakening or transient activation phases. The American Sleep Disorders Association (1992, 1997) devised a scoring system, taking sequences of 3–15 seconds into account for transient arousals which are not transferred to macroscopic behavioural awakening. Eleven further criteria must be met (see also Chapter 3, section 3.1.2).

- **Vegetative arousals** are activations of the sympathic nervous system.

- **Stage W** corresponds to the waking stage and is characterized by alpha activity or low-voltage, mixed-frequency EEG activity. Rapid eye movements (REMs), eye blinks, and tonic EMG activity are usually present.

- **Stage 1** is scored when more than 50% of an epoch is low-voltage, 2–7 Hertz (Hz) activity. Vertex waves may occur in late stage 1. Slow rolling eye movements lasting several seconds are routinely seen early in stage 1, but K complexes and sleep spindles are absent by definition. Tonic EMG activity is usually less than that of relaxed wakefulness.

- **Stage 2** requires the presence of sleep spindles or K complexes, and less than 20% of the epoch contains delta activity. Bursts of sleep spindles must last at least 0.5 seconds before they can be scored. K complexes are defined as biphasic vertex sharp waves with a total duration of greater than 0.5 seconds.

- **Stage 3** is scored when 20–50% of an epoch consists of delta activity that is 2 Hz or slower and is greater than 75 µV in amplitude. Sleep spindles may or may not be present.

- **Stage 4** is scored when more than 50% of an epoch consists of delta activity that is 2 Hz or slower and is more than 75 µV in amplitude. Reliable differentiation of stage 3 and stage 4 sleep is difficult by visual inspection, and most laboratories combine stages 3 and 4 into a single determination of slow-wave sleep (SWS).

- **Stage REM** is characterized by relatively low-voltage, mixed-frequency EEG activity with episodic REMs and absent or markedly reduced axial EMG activity. Phasic EMG activity may occur, but tonic activity must be at a level that is as low as, or lower than, that during any other time in the study. Sleep spindles and K complexes are absent. Series of 2- to 5- Hz vertex-negative "saw-tooth waves" occur, particularly just before phasic REM activity. The requirements to score sleep as REM sleep are: REMs, low or absent axial EMG, and typical mixed-frequency EEG recording that does not preclude the scoring of REM.

Movement time is scored when more than 50% of an epoch is obscured by movement artefact. Movement time must be preceded or followed by sleep and is thus distinguished from movement occurring during wakefulness.

Additional sleep values are determined from each sleep study and contribute to the clinical interpretation of the study. These additional variables include the following.

- **Recording time** is the time elapsed between "lights out" and "lights on" at the end of the study.

- **Total sleep time (TST)** is the total time occupied by stage 1, stage 2, SWS and REM sleep.

- **Sleep efficiency (SE)** is defined as total sleep time divided by recording time and is expressed as a percentage.

- **Sleep latency (SL)** is the time from "lights off" to the first epoch scored as sleep. Some authors prefer to use the first epoch of stage 2 in order to be more confident about identifying the onset of sustained sleep. However, when sleep is very disrupted, there may be an extended interval from recognition of stage 1 until an epoch that can be scored as stage 2.

- **REM latency** is the time from sleep onset (as described earlier) to the first time period scored as REM, minus any intervening epochs as wakefulness.

- **Sleep stage percentages** (% in stage 1, stage 2, SWS and REM sleep) are determined by dividing time recorded in each sleep stage by total sleep time.

- **Wake after sleep onset (WASO)** is time spent awake after sleep onset.

The objective criteria defining normal sleep are based on: sleep latency, total sleep time, sleep efficiency and the number of awakenings, including cortical arousals. However, all these parameters are age-related, sometimes also gender-related, and may vary from one individual to another.

Normal sleep has a clearly defined architecture that is relatively stable. Predictable changes in sleep architecture occur with age. Beginning in middle age, SWS becomes less prominent, the number of awakenings increase, and sleep efficiency decreases. Published information on normal sleep can serve as an outline for normal values in PSG (Williams, Karacan and Hursch, 1974; see also Table 2.1), but each laboratory must study control subjects to identify any significant effects on sleep that result from differences in technique or environment (Ebersole and Pedley, 2003).

Table 2.1
Average normal values for adults of different ages

Sleep parameter (normal values)	20–29 years	40–49 years	60–69 years
TST (min)	419	389	407
Sleep efficiency (TST/TIB[a])	95%	91%	90%
WASO	1%	6%	8%
Stage 1 (% of TST)	4%	8%	10%
Stage 2 (% of TST)	46%	55%	57%
SWS (% of TST)	21%	8%	2%
REM (% of TST)	28%	23%	23%
Sleep latency (min)	15	10	8

[a] *Time in bed*
Source: Williams, Karacan and Hursch, 1974.

Passchier-Vermeer (2003a) reports that subjects not exposed to loud night noise typically report waking up one and a half to two times during an average sleep period, while the number of EEG awakenings including cortical arousals averages 10–12 per night (Table 2.2).

Table 2.2
Parameters of normal sleep

Subjects not exposed to loud night noise	Subjective report of number of awakenings	Number of EEG awakenings
Normal adult subjects	1.5–2	10–12

Source: Passchier-Vermeer, 2003a.

Night arousals result in fragmented sleep, which in turn leads to excessive daytime sleepiness (EDS). The gold standard for the assessment of EDS is the multiple sleep latency test (MSLT) (see Table 2.3), which provides an objective quantification of "sleepiness". The preceding night's sleep requires the PSG to ensure adequate sleep and to exclude sleep disruption. During the day, four or five nap times are scheduled every two hours. For each scheduled nap time the patient lies down and assumes a comfortable sleep position with the technician's instructions to "close your eyes and attempt to sleep". Each nap is terminated 20 minutes after the nap time started if no sleep occurred; or after 15 minutes of continuous sleep as long as sleep onset (SO) criteria are met before the end of 20 minutes; or after 20 minutes if the patient awakens, even if the patient has been asleep less than 15 minutes. The patient is instructed to stay awake between the nap periods.

Table 2.3
Mean sleep latency

Group	MSLT (min)	No REM SO (% of group)	1 REM SO (% of group)	2 or more REM SO (% of group)
Narcoleptics	2.9 ± 2.7	2	2	96
EDS (non-narcoleptic, non-sleep apnocic)	8.7 ± 4.9	92	8	0
Controls	13.4 ± 4.3	100	0	0

2.1.2 DEFINITIONS OF DISTURBED SLEEP

Sleep disorders are described and classified in the International Classification of Sleep Disorders (ICSD) (American Academy of Sleep Medicine, 2005).

When sleep is permanently disturbed and becomes a sleep disorder, it is classified in the ICSD 2005 as "environmental sleep disorder". Environmental sleep disorder (of which noise-induced sleep disturbance is an example) is a sleep disturbance due to a disturbing environmental factor that causes a complaint of either insomnia or daytime fatigue and somnolence. Secondary deficits may result, including deficits in concentration, attention and cognitive performance, reduced vigilance, daytime fatigue, malaise, depressed mood and irritability. The exact prevalence is not known. Fewer than 5% of patients seen at sleep disorder centres receive this diagnosis. The sex ratio is not known. The disorder may occur at any age, although the elderly are at more risk for developing this condition (American Academy of Sleep Medicine, 2005).

2.1.2.1 Insomnia

In the ICSD 2005 the section on insomnia includes a group of sleep disorders all of which have in common the complaint of insomnia (adjustment insomnia, psychophysiological insomnia, paradoxical insomnia, idiopathic insomnia, etc.), defined as repeated difficulty with sleep initiation, duration, consolidation or quality that occurs despite adequate time and opportunity for sleep and results in some form of daytime impairment. Insomnia is a symptom that often arises from primary medical illness, mental disorders and other sleep disorders, but may also arise from abuse or exposure. However, the general criteria for insomnia are the same for all subgroups of insomnias.

2.1.2.2 General criteria for insomnia

A. A complaint is made concerning difficulty initiating sleep, difficulty maintaining sleep, waking up too early or sleep that is chronically non-restorative or poor in quality. In children, the sleep difficulty is often reported by the carer and may consist of observed bedtime resistance or inability to sleep independently.

B. The above sleep difficulty occurs despite adequate opportunity and circumstances for sleep.

C. At least one of the following forms of daytime impairment related to the night-time sleep difficulty is reported by the patient:

- fatigue or malaise
- attention, concentration, or memory impairment
- social or vocational dysfunction or poor school performance
- mood disturbance or irritability

- daytime sleepiness
- motivation, energy, or initiative reduction
- proneness to errors or accidents at work or while driving
- tension, headaches, or gastrointestinal symptoms in response to sleep loss
- concerns or worries about sleep.

Defining the cause of a sleep/wake disturbance in an insomnia patient is a complex task since it is often multifactorial. In fact, a confluence of factors that support multiple insomnia diagnoses may be judged important in many patients with insomnia. Although selection of a single diagnosis is preferable and this selection may be appropriate, such a selection should not necessarily imply the absence of a subset of factors relevant to an alternate diagnosis. When criteria for multiple insomnia diagnosis are met, all relevant diagnosis should be assigned.

2.1.2.3 Environmental sleep disorder

In the ICSD 2005, environmental sleep disorder is listed in the category of "other sleep disorders". Noise-induced sleep disturbance is one of the disturbing environmental factors that cause a complaint of either insomnia or daytime fatigue and somnolence.

The diagnostic criteria for environmental sleep disorder are the following.

A. The patient complains of insomnia, daytime fatigue or a parasomnia. In cases where daytime fatigue is present, the daytime fatigue may occur as a result of the accompanying insomnia or as a result of poor quality of nocturnal sleep.

B. The complaint is temporally associated with the introduction of a physically measurable stimulus or environmental circumstance that disturbs sleep.

C. It is the physical properties, rather than the psychological meaning of the environmental factor, that accounts for the complaint.

D. The sleep disturbance is not better explained by another sleep disorder, medical or neurological disorder, mental disorder, medication use or substance use disorder.

The prevalence of environmental sleep disorder is not known. Fewer than 5% of patients seen at sleep disorder centres receive this diagnosis.

International standardization and quantification for measurement of the depth of sleep is based on Rechtschaffen and Kales criteria from 1968. Sleep is divided into 30-second epochs, and a phase is only assessed if the specific features are evident for more than 50% of the epoch length. For example, wakefulness is scored when at least 15 seconds of continuous awakening is present. Arousal reactions not leading to macroscopic awakening were not included in the definition by Rechtschaffen and Kales. With the arousals as described by the American Sleep Disorders Association (1992) it is possible to display subvigilant sleep fragmentation, caused by intrinsic sensory and autonomic alarm reactions. An arousal index providing the arousal density (events per hour of sleep) was taken as a measure of the degree of severity. In one hour, 10–20 arousals are considered as normal in healthy adults. However, the use of EEG arousals with the American Sleep Disorders Association definition provides no sufficient explanation of daytime sleepiness (Ali, Pitson and Stradling 1996; Ayas et al., 2001) unless they are accompanied by vegetative arousals.

Regarding noise, different vigilance level assessments in various functional systems are important. Dumont, Montplaisir and Infante-Rivard (1988) proposed investigations of vegetative, motor and sensory functions independently of each other. One of the possible factors indicating disturbed sleep is a vegetative arousal index. A vegetative arousal index of more than 30 per hour is certainly considered as serious, more than 20 per hour as intermediate and more than 10 as a light form of sleep disorder.

With respect to insomnia (section 2.1.2), there is the possibility of misclassification if the general practitioner (GP) overlooks excessive noise as the possible cause of the complaint. There is also the possibility that the insomnia is aggravated by noise.

2.1.3 CONCLUSIONS

Published information on normal sleep can serve as an outline for normal values in PSG. However, these values are only informative, because each sleep laboratory must study control subjects to identify any significant effects on sleep that result from differences in technique or environment. Excessive daytime sleepiness is a consequence of disturbed night sleep and can be objectively assessed by MSLT, which provides an objective quantification of "sleepiness".

2.2 LONG-TERM HEALTH RISK MEDIATED BY SLEEP DISTURBANCES

2.2.1 STRESSORS, NEUROBEHAVIOURAL DATA AND FUNCTIONAL NEUROIMAGING

It is generally accepted that insufficient sleep and particularly sleep loss has a great influence on metabolic and endocrine functions (Spiegel, Leproult and van Cauter, 1999), as well as on inflammatory markers, and contributes to cardiovascular risk. C-reactive protein (CRP) as a major marker of the acute phase response to inflammatory reaction promotes secretion of inflammatory mediators by vascular endothelium and may be therefore directly involved in the development of atherosclerotic lesions. CRP as a risk predictor of strokes and heart attacks linearly increases with total and/or partial sleep loss (Meier-Ewert et al., 2004).

An additional factor, closely linked to cardiovascular health, glucose regulation and weight control, is leptin. Leptin is one of the major regulators of energy homeostasis and its circadian profile interacts closely with sleep.

Secretion of leptin increases at night and decreases during the day. A decreased leptin level, that is connected with sleep loss, increases appetite and predisposes to weight gain, impaired glucose tolerance and impaired host response.

Other studies have focused on how sleep loss affects neurobehavioural functions, especially neurocognitive performance. Functional brain imaging and EEG brain mapping studies show that the patterns of functional connectivity between brain regions, evident in the performance of specific cognitive tasks, are altered by sleep loss (NCSDR, 2003). According to this finding, the maintenance of sustained performance during sleep loss may depend upon regional functional plasticity.

Cumulative waking, neurocognitive deficits and instability of state that develop from chronic sleep loss have a basis in a neurobiological process that can integrate homoeostatic pressure for sleep across days. Increased efforts have helped to determine the roles of REM and non-REM sleep in memory.
Functional brain imaging techniques, such as positron emission tomography (PET), functional magnetic resonance imaging (fMRI), magnetic resonance spectroscopy (MRS), single photon emission computed tomography (SPECT) and magneto-electroencephalography (MEG), have recently been analysed in a study of sleep and waking (NCSDR, 2003). These techniques allow the measurement of metabolic and neurochemical activity throughout the brain, and can reveal dynamic patterns of regional cerebral activity during various brain states, including stages of sleep and levels of alertness during wakefulness or during functional challenge. These techniques can also help identify both normal and abnormal sleep/wake processes.

In the last five years, functional neuroimaging techniques (particularly PET) have revealed that non-REM sleep is associated with the deactivation of central encephalic regions (brainstem, thalamus, basal ganglia) and multimodal association cortices (for instance, prefrontal and superior temporal/inferior parietal regions). REM sleep is characterized by reactivation of all central encephalic regions deactivated during non-REM sleep except the multimodal association areas. PET studies during sleep-deprived wakefulness have revealed regional cerebral deactivations that are especially prominent in prefrontal and inferior parietal/superior temporal cortices, and in the thalamus. This pattern is consistent and helpful in explaining the nature of cognitive performance deficits that occur during sleep loss. As revealed by means of fMRI techniques during cognitive task performance, the maintenance of performance following sleep loss may be a function of the extent to which other cortical brain regions can be recruited for task performance in the sleep-deprived state.

PET, SPECT and fMRI studies have revealed, in depressed patients, initially elevated activation in anterior cingulate and medial orbital cortices (NCSDR, 2003). In these patients, sleep deprivation reduces this regional hyperactivation, and improvements in mood are a function of the extent to which this activity is reduced. These studies point to possible mechanisms by which antidepressant drugs may exert their effects. Further research should be oriented towards neuroimaging and measurements of changes in the brain's metabolic activity at the neurotransmitter level.

2.2.2 SIGNALS MEDIATED BY A SUBCORTICAL AREA (THE AMYGDALA), THE ROLE OF STRESS HORMONES IN SLEEP DISTURBANCE AND THEIR HEALTH CONSEQUENCES

Experimental as well as clinical studies (Waye et al., 2003; Ising and Kruppa, 2004) showed that the first and fastest signal of stressors introduced by noise is detected and mediated by a subcortical area represented by the amygdala while the stress response to noise is mediated primarily by the hypothalamus-pituitary-adrenal (HPA) axis. A major intrinsic marker of the circadian rhythm is in the level of circulating corticosteroids derived from activity within the HPA axis. A protracted stress response with activation of the HPA axis is a major physiological response to environmental stressors. The cortisol response to awakening is an index of adrenocortical activity, and long-term nocturnal noise exposures may lead, in persons liable to be stressed by noise, to permanently increased cortisol concentration above the normal range. The hypothesis that an increased risk of cardiovascular diseases is connected with stress concepts is generally accepted (Ekstedt, Åkerstedt and Soderstrom, 2004; Ising and Kruppa, 2004). Stress reactions may lead to derangement of normal neurovegetative and hormonal processes and influence vital body functions. Cardiovascular parameters such as BP, cardiac function, serum cholesterol, triglycerides, free fatty acids and haemostatic factors (fibrinogen) impede the blood flow through increased viscosity and presumably blood sugar concentration as well. Insulin resistance and diabetes mellitus, stress ulcers and immune system deficiency are also frequent consequences of stress reaction. Disturbed sleep may lead to immunosuppression and diminished protein synthesis (Horne, 1988).

As well as nonspecific effects of the stress response on the functioning of the immune system, there is considerable evidence for a relation between sleep, especially SWS, and the immune system (Brown, 1992). This evidence includes surges of certain immune parameters and growth hormones at onset of SWS, correlation of non-REM sleep, total sleep time and sleep efficiency with natural killer cell activity, and correlation of SWS with recovery from infections. These data, taken together with information on the effect of intermittent transportation noise on SWS during the first sleep cycles and overnight, suggest that the immune response could also be impacted directly by environmental noise during sleep (Carter, 1996).

2.2.3 SLEEP RESTRICTION, ENVIRONMENTAL STRESSORS (NOISE) AND BEHAVIOURAL, MEDICAL AND SOCIAL HEALTH CONSEQUENCES OF INSUFFICIENT SLEEP: RISK OF MORBIDITY AND MORTALITY

Sleep restriction due to environmental stressors leads to primary sleep disorders, but health is also influenced by the consequence of stress response to noise mediated by the HPA axis and/or by restriction of specific sleep stages (see above).

Sleep restriction leads, in approximately 40% of affected subjects, to daytime sleepiness that interferes with work and social functioning. Excessive daytime sleepiness is thus a major public health problem, as it interferes with daily activities, with consequences including cognitive problems, motor vehicle accidents (especially at night), poor job performance and reduced productivity (Lavie, Pillar and Malhotra, 2002). In the last decade, experimentally based data have been collected on chronic restriction of sleep (by 1–4 hours a night), accumulating daytime sleepiness and cognitive impairment. Most individuals develop cognitive deficits from chronic sleep debt after only a few nights of reduced sleep quality or quantity. New evidence suggests additional important health-related consequences of sleep debt related to common viral illnesses, diabetes, obesity, heart disease, depression and other age-related chronic disorders.

The effects and consequences of sleep deprivation are summarized in Table 2.4 (Lavie, Pillar and Malhotra, 2002).

The relationship between sleep quantity and quality and estimates of morbidity and mortality remains controversial. Epidemiological data (NCSDR, 2003) suggest that habitually short sleep (less than 6 hours sleep per night) is associated with increased mortality. Epidemiological studies in recent years elucidated, however, that too much sleep is a problem as well. Kripke et al. (2002) evaluated a questionnaire study of 1.1 million men and women aged 30–102 years and found the lowest mortality risk between respondents sleeping 7 hours per night.

Type	Short-term	Long-term
Behavioural	Sleepiness Mood changes Irritability and nervousness	Depression/mania Violence
Cognitive	Impairment of function	Difficulty in learning new skills Short-term memory problems Difficulty with complex tasks Slow reaction time
Neurological	Mild and quickly reversible effects	Cerebellar ataxia, nystagmus, tremor, ptosis, slurred speech, increased reflexes, increased sensitivity to pain
Biochemical	Increased metabolic rate Increased thyroid activity Insulin resistance	Decreased weight despite increased caloric intake (in animals) Diabetes, obesity (in humans)
Others	Hypothermia Immune function impairment	Susceptibility to viral illness

Table 2.4
Consequences of sleep deprivation

Mortality risk significantly increased when sleep duration was less than 6 or higher than 8 hours per night. Other authors have also published similar results (Patel et al., 2004; Tamakoshi and Ohno, 2004). Patel et al. (2004) in a prospective study of sleep duration and mortality risk in 5409 women confirmed previous findings that mortality risk is lowest among those sleeping 6–7 hours per night. The mortality risk for death from other causes significantly increased in women sleeping less than 5 and more than 9 hours per night. It is not clear how the length of sleep can increase this risk, although animal evidence points to a direct link between sleep time and lifespan (see section 2.5 in this chapter). Up to now, no epidemiological prospective study has been published that examines the relationship between sleep and health outcomes (morbidity and mortality) with subjective and objective estimates. Recent studies, however, show that sleep duration of least 8 hours is necessary for optimal performance and for prevention of daytime sleepiness and accumulation of sleep debt.

Environmental stressors, including noise, mostly cause insomnia. Insomnia also involves daytime consequences, such as tiredness, lack of energy, difficulty concentrating and irritability. A reasonable prevalence estimate for chronic insomnia in the general population is about 10%; for insomnia of any duration or severity this rises to between 30% and 50%, and incidence increases with ageing. In the course of perimenopausal time, women are particularly vulnerable to developing this complaint. The major consequences and co-morbidity of chronic insomnia (see Table 2.5) consist of behavioural, psychiatric and medical problems. Several studies also report a higher mortality risk (Zorick and Walsh, 2000).

Table 2.5 Consequences of chronic insomnia

Type	Consequence
Behavioural	Poor performance at work, fatigue, memory difficulties, concentration problems, motor vehicle accidents
Psychiatric	Depression, anxiety conditions, alcohol and other substance abuse
Medical	Cardiovascular, respiratory, renal, gastrointestinal, musculoskeletal disorders Obesity Impaired immune system function
Mortality	Increased risk is reported

2.2.3.1 *Behavioural consequences*

Transient (short-term) insomnia is usually accompanied by spells of daytime sleepiness and performance impairment the next day. Persistent (long-term) insomnia tends to be associated with poor performance at work, fatigue, memory difficulties, concentration problems and twice as many fatigue-related motor vehicle accidents as in good sleepers.

2.2.3.2 *Psychiatric conditions*

Epidemiological research indicates that the prevalence of any psychiatric disorder is two or three times higher in insomniacs. The risk of depression as a co-morbid state appears to be particularly strong, being approximately four times more likely in insomnia patients. Furthermore, insomnia may be an early marker for psychiatric disorders such as depression, anxiety conditions and alcohol abuse. Anxiety has been quite commonly found in insomniacs compared with the general population. About 25–40% of insomnia patients are estimated to have significant anxiety, and the abuse of alcohol and other substances is increased in insomniacs relative to good sleepers (Ford and Kamerow, 1989). Samples of unselected psychiatric patients have about a threefold increase in the frequency of insomnia compared with healthy control subjects, and the severity of the condition correlates with the intensity of the psychiatric symptoms. Among samples of outpatients who consulted their GPs for insomnia, about 50% presented with psychiatric conditions, and about half of these patients were probably depressed (Zorick and Walsh, 2000).

2.2.3.3 *Medical consequences*

Insomnia has been statistically associated with various medical conditions, including disorders of the cardiovascular, respiratory, gastrointestinal, renal and musculoskeletal systems. A large series of insomniac patients showed that poor sleepers are more than twice as much at risk of ischaemic heart disease (IHD) as good sleepers (Hyyppa and Kronholm, 1989). Insomnia patients were also shown (Irwin, Fortner and Clark, 1995) to have impaired immune system function. Keith et al. (2006) hypothesize a connection between sleep deficit as one of the possible factors to explain the rise in obesity. Hormone changes and animal experiments apparently support this.

2.2.3.4 *Mortality risk*

Only a few epidemiological studies deal with mortality in insomniacs. According to Kripke et al. (1979), reduced sleep time is a greater mortality risk than smoking, hypertension and cardiac disease. Higher death rates are also reported among short sleepers. In this respect, however, further systematic investigation of the link between insomnia, short sleep and death is desirable.

2.3 RISK GROUPS

Risk groups are people who may be either sensitive (showing more reaction to a stimulus than the average), are more exposed (also called vulnerable) or both.

2.3.1 HEALTH EFFECTS OF DISTURBED SLEEP IN CHILDREN

Although children appear to tolerate a single night of restricted sleep with no detrimental effect on performance of brief tasks, perhaps more prolonged restriction and prolonged tasks similar to those required in school would show negative effects. In addition, as children seem to require more time to recuperate fully from nocturnal sleep restriction than adults (Carskadon, Harvey and Dement, 1981a), with additional nights of partial sleep deprivation, cumulative sleepiness might become a significant problem.

Empirical data that directly address the effects of repeated sleep loss on children's mood or cognitive function are sparse. A range of clinical and observational data support a general picture that inadequate sleep results in tiredness, difficulties in focusing attention, low thresholds for negative reactions (irritability and easy frustration), as well as difficulty in controlling impulses and emotions. In some cases, these symptoms resemble attention-deficit hyperactivity disorder (ADHD).

Environmental noise experienced at home during night-time is a sometimes unpredictable and most often discontinuous event (for example traffic noise, aircraft or train noise, a noisy environment for other reasons, for instance proximity with a discotheque, etc.), that might lead to sleep disruption without leading to behavioural awakenings through the alteration of sleep microstructure, in a similar manner as other sleep disturbing events such as respiratory disturbances.

Therefore, in respect of clinical settings, we can assume that, in children, an experimental model for the consequences of noise can be represented by respiratory disturbances during sleep, such as snoring, upper airway resistance syndrome (UARS) or obstructive sleep apnoea syndrome (OSAS), either for the noise produced by snoring or for the effects on the arousal system and sleep microstructure.

For this reason, this section describes the well-studied effects of sleep breathing disorders on children's health and then evaluates the indicators of sleep disruption from the point of view of sleep microstructure.

In the literature few data on the medium- and long-term effects of disturbed sleep in children are available from the longitudinal point of view. Most reports focused on respiratory disturbances during sleep as a theoretical model to evaluate the long-term effects of disturbed sleep in children. This review reports on the medium- and long-term negative consequences of disturbed sleep on cognitive functioning, behaviour, mental health, growth and the cardiovascular system.

2.3.1.1 Sleep deprivation in children

The effects of sleep deprivation were evaluated in children. The findings only indirectly pertain to this general report, although repeated noise-induced sleep disruption favours sleep deprivation.

In another study, 15 healthy infants aged 78+/-7 days were studied during two nights: one night was preceded by sleep deprivation (kept awake for as long as possible beyond their habitual bedtime: median onset 150 min; range 0–210 min) (Thomas et al., 1996). Of the 15 children, 13 slept supine, 12 were breastfed and 4 were from smoking parents. Following sleep deprivation, infants maintained a greater proportion of quiet sleep (44% vs. 39%; p=.002). There was no measurable change in arousal propensity by either graded photic (stroboscope) or auditory stimuli (1 kHz pure tone, delivered in the midline of the cot, from 73 dB and increased in 3 dB steps to 100 dB) during quiet sleep.

Forty-nine Finnish children (26 boys/23 girls) aged 7–12 years were interviewed together with their parents and school teachers, and recorded for 72 hours with a belt-worn activity monitor during weekdays.

The objectively measured true sleep time was associated with psychiatric symptoms reported by a teacher. The decreased amount of sleep was associated more with externalizing than internalizing types of symptoms (aggressive and delinquent behaviour, attention, social, and somatic problems) (Aronen et al., 2000).

In a survey, it was also shown that out of 100 Belgian school children, aged between 9 and12 years, those with poor sleep (insomnia) were also showing more frequent poor school performance (failure to comply with expected grades) than good sleepers. The relation between poor sleep and a noisy environment was, however, not evaluated (Kahn et al., 1989).

2.3.1.2 Neurocognitive manifestations

Several studies in adults have shown that sleep fragmentation and hypoxaemia can result in daytime tiredness and loss of concentration, retrograde amnesia, disorientation, morning confusion, aggression, irritability, anxiety attacks and depression. One could hypothesize that sleep fragmentation and hypoxaemia would affect the neuropsychological and cognitive performance also in children, where the impact of abnormal sleep may be even greater than in adults. In fact, neurocognitive and behavioural deficits and school problems have been reported recently in children with sleep-related obstructive breathing disorders (SROBD).

2.3.1.3 Attention capacity

This represents the ability to remain focused on a task and appropriately attend to stimuli in the environment. Taken together the studies to date indicate that children with SROBD are less reflective, more impulsive, and show poorer sustained and selective attention. Blunden et al. (2000) reported that, compared to 16 controls, 16 children with mild SROBD showed reduced selective and sustained attention. Owens-Stively et al. (1997) suggested a dose–response in attention–impulsivity with moderate to severe obstructive sleep apnoea syndrome (OSAS) children showing greater deficits than mild OSAS children. Importantly, early treatment showed that attention deficits in children with OSAS are reversible (Guilleminault et al., 1982b). In another study, 12 children with moderate to severe OSAS showed a significant reduction in inattention and an improvement in aggressive and hyperactive behaviours and vigilance after surgical treatment (Ali, Pitson and Stradling, 1996).

2.3.1.4 Memory

Rhodes et al. (1995) found inverse correlations between memory and learning performance and the apnoea hypopnea index in 14 morbidly obese children. Smaller deficits were observed by Blunden et al. (2000), who found in their sample of children with mild SROBD that mean global memory performance was in the lower end of the normal range compared to controls.

A recent study using actigraphy in normal school-age children showed that lower sleep efficiency and longer sleep latency were associated with a higher percentage of incorrect responses in working memory tasks; shorter sleep duration was associated with performing tasks at the highest load level only. Also, controlling for age, gender, and socioeconomic status, sleep efficiency and latency were significantly associated with the mean incorrect response rate in auditory working memory tasks. This study showed that sleep quality (evaluated as sleep efficiency = 100* [sleep + light sleep]/duration) is more strongly associated with performance in working memory tasks than sleep duration, suggesting that in assessing sleep, attention should be directed not only at the amount of sleep but also at sleep quality.

2.3.1.5 *Intelligence*

Inspection of the mean IQ scores reported in the study by Rhodes et al. (1995) suggested that their sample of five obese children with moderate to severe OSAS performed in the borderline range whereas controls performed in the normal range. Blunden et al. (2000) showed smaller deficits in children with mild SROBD whose mean verbal and global IQ were in the lower end of the normal range.

It remains unclear as to whether the putative negative effects of SROBD on intelligence are global in nature or confined to specific areas such as verbal rather than performance or visuospatial intelligence and whether these impairments can be reversed.

2.3.1.6 *Learning and school performance*

It has been widely reported (Stradling et al., 1990; Guilleminault et al., 1996; Richards and Ferdman, 2000) that children with SROBD show reduced academic performance and learning.

Weissbluth et al. (1983) found that poor academic achievers had a higher prevalence of night-time snoring (38% vs. 21%) and breathing difficulties (13% vs. 6%). Out of 297 children with SROBD (22% snorers and 18% sleep-associated gas exchange abnormalities), 40% were in the lowest 10th percentile of academic performance (Gozal, 1998) and SROBD in early childhood may continue to adversely affect learning in later years (Gozal and Pope, 2001). Gozal (1998) found in his sample of poor academic achievers that school grades improved post-adenotonsillectomy in treated but not untreated children.

As well as those with SROBD, healthy normal children with fragmented sleep (measured by actigraphy) also showed lower performance on neurobehavioural functioning (NBF) measures, particularly those associated with more complex tasks, and also had higher rates of behavioural problems (Sadeh, Gruber and Raviv, 2002). Furthermore, in normal children without sleep disorders, modest sleep restriction can also affect children's NBF. Sadeh, Gruber and Raviv (2003) monitored 77 children for 5 nights with activity monitors. On the third evening, the children were asked to extend or restrict their sleep by an hour on the following three nights. Their NBF was reassessed on the sixth day following the experimental sleep manipulation and showed that sleep restriction led to improved sleep quality and to reduced reported alertness.

These studies suggest that fragmented sleep or insufficient sleep is highly relevant during childhood and that children are sensitive to modest alterations in their natural sleep duration.

Early reports documented that untreated OSAS can have long-term negative effects, such as failure to thrive, cor pulmonale and mental retardation. These severe consequences are less common now due to early diagnosis and treatment, but recent reports have focused on other long-term effects mainly related to neurocognitive deficits, such as poor learning, behavioural problems and ADHD (Marcus, 2001).

Gozal and Pope (2001) tried to determine the potential long-term impact of early childhood snoring. Analysing questionnaires of 797 children in a low academic performance group (LP) and 791 in a high academic performance (HP) group, they found that frequent and loud snoring during early childhood was reported in 103 LP children (12.9%) compared with 40 HP children (5.1%). Therefore, children with lower academic performance in middle school are more likely to have snored during early childhood and to require surgery for snoring compared with better performing schoolmates. These findings suggest that children who experienced sleep-disordered breathing during a period traditionally associated with major brain growth and substantial acquisition of cognitive and intellectual capabilities may suffer from a partially irreversible compromise of their a priori potential for academic achievement. Three major components that result from the intermittent upper airway obstruction that occurs during sleep in children could theoretically contribute to such neurocognitive deficits, namely episodic hypoxia, repeated arousal leading to sleep fragmentation and sleep deprivation, and periodic or continuous alveolar hypoventilation.

Schooling problems may underlie more extensive behavioural disturbances such as restlessness, aggressive behaviour, EDS and poor neurocognitive test performances. Nearly 20–30% of children affected by OSAS or loud and frequent snoring show important signs of behavioural problems such as inattention and hyperactivity. Problems similar to symptoms of ADHD are linked to the presence of repeated sleep arousals, and intermittent hypoxic events, inducing a lack of behavioural inhibition with negative implications for working memory, motor control and self-regulation of motivation and affect.

In contrast with these data, Engle-Friedman et al. (2003) recently found a significant improvement of functions, at least in mild to moderate OSAS, when measured several months following an adenotonsillectomy, but they confirmed that their results could not rule out the possibility, even after treatment, of partial irreversible damage to academic function that may be detected only later in life. In addition, they stated that adults who also had deficits of neurocognitive executive functions related to the prefrontal area failed to improve significantly after treatment.

The negative long-term effects may be mediated by the irreversible alteration of the prefrontal cortex (PFC) and be related to structural changes of the brain as a consequence of both hypoxaemia and sleep fragmentation induced by OSAS or other pathologies affecting sleep.

In a recent report concerning OSAS adults, Macey et al. (2002) demonstrated grey matter loss in cerebral sites involved in motor regulation of the upper airway as well as in areas contributing to cognitive function (frontal and parietal cortex, temporal lobe, anterior cingulate, hippocampus and cerebellum). It can be argued that, in critical stages of brain development (that is, in childhood), these effects can lead to even more severe consequences, which could explain the negative long-term effects.

It is speculative to think that the remodelling of the brain could also be mediated by sleep and, therefore, sleep fragmentation could affect the process of brain plasticity (that is, the capacity of the brain to modify its structure and function over time). Recent studies showing experience-dependent gene-expression of gene *zif-268* during paradoxical sleep in rats exposed to a rich sensorimotor environment, and the role of sleep in enhancing the remodelling of ocular dominance in the developing visual cortex are also in line with the hypothesis that sleep affects neuronal plasticity and memory processes (Peigneux et al., 2001).

2.3.1.7 Neurobehavioural manifestations

Behavioural disturbances are common in children with SRODB, with higher prevalence rates of both internalized (for instance being withdrawn, shy, anxious and psychosomatic) and externalized (for instance impulsivity, hyperactivity, aggression and delinquency) problematic behaviours (Blunden, Lushington and Kennedy, 2001). The most frequently documented problematic behaviour in children with SROBD is attention deficit hyperactivity with a prevalence rate of 20–40% (Weissbluth et al., 1983; Ali, Pitson and Stradling, 1993). Conversely, children with ADHD showed a high prevalence rate of snoring (Chervin et al., 1997) and a co-diagnosis of ADHD has been reported in 8–12% of children with OSAS (O'Brien and Gozal, 2002).

A few studies have documented that children with sleep disorders tend to have behavioural problems similar to those observed in children with ADHD. A survey of 782 children documented daytime sleepiness, hyperactivity, and aggressive behaviour in children who snored, with 27% and 38% of children at high risk for a sleep or breathing disorder displaying clinically significant levels of inattention and hyperactive behaviour, respectively (Ali, Pitson and Stradling, 1994).

At 3 years of age children with persistent sleep problems (n = 308) were more likely to have behaviour problems, especially tantrums and behaviour management problems (Zuckerman, Stevenson and Bailey, 1987).

In a study of 16 children with a mean age of 12+/-4 years suffering from chronic pain due to juvenile rheumatoid arthritis and secondary poor sleep, polysomnographic recordings showed poorer night-time sleep, longer afternoon naptime and more daytime sleepiness than normal values from the literature (Zamir et al., 1998). In a school survey of children aged 9–12 years (n = 1000), those with poor sleep (insomnia for more than 6 months) had poorer school performance, defined as failure to comply with expected grades, than good sleepers. Their learning problems were tentatively attributed to the long-term effect of poor sleep (Kahn et al., 1989).

A questionnaire administered to children aged 4–12 years (n = 472) showed a relation between sleep problems and tiredness during the day (Stein et al., 2001).

In children aged 9–12 years (n = 77), shortening sleep by one hour was associated with reduced alertness and significant lowering of neurobehavioural functioning (Sadeh, Gruber and Raviv, 2003). In school-age children (n = 140) recorded at home with an actigraph, a significant relation was shown between the presences of fragmented sleep, daytime sleepiness and lower performance in neurobehavioural functioning evaluated by various performance tests (Sadeh, Gruber and Raviv, 2000). These children also had higher rates of behavioural problems, as reported by their parents (Sadeh, Gruber and Raviv, 2002).

In Finland, children aged 7–12 years (n = 49) were interviewed together with their parents and schoolteachers and recorded for 72 hours with a belt-worn activity monitor during weekdays. The decreased amount of sleep was associated with symptoms such as aggressive and delinquent behaviour, attention, social and somatic problems. The findings of this research were better associated with the teachers' than the parents' reports, suggesting that parents may be unaware of their child's sleep deficiencies as the behavioural problems may be more evident at school than at home (Aronen et al., 2000).

A prospective long-term study conducted in Sweden on 2518 children revealed that within a subgroup of 27 children with severe and chronic sleep problems, 7 children developed symptoms that met the criteria for ADHD by the age of 5.5 years (Thunström, 2002). Compared to the other children with sleep problems, these subjects had more frequent psychosocial problems in the family, bedtime struggles and long sleep latency at bedtime.

A population-based, cross-sectional questionnaire survey was conducted in Massachusetts on 30 195 children aged 5 years (Gottlieb et al., 2003). Children described by their parents as having sleep-disordered breathing (snoring, noisy breathing, apnoea) were significantly more likely to have daytime sleepiness and problem behaviours, including hyperactivity, inattention and aggressiveness (all with an odds ratio >2.0). These problem behaviours were suggestive of ADHD.

Similar findings were found in a group of children aged 5–7 years with periodic limb movement disorder who were studied polygraphically and their recording compared with those of age-matched children with ADHD. Their repeated sleep fragmentation resulting from the periodic limb movement disorder favoured the development of symptoms similar to those seen in ADHD (Crabtree et al., 2003).

The parents of a group of children with an average age of 8.6 years (range 2–17 years) reported that their children had difficult behaviours on the day that followed a 4-hour night-time sleep restriction (Wassmer et al., 1999). In one study, a 2-hour sleep reduction induced by delayed bedtime has been shown to increase daytime sleepiness, mainly during morning hours (Ishihara and Miyke, 1998; Ishihara, 1999).

Following one night of 4 hours of sleep deprivation imposed on children (aged 11–13 years), a decrease in performance tests has been observed (Carskadon, Harvey and Dement, 1981a).

Following one night's sleep loss, adolescents showed increased sleepiness, fatigue and reaction time. They selected less difficult academic tasks during a set of tests, but the percentages of correct responses were comparable to those seen following a normal night's sleep (Engle-Friedman et al., 2003).

Another study has been conducted on 82 children, aged 8–15 years. They were assigned an optimized, 10-hour night of sleep, or a restricted 4-hour night of sleep. Sleep restriction was associated with shorter daytime sleep latency, increased subjective sleepiness, and increased sleepy and inattentive behaviours, but was not associated with increased hyperactive-impulsive behaviour or impaired performance in tests of response inhibition and sustained attention (Fallone et al., 2001).

2.3.1.8 *Mental health*

A recent longitudinal study on the outcomes of early life sleep problems and their relation to behaviour problems in early childhood stressed the importance of studying the natural history of sleep problems and their consequences in order to identify whether persistent or recurrent sleep problems at age 3–4 years are associated with co-morbidities such as child behaviour problems, maternal depression and poor family functioning (Peiyoong, Hiscock and Wake, 2003).

The authors found that night waking at 3–4 years of age continued to be common. Seventy eight percent of mothers reported that their child awoke during the night at least once during the week, and of these waking children, 43% were reported to have awakenings 4 or more nights per week. Children with early sleep problems had significantly higher mean scores on internalizing and externalizing behaviour and the aggressive behaviour and somatic problems subscales of the Child Behavior Checklist (CBCL).

It has been noted that within groups of children and adolescents with psychiatric, behavioural or emotional problems, rates of sleep disorders are elevated (Sadeh et al., 1995). On the other hand, children and adolescents with disturbed sleep report more depression, anxiety, irritability, fearfulness, anger, tenseness, emotional instability, inattention and conduct problems, drug use and alcohol use.

Only a few longitudinal studies in adolescents have evaluated the impact of insomnia on future functioning. In a large sample of 11–17-year-old adolescents, followed for one year, using symptoms of DSM-IV criteria for insomnia, Roberts, Roberts and Chen (2002) found that nearly 18% of the youths 11–17 years of age reported non-restorative sleep almost every day in the past month, over 6% reported difficulty in initiating sleep, over 5% waking up frequently during the night, another 3% had early-morning awakening almost every day, over 7% reported daytime fatigue and 5% daytime sleepiness. Combining "often" and "almost every day" response categories dramatically increases prevalence, ranging from 60% for non-restorative sleep to 23% for daytime fatigue and 12% for waking up at night with difficulty going back to sleep. The re-evaluation of the sample at follow-up showed that insomnia predicted two indicators of psychological functioning: self-esteem and symptoms of depression (Roberts, Roberts and Chen, 2002).

2.3.1.9 *Growth impairment*

Failure to thrive is a well-known complication of disturbed sleep and childhood OSAS. The cause of poor growth is not known, although many different reasons have been implicated: (a) poor caloric intake associated with adenotonsillar hypertrophy; (b) excessive caloric expenditure secondary to increased work of breathing; (c) abnormal growth hormone (GH) release secondary to loss of deep non-REM sleep. The relative roles of these factors are unclear (Marcus et al., 1994; ATS, 1999). Circulating concentrations of insulin-like growth factor-I (IGF-I) and IGF-binding protein 3 (IGFBP-3) reflect mean daily GH levels, and seem to correlate well with physiological changes in GH secretion. In the operated children with initial OSAS a highly significant reduction in the apnoea-hypopnea index (AHI) was found and both the IGF-I and the IGFBP-3 concentrations increased significantly. GH is released in a pulsatile fashion; the initial secretion is synchronized with the onset of SWS and strongly correlated with slow-wave activity, within 90 to 120 minutes from the onset of sleep (Nieminen et al., 2002). In OSAS children, the sleep architecture is relatively well-preserved, but the microstructural alteration of SWS due to micro-arousals induced by respiratory disturbance could play a role in the abnormal profile of GH secretion.

2.3.1.10 *Cardiovascular complications*

Children with OSAS had a significantly higher diastolic blood pressure (BP) than those with primary snoring. Multiple linear regression showed that BP could be predicted by apnoea index, body mass index and age. The aetiology of OSAS-related hypertension is thought to be due to a number of factors, particularly sympathetic nervous system activation secondary to arousal and, to a lesser degree, hypoxaemia.

Although cortical arousals at the termination of obstructive apnoeas are less common in children than in adults, children may manifest signs of subcortical arousal, including autonomic changes such as tachycardia. It is therefore possible that these subcortical arousals are associated with elevations of BP. A correlation between the frequency of obstructive apnoea and BP, but no correlation between SaO2 (arterial oxygen saturation) and BP was found, suggesting that respiratory-related subcortical arousals rather than hypoxaemia may be a major determinant of BP elevation in children (Marcus, Greene and Carroll, 1998). Similarly to BP variations induced by OSAS, other studies suggest that chronic exposure to environmental noise during sleep could contribute to a permanent increases in BP in otherwise healthy individuals and that no habituation to noise was apparent over three consecutive sleep sessions (Carter et al., 2002). This is further elaborated in Chapter 4, section 4.5.

2.3.1.11 Risk of accidents

Only one study was found that evaluated the association between sleep and duration of wakefulness and childhood unintentional injury (Valent, Brusaferro and Barbone, 2001).

Two hundred and ninety-two injured children who attended the Children's Emergency Centre in Udine, Italy, or their parents were interviewed following a structured questionnaire. The sleeping time and wakefulness of the child was assessed retrospectively for each of the 48 hours before injury. For each child, the authors compared the 24 hours immediately before the injury (hours 1–24; case period) with hours 25–48 (control period).

Overall, more children had longer hours of sleep during the control period than during the case period. A direct association between injury risk and sleeping less than 10 hours was found among boys (RR: 2.33; 95% CI: 1.07–5.09) but not among girls (RR: 1.00; 95% CI: .29–3.45). The study also found a direct association between injury occurring between 16.00 and midnight, and being awake for at least 8 hours before injury occurred (both sexes, RR: 4.00; 95% CI: 1.13–14.17). Sleeping less than 10 hours a day was associated with an 86% increase in injury risk. A significantly increased risk did not emerge in all subgroups of patients but it was evident among children aged 3–5 years, boys in particular. A fourfold increase in injury risk was also associated with being awake for at least 8 hours among males only. These findings demonstrated that inadequate sleep duration and lack of daytime naps are transient exposures that may increase the risk of injury among children. Results of a study on sleep disturbance and injury risk in young children show inadequate sleep duration and lack of daytime naps. A lack of daytime naps means transient exposures that may increase the risk of injury among children. Among children (boys in particular) aged 3–5 years, sleeping less than 10 hours a day was associated with an 86% increase in injury risk. A fourfold increase in injury risk was also associated with being awake for at least 8 hours.

Daytime sleepiness in children is often manifested by externalizing behaviours noted by parents or teachers, such as increased activity levels, aggression, impulsivity, as well as by poor concentration, instantiation irritability and moodiness (Fallone, Owens and Deane, 2002).

Analysing attendance at school, data show that accidents took place at school (25.6%) and at home (22.0%), and statistics show that there is a highly significant greater total accident rate among boys than among girls. The most frequent injuries happening at school are fractures and dislocation of joints, head injuries being more common among school injuries compared with spare-time injuries. Most injuries occurred when children were in sports areas and it is noteworthy that 25% of all injuries were caused through intentional violence by other pupils.

2.3.1.12 Use of sleeping pills

Several studies demonstrated that the use of sleeping pills is common among children and that paediatricians are prone to prescribe these medications. Twenty-five percent of firstborn infants had been given "sedatives" by 18 months (Ounsted and Hendrick, 1977). A research study into parental reports of 11 000 preschool children showed that 12% took psychoactive drugs, most commonly for sleep: 39% daily and 60% intermittently for 1–2 years (Kopferschmitt et al., 1992). Another study (Trott et al., 1995) revealed that 35% of prescriptions for children less than a year old were for sleep disturbances and that sleep disturbances were also the most common reason for prescribing medications to preschool children (23%). Two French surveys on adolescents showed that 10–12% of the respondents reported use of prescription or over-the-counter drugs for sleep disturbances (Patois, Valatz and Alperovitch, 1993; Ledoux, Choquet and Manfredi, 1994). Recently it has been reported that of 671 community-based United States paediatricians, 75% had recommended over-the-counter and 50% prescription medicines for insomnia during the past 6 months (Owens, Rosen and Mindell, 2003). In addition, an Italian survey showed that pharmacological treatment for sleep problems was prescribed during the past 6 months by 58.54% of paediatricians and by 61.21% of child neuropsychiatrists (Bruni et al., 2004).

2.3.2 BASIC INDIVIDUAL FACTORS: GENDER AND AGE

Gender shows itself to be an important predictor of disturbed sleep in virtually all epidemiological studies (Karacan et al., 1976; Bixler, Kales and Soldatos, 1979; Ancoli-Israel and Roth, 1999; Leger et al., 2000; Sateia et al., 2000). On the other hand, there does not seem to be much of a difference in polysomnographical parameters between males and females, except for the former losing SWS with increasing age and having slightly reduced sleep efficiency also with increasing age (Williams, Karacan and Hursch, 1974; Hume, Van and Watson, 1998). Ehlers and Kupfer (1997) timed the start of differences between genders to between 20 and 40 years. Spectral analysis also indicates slightly larger amounts of low frequency activity in females (Dijk, Beersma and Bloem, 1989; Dijk, Beersma and Van den Hofdakker, 1989). In addition, men seem to run a higher risk of morbidity and mortality related to sleep problems than women (Nilsson et al. 2001). The inconsistency between polysomnography and subjective measures has not been resolved but it may be important that most polysomnographical studies have controlled for anxiety and depression. Thus, it is conceivable that the higher level of subjective complaints in women reflects a higher prevalence of anxiety. The latter is a speculation, however. A confounding factor in gender comparisons is that phases in female biological cycles are also usually controlled for in polysomnographical studies, meaning that potential effects of, for example, menstruation, may not receive their proper weight. A recent review has gone through the literature in this area (Moline et al., 2003). It found that the luteal phase of the menstrual cycle is associated with subjective sleep problems, but polysomnographical studies have not supported this. Pregnancy affects sleep negatively as early as in the first trimester and the effects mainly involve awakenings and difficulties getting back to sleep. Napping is a frequent coping method. The post-partum period is often associated with severe sleep disruption, mainly due to feeding and comforting the infant. There seems to be some relation between sleep disruption and post-partum mood, but nothing is known about the causal relations. Menopause seems to involve disrupted sleep in relation to hot flushes, depression/anxiety and sleep-disordered breathing. Oestrogen is associated with improved sleep quality but it is not clear whether the effects are due to a reduction of hot flushes. Oestrogen also improves sleep-disordered breathing.

With respect to background factors, age is an established predictor of disturbed sleep (Karacan et al., 1976; Bixler, Kales and Soldatos, 1979; Ancoli-Israel and Roth, 1999; Ribet and Derriennic, 1999; Leger et al., 2000; Sateia et al., 2000). Interestingly, however, older age may be related to a lower risk of impaired awakening (Åkerstedt et al., 2002c), that is, in this study it was easier to wake up and one felt better rested with increasing age, while at the same time sleep quality was lower. The increased risk of disturbed sleep is consistent with the increasingly strong interference of the circadian morning upswing of the metabolism with increasing age (Dijk and Duffy, 1999). Thus sleep maintenance is impaired and when sleep is interrupted "spontaneously", the awakening is, by definition, easily accomplished and will be lacking in inertia. This ease of awakening may be interpreted as "being well-rested", and obviously the need for sleep is not great enough to prevent an effortless transition into wakefulness.

In addition, sleep homeostasis seems to be weakened with age in the sense that sleep becomes more fragmented and SWS or power density in the delta bands decrease (Williams, Karacan and Hursch, 1974; Bliwise, 1993; Dijk et al., 1999). As mentioned above, the effects are more pronounced in males, a fact that may be linked to reduced levels of growth hormone and testosterone.

2.3.3 PERSONS EXPOSED TO STRESSORS AS A RISK GROUP

A number of epidemiological studies point to a strong link between stress and sleep (Åkerstedt, 1987; Urponen et al., 1988; Ancoli-Israel and Roth, 1999). In fact, stress is considered the primary cause of persistent psychophysiological insomnia (Morin, Rodrigue and Ivers, 2003). That stress can affect proper sleep seems obvious, but Vgontzas et al. (2001) at Pennsylvania State University College of Medicine have found another reason why middle-aged men may be losing sleep. It is not just because of what they worry about; rather, it is due to "increased vulnerability of sleep to stress hormones".

As men age, it appears they become more sensitive to the stimulating effects of corticotropin-releasing hormones (CRH). When both young and middle-aged men were administered CRH, the older men remained awake longer and slept less deeply. (People who don't get enough of this "slow-wave" sleep may be more prone to depression.)

The increased prevalence of insomnia in middle age may, in fact, be the result of deteriorating sleep mechanisms associated with increased sensitivity to arousal-producing stress hormones, such as CRH and cortisol. In another study, the researchers compared patients with insomnia to those without sleep disturbances. They found that "insomniacs with the highest degree of sleep disturbance secreted the highest amount of cortisol, particularly in the evening and night-time hours", suggesting that chronic insomnia is a disorder of sustained hyperarousal of the body's stress response system. Also, recent epidemiological studies have shown a connection between disturbed sleep and later occurrence of stress-related disorders such as cardiovascular diseases (Parish and Shepard, 1990; Nilsson et al., 2001;

Leineweber et al., 2003) and diabetes type II (Nilsson et al., 2002). The mechanism has not been identified but both lipid and glucose metabolisms are impaired in relation to experimentally reduced sleep (Åkerstedt and Nilsson, 2003). Burnout is another result of long-term stress and a growing health problem in many industrialized countries (Weber and Jaekel-Reinhard, 2000). In Sweden, burnout is thought to account for most of the doubling of long-term sickness absence since the mid-1990s (RFV, 2003). The characteristic clinical symptoms of the condition are excessive and persistent fatigue, emotional distress and cognitive dysfunction (Kushnir and Melamed, 1992; Melamed, Kushnir and Sharom, 1992). Self-reports of disturbed sleep are pronounced in subjects scoring high on burnout (Melamed et al., 1999; Grossi et al., 2003). Since shortened and fragmented sleep is related to daytime sleepiness and impaired cognitive performance (Bonnet, 1985, 1986a, 1986b; Dinges et al., 1997; Gillberg and Åkerstedt, 1998; Åkerstedt, 1990), disturbed sleep might provide an important link between the state of chronic stress and the complaints of fatigue and cognitive dysfunction seen in burnout.

Partinen, Eskelinen and Tuomi (1984) investigated several occupational groups and found disturbed sleep to be most common among manual workers and much less so among physicians or managing directors. Geroldi et al. (1996) found in a retrospective study of older individuals (above the age of 75) that former white-collar workers reported better sleep than blue-collar workers. Kupperman et al. (1995) reported fewer sleep problems in subjects satisfied with work.

In what seems to be the most detailed study so far, Ribet and Derriennic (1999) studied more than 21 000 subjects in France, using a sleep disturbance index and logistic regression analysis. They found that shift work, a long working week, exposure to vibrations, and "having to hurry" appeared to be the main risk factors, controlling for age and gender. Disturbed sleep was more frequent in women (Karacan et al., 1976; Bixler, Kales and Soldatos, 1979; Ancoli-Israel and Roth, 1999) and in higher age groups.

The particular stressor linked to disturbed sleep may be linked to pressure of work (Urponen et al., 1988; Ancoli-Israel and Roth, 1999; Ribet and Derriennic, 1999; Åkerstedt et al., 2002b). The demands of work are a classical work stress factor and, when combined with low decision latitude, a relation has been shown to cardiovascular diseases (Theorell et al., 1998) and absenteeism (North et al., 1996). Interestingly, when "persistent thoughts about work" was added to the regression in the study by Åkerstedt et al. (2002b) this variable took over part of the role of work demands as a predictor. This suggests that it may not be work demands per se that are important, but rather their effect on unwinding after work. In two studies it has been demonstrated that even moderate worries about being woken during the night or having a negative feeling about the next day will affect sleep negatively, mainly reducing SWS (Torsvall and Åkerstedt, 1988; Kecklund and Åkerstedt, 1997). On the other hand, there is very little data to connect real life stress with polysomnographical indicators of disturbed sleep. Most studies have used rather innocuous and artificial stressors in a laboratory environment. Field studies of stress are virtually lacking, with some exceptions (Hall et al., 2000).

A lack of social support at work is a risk indicator for disturbed sleep (Åkerstedt et al., 2002b). Few previous data of this type have been found, but poor (general) social support has been associated with sleep complaints in Vietnam veterans (Fabsitz, Sholinsky and Goldberg, 1997). On the other hand, there are several studies indicating a close connection with poor social support for, for example, cardiovascular diseases (Arnetz et al., 1986) or muscle pain (Ahlberg-Hultén, Theorell and Sigala, 1995).

Interestingly, the metabolic changes seen after sleep curtailment in normal sleepers or in insomniacs and sleep apnoeics are similar to those seen in connection with stress. That is, lipid and glucose metabolisms are increased, as are cortisol levels (Spiegel, Leproult and van Cauter, 1999; Vgontzas et al., 2000, 2001). Together with the prospective links to stress-related diseases such as diabetes type II, to cardiovascular diseases as discussed above and with mortality (Kripke et al., 1979, 2002; Åkerstedt et al., 2002a; Dew et al., 2003), the findings could suggest that disturbed sleep may be an important mediator in the development of stress-related diseases.

2.3.4 SHIFT WORK AS A RISK FACTOR FOR SLEEP DISTURBANCE AND HEALTH EFFECTS

The dominating health problem reported by shift workers is disturbed sleep and wakefulness. At least three quarters of the shift working population is affected (Åkerstedt, 1988). When comparing individuals with a very negative attitude to shift work with those with a very positive one, the strongest discriminator seems to be the ability to obtain sufficient quality of sleep during the daytime (Axelsson et al., 2004). EEG studies of rotating shift workers and similar groups have shown that day sleep is 1–4 hours shorter than night sleep (Foret and Lantin, 1972; Foret and Benoit, 1974; Matsumoto, 1978; Tilley, Wilkinson and Drud, 1981; Torsvall et al., 1989; Mitler et al., 1997). The shorter time is due to the fact that sleep is terminated after only 4–6 hours without the individual being able to return to sleep. The sleep loss is primarily taken out of stage 2 sleep and stage REM sleep (dream sleep). Stages 3 and 4 ("deep" sleep) do not seem to be affected. Furthermore, the time taken to fall asleep (sleep latency) is usually shorter. Night sleep before a morning shift is also reduced but the termination is through artificial means and the awakening usually difficult and unpleasant (Dahlgren, 1981a; Tilley et al., 1982; Åkerstedt, Kecklund and Knutsson, 1991; Kecklund, 1996).

Interestingly, day sleep does not seem to improve much across a series of night shifts (Foret and Benoit, 1978; Dahlgren, 1981b). It appears, however, that night workers sleep slightly better (longer) than rotating workers on the night shift (Kripke, Cook and Lewis, 1971; Bryden and Holdstock, 1973; Tepas et al., 1981). The long-term effects of shift work on sleep are rather poorly understood. However, Dumont, Montplaisir and Infante-Rivard (1988) found that the amount of sleep/wake and related disturbances in present day workers were positively related to their previous experience of night work. Guilleminault et al. (1982a) found an over-representation of former shift workers with different clinical sleep/wake disturbances appearing at a sleep clinic. Recently, we have shown that in pairs of twins with different night work exposure, the exposed twin reports somewhat deteriorated sleep quality and health after retirement (Ingre and Åkerstedt, 2004).

The main reason for short daytime sleep is the influence exerted by the circadian rhythm. The more sleep is postponed from the evening towards noon next day, the more truncated it becomes and when noon is reached the trend reverts (Foret and Lantin, 1972; Åkerstedt and Gillberg, 1981). Thus, sleep during the morning hours is strongly interfered with, despite the sizeable sleep loss that, logically, should enhance the ability to maintain sleep (Czeisler et al., 1980). Also, homeostatic influences control sleep. For example, the expected 4–5 hours of daytime sleep, after a night spent awake, will be reduced to 2 hours if a normal night's sleep precedes it and to 3.5 hours if a 2-hour nap is allowed (Åkerstedt and Gillberg, 1986). Thus, the time of sleep termination depends on the balance between the circadian and homeostatic influences. The circadian homeostatic regulation of sleep has also been demonstrated in great detail in studies of forced or spontaneous desynchronization under conditions of temporal isolation and ad lib sleeping hours (Czeisler et al., 1980; Dijk and Czeisler, 1995).

2.3.4.1 Alertness, performance and safety

Night-oriented shift workers complain as much of fatigue and sleepiness as they do about disturbed sleep (Åkerstedt, 1988). The sleepiness is particularly severe on the night shift, hardly appears at all on the afternoon shift and is intermediate on the morning shift. The maximum is reached towards the early morning (05.00–07.00). Frequently, incidents of falling asleep occur during the night shift (Prokop and Prokop, 1955; Kogi and Ohta, 1975; Coleman and Dement, 1986). At least two thirds of the respondents report that they have experienced involuntary sleep during night work.

Ambulatory EEG recordings verify that incidents of actual sleep occur during night work in, for example, process operators (Torsvall et al., 1989). Other groups, such as train drivers or truck drivers show clear signs of incidents of falling asleep while driving at night (Caille and Bassano, 1977; Torsvall and Åkerstedt, 1987; Kecklund and Åkerstedt, 1993). This occurs towards the second half of the night and appears as repeated bursts of alpha and theta EEG activity, together with closed eyes and slow undulating eye movements. As a rule the bursts are short (1–15 seconds) but frequent, and seem to reflect lapses in the effort to fend off sleep. Approximately a quarter of the subjects recorded show the EEG/EOG patterns of fighting with sleep. This is clearly a larger proportion than what is found in the subjective reports of episodes of falling asleep.

As may be expected, sleepiness on the night shift is reflected in performance. One of the classics in this area is the study by Bjerner, Holm and Swensson (1955) who showed that errors in meter readings over a period of 20 years in a gas works had a pronounced peak on the night shift. There was also a secondary peak during the afternoons. Similarly, Brown (1949) demonstrated that telephone operators connected calls considerably slower at night. Hildebrandt, Rohmert and Rutenfranz (1974) found that train drivers failed to operate their alerting safety device more often at night than during the day. Most other studies of performance have used laboratory type tests and demonstrated, for example, reduced reaction time or poorer mental arithmetic on the night shift (Tepas et al., 1981; Tilley et al., 1982). Flight simulation studies have furthermore shown that the ability to "fly" a simulator (Klein, Bruner and Holtman, 1970), or to carry out a performance test (Dawson and Reid, 1997) at night may decrease to a level corresponding to that after moderate alcohol consumption (>0.05% blood alcohol) Interestingly, Wilkinson et al. (1989) demonstrated that reaction time performance on the night shift (nurses) was better in permanent than rotating shift workers.

If sleepiness is severe enough, interaction with the environment will cease and if this coincides with a critical need for action an accident may ensue. Such potential performance lapses due to night work sleepiness were seen in several of the train drivers discussed earlier (Torsvall and Åkerstedt, 1987). The transport area is where most of the available accident data on night shift sleepiness has been obtained (Lauber and Kayten, 1988). Thus, Harris (1977) and Hamelin (1987) demonstrated that single vehicle accidents have by far the greatest probability of occurring at night.

So do fatigue-related accidents (Reyner and Horne, 1995) but also most other types of accidents, for example head-on collisions and rear-end collisions (Åkerstedt, Kecklund and Horte, 2001). The National Transportation Safety Board ranks fatigue as one of the major causes of heavy vehicle accidents (NTSB, 1995).

For conventional industrial operations very little relevant data is available but fatal work accidents show a higher risk in shift workers (Åkerstedt et al., 2002a) and accidents in the automotive industry may exhibit night shift effects (Smith, Folkard and Poole, 1994). An interesting analysis has been put forward by the Association of Professional Sleep Societies' Committee on Catastrophes, Sleep and Public Policy (Mitler et al., 1988). Their consensus report notes that the nuclear plant meltdown at Chernobyl occurred at 01.35 and was due to human error (apparently related to work scheduling). Similarly, the Three Mile Island reactor accident occurred between 04.00 and 06.00 and was due not only to the stuck valve that caused a loss of coolant water but, more importantly, to the failure to recognize this event, leading to the near meltdown of the reactor. Similar incidents, although with the ultimate stage being prevented, occurred in 1985 at the Davis Besse reactor in Ohio and at the Rancho Seco reactor in California. Finally, the committee also states that the NASA Challenger space shuttle disaster stemmed from errors in judgement made in the early morning hours by people who had had insufficient sleep (through partial night work) for days prior to the launch. Still, there is very limited support for the notion that shift work outside the transport area actually carries a higher overall accident risk.

As with sleep, the two main factors behind sleepiness and performance impairment are circadian and homeostatic factors. Their effects may be difficult to separate in field studies but are clearly discernible in laboratory sleep deprivation studies (Fröberg et al., 1975) as well as in studies of forced desynchronization (Dijk, Duffy and Czeisler, 1992). Alertness falls rapidly after awakening but gradually levels out as wakefulness is extended. The circadian influence appears as a sine-shaped superimposition upon this exponential fall in alertness. Space does not permit a discussion of the derivation of these functions, but the reader is referred to Folkard and Åkerstedt (1991) in which the "three-process model of alertness regulation" is described. This model has been turned into computer software for predicting alertness and performance and to some extent accident risk.

2.3.4.2 Health effects

Gastrointestinal complaints are more common among night shift workers than among day workers. A review of a number of reports covering 34 047 persons with day or shift work found that ulcers occurred in 0.3–0.7% of day workers, in 5% of people with morning and afternoon shifts, in 2.515% of persons with rotating shift systems with night shifts, and in 10–30% of ex-shift workers (Angersbach et al., 1980). Several other studies have come to similar conclusions (Thiis-Evensen, 1958; Segawa et al., 1987; Harrington, 1994). Other gastrointestinal disorders, including gastritis, duodenitis and dysfunction of the digestive system are more common in shift workers than in day workers (Koller, 1983).

The pathophysiologic mechanism underlying gastrointestinal disease in shift workers is unclear, but one possible explanation is that intestinal enzymes and intestinal mobility are not synchronized with the sleep/wake pattern. Intestinal enzymes are secreted according to the circadian rhythm, and shift workers' intake of food is irregular compared with intestinal function (Suda and Saito, 1979; Smith, Colligan and Tasto, 1982). A high nightly intake of food may be related to increased lipid levels (Lennernås, Åkerstedt and Hambraeus, 1994) and eating at the circadian low point may be associated with altered metabolic responses (Hampton et al., 1996). In addition, reduced sleep affects lipid and glucose metabolism (Spiegel, Leproult and van Cauter, 1999).

A number of studies have reported a higher incidence of cardiovascular disease, especially coronary heart disease, in male shift workers than in men who work days (for review see Kristensen, 1989; Boggild and Knutsson, 1999). A study of 504 paper mill workers followed for 15 years found a dose–response relationship between years of shift work and incidence of coronary heart disease in the exposure interval 1–20 years of shift work (Knutsson et al., 1986). A study of 79 000 female nurses in the United States gave similar results (Kawachi et al., 1995) as did a study with more than 1 million Danish men (Tüchsen, 1993) and a cohort of Finnish workers (Tenkanen et al.,1997). As with gastrointestinal disease, a high prevalence of smoking among shift workers might contribute to the increased risk of coronary heart disease, but smoking alone cannot explain the observed excess risk (Knutsson, 1989b). Another possibility is disturbances of metabolic parameters such as lipids and glucose for which there is some support as discussed above.

Only a few studies have addressed the issue of pregnancy outcome in shift workers. In one study of laboratory employees, shift work during pregnancy was related to a significantly increased risk of miscarriage (RR: 3.2) (Axelsson, Lutz and Rylander, 1984). Another study of hospital employees also demonstrated an increased risk of miscarriage (RR: 1.44, 95% CI: 0.83–2.51) (Axelsson and Rylander, 1989). Lower birth weight in infants of mothers who worked irregular hours has been reported (Axelsson and Rylander, 1989; Nurminen, 1989). No teratogenic risk associated with shift work was reported (Nurminen, 1989).

The mortality of shift and day workers was researched by Taylor and Pocock (1972), who studied 8603 male manual workers in England and Wales between 1956 and 1968. Day, shift, and ex-shift workers were compared with national figures. The Standardized Mortality Ratio (SMR) can be calculated from observed and expected deaths reported in the paper. SMRs for deaths from all causes were 97, 101 and 119 for day, shift, and ex-shift workers respectively. Although the figures might indicate an increasing trend, the differences were not statistically significant. However, the reported SMR close to 100 is remarkable because the reference population was the general male population. Most mortality studies concerned with occupational cohorts reveal SMRs lower than 100, implying a healthy workers' effect (Harrington, 1978). The same study showed a significantly increased incidence of neoplastic disease in shift workers (SMR 116). A Danish study of 6000 shift workers failed to demonstrate any excess mortality in shift workers (Boggild et al., 1999). Not much evidence exists on the connection between shift work and cancer. The mortality study by Taylor and Pocock (1972) reported an increased incidence of neoplasms in shift workers compared with the general population. A recent Danish case–control study reported an increased risk of breast cancer among 30–45-year-old women who worked mainly nights (Hansen, 2001). Among 75 000 nurses those with more than 15 years of night work showed an increased risk of colorectal cancer (Schernhammer et al., 2003). If the results are confirmed, a possible mechanism may be the low levels of the hormone melatonin, due to light exposure during the night with a subsequent suppression of melatonin.

Very few studies are available but Koller, Kundi and Cervinka (1978) found a prevalence of endocrine and metabolic disease of 3.5% in shift workers and 1.5% in day workers. Kawachi et al. (1995) found in a prospective study of shift workers that the age-standardized prevalence was 5.6% at 15 years of shift work experience compared with 3.5% for no exposure. Nagaya et al. (2002) found that markers of insulin resistance were more frequent in shift workers above the age of 50 than in day workers. Other indicators, such as body mass index, glucose levels and so forth, give a rather inconclusive impression as indicated in a review by Boggild and Knutsson (1999).

Another contributing factor to gastrointestinal diseases might be the association between shift work and smoking. A number of studies have reported that smoking is more common among shift workers (Angersbach et al., 1980; Knutsson, Åkerstedt and Jonsson, 1988). Studies concerned with alcohol consumption comparing day workers and shift workers have produced conflicting results (Smith, Colligan and Tasto, 1982; Knutsson, 1989a; Romon, Nuttens and Fievet, 1992), probably due to local cultural habits. One study, which used g-glutamyltransferase as a marker of alcohol intake, did not indicate that the shift workers had a higher intake of alcohol than the day workers (Knutsson, 1989a).

Sickness absence is often used as a measure of occupational health risks. However, sickness leave is influenced by many irrelevant factors and cannot be considered as a reliable measure of true morbidity. Studies on sickness absence in day and shift workers have revealed conflicting results and there is no evidence that shift workers have more sickness absence than day workers (for review, see Harrington, 1978).

2.3.4.3 Conclusion

Shift work or similar arrangements of work hours clearly affects sleep and alertness and there is a moderate risk of cardiovascular and gastrointestinal disease. Other diseases such as cancer or diabetes may be related to shift work but the evidence is as yet rather weak.
The present review suggests that the risk of disturbed sleep increases with age but there also seems to be a recent stress-related increase in sleep disturbance in young adults. The long-term health consequences are not yet understood.

The relation between gender and disturbed sleep is confusing. Females, as a rule, complain more of sleep problems, but do not exhibit any objective indications of more disturbed sleep, at least not among otherwise healthy women. With increasing age the sleep of males deteriorates whereas that of women is relatively well upheld. Pregnancy, however, is a period of increased risk of disturbed sleep, whereas the menstrual cycle and menopause show less evidence of sleep disturbance. Clearly there is a great need for longitudinal research on gender and sleep and, in particular, on the possible health consequences connected with pregnancy.

Stress due to work or family seems to be one of the major causes of disturbed sleep. The link to the risk of insomnia is well-established, but reduced sleep in itself seems to yield the same physiological changes as stress. This suggests that several of the major civilization diseases in Europe and the United States (diabetes, cardiovascular diseases and burnout) could be mediated via disturbed sleep. This link clearly warrants longitudinal studies with interventions.

Shift workers constitute a group that suffers from disturbed sleep for most of their occupational life. The reason is the interference of work hours with the normal timing of sleep. This leads to an increased risk of accidents, directly due to excessive sleepiness, but also to cardiovascular and gastrointestinal diseases, although it is not clear whether the latter effects are sleep related or due to circadian factors – or to a combination. Recent studies also suggest that breast cancer may result from shift work due to the effects of light on melatonin secretion. This still needs verification, however. Future research needs to identify countermeasures, the reasons for large individual differences in tolerance and the possible carcinogenic and other effects.

The conclusions above should be seen against the profound effects of reduced or fragmented sleep on the neuroendocrine (including glucose and lipid regulation) and immune systems as well as the effects on mortality, diabetes and cardiovascular disease.

2.3.5 CONCLUSION

Children, the elderly, pregnant women, people under stress and shift workers are vulnerable to (noise) disturbance of their sleep.

2.4 ACCIDENTS RELATED TO SLEEP QUALITY

As already stated in the earlier section on cardiovascular complications, children with disturbed sleep present cognitive dysfunction and behavioural disturbances, abnormal growth hormone release, increase of diastolic BP and an increased risk of accidents and use of sleeping pills.

Regarding sleep disturbance and accidents in adults, data show that 15–45% of all patients suffering from sleep apnoea, 12–30% of all patients suffering from narcolepsy and 2–8% of all patients suffering from insomnia have at least one accident (in a lifetime) related to sleepiness (statistics from the Stanford Sleep Disorders Clinic).

As already discussed in section 2.3.4, the biggest industrial catastrophes, such as the Three Mile Island, Bhopal, Chernobyl and Exxon Valdez disasters, have occurred during the night shift. The shift schedules, fatigue and sleepiness were cited as major contributing factors to each incident.

The LARES study (Large Analysis and Review of European housing and health Status) is one of the few studies analysing this issue directly. The results show that the likelihood of home accidents is significantly greater when the individual is tired all the time or most the time and there is an association between sleep disturbance and accidents, with 22% of those reporting an accident also reporting having their sleep disturbed during the previous four weeks.

The data available to document the impact of environmental noise on sleep deprivation and accidents are largely inadequate. There is no estimation of relative risk. Further research is needed in order to identify the accident-related burden of diseases attributable to noise during the night-time.

2.5 ANIMAL STUDIES

As pet owners know, cats sleep (most of the time it seems) and so do dogs. But do fish sleep? And flies? Yes, most animals sleep, and they even show the same phenomena as in humans; from deep sleep, dream sleep to sleep disorders. There are also many differences and weird behaviour, such as sleeping with only one half of the brain at a time (dolphins and ducks).

As Ising points out (Appendix 3), in animal experiments it is possible to assess the complete causal chain from noise exposure via physiological reactions and biological risk factors to morbidity or even mortality. However, a quantitative application of the results to humans is not possible. Instead, the method is useful in studying the pathomechanisms qualitatively. Rechtschaffen and Bergmann (1965) studied sleep deprivation in rats, showing that total sleep deprivation leads to mortality in 16 to 20 days. As the animals in the last stage died from microbial infection, Everson and Toth (2000) proceeded to show early infection of the lymph nodes and other tissues and hypothesized that daily sleep of some amount is necessary to maintain an intact immune system that will prevent bacterial invasion, a view that has been challenged.

Surprisingly, sleep in the common fruit fly – *Drosophila melanogaster* – has many similarities with mammalian sleep, including sleep deprivation leading to impaired performance. Genetic studies in fruit flies (Cirelli et al., 2005) led to mutant flies that can get by on 30% less sleep than their normal counterparts, thanks to a single mutation in one gene. While they sleep 30% less they show no immediate ill effects. The lifespan of the flies is, however, reduced by 30%.

These animal models certainly lead one to believe that sleep is a biological necessity, and tampering with it is dangerous for survival.

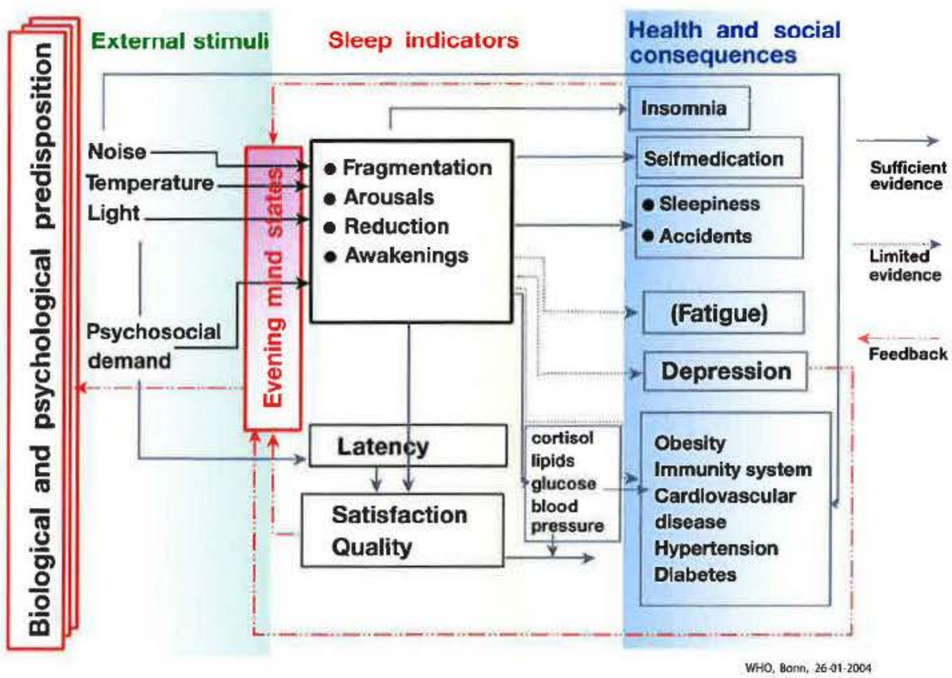
As Ising shows (Appendix 3) noise may play a role in this. Under stressful circumstances the death rate of rats is increased when noise levels are increased from "ambient" to L_{eq}=69 dB(A). Are noise and sleep deprivation stressors that both lead to early death? Is the noise effect due to sleep deprivation? A carefully planned study may sort this out. The question still remains, however, as to how far this is relevant to humans.

2.6 CONCLUSIONS

From the evidence presented so far it can be deduced that sleep is important for human functioning. Why exactly is less evident, but it is clear that disturbed sleep (either from internal factors or from external factors) leads to or is at least associated with fatigue, lower cognitive performance, depression, viral illness, accidents, diabetes, obesity and cardiovascular diseases. Animal experiments show that sleep deprivation shortens lifespan. The fact that – in comparison– relatively mild effects turn up in human sleep deprivation experiments could be due to the short period (about 10 days in controlled experiments) and the limitation to young and healthy adults.
The central position of sleep in human functioning is summarized in Fig. 2.1. In this figure relations with sufficient evidence are indicated with solid lines, while relations for which limited evidence exists are indicated with interrupted lines. Feedback connections are in red and double-dotted.

The presence of feedback loops in the system is an indication that it may be difficult to prove direct cause–effect relations. One example is the relation between sleep quality and depression. They are strongly associated, but it is uncertain if depression causes bad sleep, or bad sleep causes depression (see also Chapter 4, section 4.8.11). This may also depend on one of the many other factors, so it could be different for different personality types.

Fig.2.1
Expert view on the relations between sleep and health



Impaired sleep is widely considered as a health problem per se, and this chapter has shown that there are many internal and external causes. In the next chapter the relation between noise and sleep quality is further unravelled.

CHAPTER 3

EFFECTS OF NIGHT-TIME NOISE ON SLEEP

Best travel tip: Never ever forget to pack ear plugs.

3.1 SHORT-TERM EFFECTS OF TRANSPORTATION NOISE ON SLEEP WITH SPECIFIC ATTENTION TO MECHANISMS AND POSSIBLE HEALTH IMPACT

3.1.1 INTRODUCTION

In this section reactions to single events are presented. In Chapter 2 normal sleep and sleep disorders are described in medical terms, but here the focus is on the mechanisms underlying the relation between noise and sleep quality. How does a sound penetrate the brain and cause a disruption of sleep?

3.1.2 HOW NOISE INFLUENCES NORMAL SLEEP

Noise can induce changes in the EEG or in autonomic variables that are called arousals or phasic activations. Similar brief episodes of activity also occur without noise in normal sleep, and, more frequently, in sleep that is otherwise disturbed, for example by apnoea. Arousal during sleep is not a uniform concept and has been defined differently by different researchers. Commonly, the occurrence of alpha rhythms is required for EEG arousal. Depending on the additional requirements and on the length of time that the slower cortical rhythms are interrupted, arousals have been called, for instance, micro-arousal, minor arousal, EEG awakening or transient activation phases. EEG awakening requires an interruption of the sleep patterns of at least 15 seconds (half the period) when sleep staging is scored by periods of 30 seconds, but need not be experienced consciously. Because normal REM sleep is a state characterized by cerebral arousal with frequently occurring alpha rhythms, additional criteria are needed to define arousal from REM. The criteria used are increased heart rate, EMG, or irregular respiration. However, since the mechanisms of such autonomic responses appear to be at least partly different from the causal mechanisms of EEG arousal, such definitions seem to make arousal from sleep a heterogeneous concept that may not have simple relationships with noise exposure.

EEG arousals lasting at least 30 seconds have been found to occur as often as 4 times (95% CI: 1–15) per hour during sleep on average, while micro-arousals occurred 21 times (95% CI: 7–56) per hour (Mathur and Douglas, 1995). Since these figures are from a laboratory study, they almost certainly are higher than the figures that hold for the natural situation at home. Sleep pressure decreases the density of micro-arousals (Sforza, Jouny and Ibanez, 2000). While the number of EEG arousals (during sleep stages 1 and 2) increases with age (Mathur and Douglas, 1995; Boselli et al., 1998) possibly only for men (Hume, Van and Watson, 2003), their average length is stable and circa 15 seconds (Boselli et al., 1998). Also the threshold for auditory arousal decreases with age (Zepelin, McDonald and Zammit, 1984; Busby and Pivik, 1985; Busby, Mercier and Pivik, 1994) and towards the end of the night (Basner et al., 2004). Recovery after EEG awakenings takes longer for noise-induced awakenings than for spontaneous awakenings (Basner et al., 2004). The time required for falling asleep again depends on the sound level and especially for loud events this latency is considerably longer than after spontaneous awakenings. Thus, in general, noise-induced EEG awakenings are more disruptive than spontaneous awakenings and therefore will more often be experienced consciously and remembered afterwards. In common situations with aircraft overflight noise at home, (minor) arousals were found in 10.3% of the 64-second intervals without aircraft noise and this percentage was found to be increased by circa 4% up to 14.3% in intervals with an aircraft noise event (Hume, Van and Watson, 2003). Thus, in that particular (exposure) situation, about 1 in 24 aircraft overflights caused a (minor) arousal.

3.1.3 MECHANISMS

Activity in the auditory system up to the brainstem nucleus inferior colliculus occurs within 10 milliseconds after the onset of a sound. This early activity appears to be obligatory and is hardly affected by the state (sleeping or awake). Being asleep or awake does influence later activity. The auditory pathways proceed from the inferior colliculus to the thalamus and from there to the auditory cortex. The state (asleep or awake) affects the activity in the thalamocortical circuits, which occurs after 10–80 milliseconds. In particular, during SWS the transmission of auditory information through the thalamus is suppressed. This is not the case during REM sleep or when awake.

Thus, while in all (sleep) stages, sound activates the auditory system up to the inferior colliculus, the sound-induced activation of higher areas is suppressed in SWS. Therefore, further activation depending on those higher areas (for example, extracting meaning) is not likely to occur as a primary reaction to sound during SWS. For understanding arousal during SWS, it is important that the inferior colliculus and the earlier auditory nucleus of the lateral lemniscus, and also the (dorsal and ventral) cochlear nuclei project to reticular arousal system. Presumably, sound is always capable of arousing the sleeping subject through these connections. The ascending arousal system is heterogeneous and encompasses mono-aminergic, glutamatergic, and cholinergic nuclei that can directly or indirectly activate the thalamus and cortex. An important indirect route is the activation of the basal forebrain, which can activate the cerebral cortex through widespread, mainly cholinergic projections. The activation of the thalamus and cortex is indicated by an increase in EEG rhythm frequency and a reduction of the inhibition in the thalamic sensory relay nuclei. As a consequence of the latter effect, subsequent sound-induced activation may pass the thalamus and may be subject to more elaborate processing than initial sound. It can be speculated that sound in this way also reduces the threshold for somatosensory information that initiates body movements so that more body movements are observed when exposed to sound. The occurrence of habituation of cortical responses suggests an active role played by a part of the brain that blocks or at least limits the impact of the activated ascending pathways.

The parasympathetic autonomic nervous system seems to be responsible for the bradycardia observed in non-REM sleep and mainly in tonic REM sleep through the increase in vagal activity (Guazzi et al., 1968). The variability of heart rate in REM sleep could be placed under the same control, as vagotomy strongly reduced the heart rate instability (Baust and Bohnert, 1969). During falling asleep, respiration is unstable and alternates between hypo- and hyperventilation episodes. This respiration, called "periodic respiration" (Mosso, 1886), disappears when stable sleep occurs (stage 2). The main hypotheses concerning this periodic ventilation refer to metabolic control and chemoreceptor responses to levels of $PaCO_2$ and PaO_2 (Chapman et al., 1988). In stable non-REM sleep, respiration is regular in amplitude and frequency, although ventilation per minute is lower than during awakening. In REM sleep, respiration appears irregular with sudden variations in amplitude and frequency. This irregularity appears to be not modifiable by metabolic factors and, therefore, it is possibly linked to mechanisms leading to REM expression. The non-habituation of the cardiovascular responses would be explained by the absence of an inhibitory influence on the part of the arousal system that affects the centres regulating the autonomous response.

3.1.4 EEG RESPONSE

The sleep polygraph continuously records EEG activity, eye movement (EOG) and muscle tone (EMG). These data are used to classify sleep into various stages, and to assess times of falling asleep and waking up. Also, sleep variables such as total sleep time and total time spent in SWS (consisting of sleep stages 3 and 4, the stages of deep sleep) and in the REM stage (also called dream or paradoxical sleep) can be assessed on the basis of sleep polygraph recordings. Polygraphic indicators of responses to individual noise events are changes from a deeper to a less deep sleep and EEG awakening. Several field studies (Pearsons, Bennett and Fidell, 1973; Vernet, 1979; Vallet et al., 1983; Hume, Van and Watson, 2003; Basner et al., 2004) have been conducted regarding noise-induced changes in sleep stage and awakening using EEG recordings. Transition from a deep stage of sleep to a shallower sleep stage can be the direct consequence of a nocturnal noise event. Although not perceived by the sleeper, these transitions modify the sleep architecture and may reduce the amount of SWS (Carter, 1996; Basner et al., 2004) and the amount and rhythmicity of REM sleep may be markedly affected (Naitoh, Muzet and Lienhard, 1975; Thiessen, 1988). In addition to their results from a laboratory study, Basner et al. (2004) present results from a field study with valid data for 63 subjects (aged 18–65 years) with 15 556 aircraft noise events included in the final analyses. They established a curve that gives the probability of awakening as a function of L_{Amax} with a model that assumed a background noise level just prior to the aircraft noise event of 27 dB(A). The L_{Amax} threshold for noise-induced awakenings was found to be about 35 dB(A). Above this threshold the probability of noise-induced awakenings increases monotonically up to circa 10% when L_{Amax} = 73 dB(A). This is the extra probability of awakening associated with the aircraft noise event, on top of the probability of awakening spontaneously in a 90 second interval.

Some arousals provoked by noise events are so intense that they induce awakening. Frequent awakening leads to sleep fragmentation and overall sleep disturbance. The noise threshold for awakening is particularly high in deep SWS (stages 3 and 4) while it is much lower in shallower sleep stages (stages 1 and 2). In REM sleep the awakening threshold is variable and depends on the significance of the stimulus. Total sleep time can be reduced by both a longer time to fall asleep and premature final awakening. It has been reported that intermittent noises with maximum noise levels of 45 dB(A) and above can increase the time taken to fall asleep by a few to 20 minutes (Öhrström, 1993). In the morning hours, the sleeper can be more easily awakened by ambient noise and has more difficulty going back to sleep because sleep pressure is progressively reduced with time (Rechtschaffen, Hauri and Zeitlin, 1966; Keefe, Johnson and Hunter, 1971).

Terzano et al. (1990, 1993) showed that with increasing intensity of sound pressure level (white noise at 45, 55, 65 and 75 dB(A), white noise induced a remarkable enhancement of cyclic alternating patterns (CAP)/non-REM, characterized by a linear trend from the lowest to the highest intensities, revealed by a significant increase in the CAP rate already at 45 dB(A). Noise decreased mainly SWS, REM and total sleep time, and increased waking after sleep onset, stage 1 non-REM and CAP rate (Terzano et al., 1993). For CAP/non-REM values between 45% and 60%, subjects generally recalled a moderate nocturnal discomfort and values of CAP/non-REM over 60% corresponded to a severe complaint.

This result corroborates previous findings described by Lukas (1972a) who reported that reactions less intense than a sleep stage change correlate better to the noise intensity than awakening reactions.

3.1.5 CARDIOVASCULAR RESPONSE

For sleeping persons, mean heart rate, mean systolic and diastolic BP and variability in heart rate are usually assessed. Indicators of responses to individual noise events are instantaneous changes in (variability of) heart rate and changes in systolic BP. Several field studies (Carter et al., 1994) have been conducted regarding momentary change in heart rate. Intermittent noise during sleep has been found to induce a biphasic cardiac response and a transient constriction of peripheral vessels together with a short phasic activation in the EEG, while no other behavioural effect can be seen (Muzet and Ehrhart, 1978). This biphasic cardiac response starts with an increase in heart rate, probably due to a phasic inhibition of the parasympathetic cardio-inhibitory centre, followed by a compensatory decrease due to a phasic decrease in orthosympathetic activity (Keefe, Johnson and Hunter, 1971; Muzet and Ehrhart, 1980). The vasoconstrictive response was reported to be due to the sympathetic peripheral stimulation provoked by the auditory reflex (Kryter and Poza, 1980). More recently, Carter et al. (2002) have shown that beat-by-beat BP changes can be induced by suddenly occurring noises. Although habituation in some effect parameters can occur in a few days or weeks, this habituation is not complete and the measured modifications of the cardiovascular functions remain unchanged over long periods of exposure time (Muzet and Ehrhart, 1980; Vallet et al., 1983). Most striking is that none of the cardiovascular responses show habituation to noise after a prolonged exposure, while subjective habituation occurs within a few days. In people that are used to sleep in a noisy surrounding, noise-induced changes in heart rate are dependent on the maximum sound level of a noise event, but not on the EEG sleep stage).

3.1.6 BODY MOVEMENT

Motility is the term used for accelerations of the body or body parts during movement. It is measured with actimeters, usually worn on the wrist in field research and the laboratory. Brink, Müller and Schierz (2006) describe a more sophisticated method which is based on the bed being placed on accelerometers. This allows the tracking of whole body movements.

Motility is related to many variables of sleep and health (Reyner, 1995; Reyner et al., 1995; Passchier-Vermeer et al., 2002). Clinical research shows that the sleep/wake cycle (assessed by polysomnography, EEG, EOG, EMG) passes through the 24-hour period synchronously with the rest/activity cycle (assessed by actimetry) (Borbely et al., 1981). A number of investigations have compared the results of polysomnographic recordings (number of EEG-awakenings during sleep period, duration of sleep period, sleep onset time, wake-up time) with results of actimetry. The correlation between actimetrically assessed duration of sleep period, sleep onset time, wake-up time and similar variables assessed with polysomnography was found to be very high (correlation coefficients between individual test results in the order of 0.8–0.9). Measures of instantaneous motility are the probability of motility and the probability of onset of motility in a fixed time interval, for example a 15-, 30- or 60-second interval. Increased instantaneous motility during sleep is considered to be a sensitive behavioural marker of arousal, but the relation with arousal is not simple. Also other factors, such as the need to relieve the pressure on body parts for better blood circulation, cause motility, and spontaneously occurring arousals are part of the normal sleep process. The noise-induced probability of (onset of) motility is the difference between the probability of (onset of) motility during noise events minus the probability in the absence of noise.

Onset of motility and minor arousal found on the basis of EEG recordings are highly correlated. In the United Kingdom sleep disturbance study, Ollerhead et al. (1992) found for their study population that during sleep there is on average an EEG (minor) arousal in 40% of the 30-second intervals with onset of motility. Unfortunately, it is unknown whether this 40% is also valid for noise-induced awakenings. In 12% of the 30-second intervals with an EEG (minor) arousal, motility does not occur. Several field studies (Horne et al., 1994; Fidell et al., 1998, 2000; Flindell, Bullmore and Robertson, 2000; Griefahn et al., 2000; Passchier-Vermeer et al., 2002, 2004) have been conducted regarding noise-induced instantaneous motility. For this effect, relationships have been established with SEL or L_{Amax}, for aircraft noise only. In Passchier-Vermeer et al. (2002) relationships between noise-induced increase in motility or noise-induced increase in onset of motility in the 15-second interval with the maximum noise level of an overflight, and L_{Amax} or SEL have been approximated by quadratic functions (see, for instance, Fig. 3.2). It may be noted that the threshold of motility (L_{Amax} = 32 dB(A)) is in the same range as the threshold found by Basner et al. (2004) for EEG awakenings, with a definition that also encompassed transitions to steep stage 1 (L_{Amax} = 35 dB(A)). The probability of motility at 70 dB(A) of about 0.07 is lower than the probability of noise-induced EEG awakening at L_{Amax} = 73 dB(A) of about 0.10. There is no a priori reason to expect the above threshold probabilities to be the same for these two measures of sleep disturbance, but, taking into account that motility is assessed for shorter intervals (15 seconds vs. 90 seconds), the differences in probabilities above threshold appear to be limited.

One of the variables influencing the relationships between noise-induced instantaneous motility and L_{Amax} or SEL, is long-term aircraft noise exposure during sleep. The probability of instantaneous aircraft noise-induced motility is lower when the long-term exposure is higher. This may be partly due to the higher base rate motility in quiet intervals in higher long-term exposure, which is used as a reference for the instantaneous noise-induced motility. Other factors influencing the relationships between instantaneous motility and L_{Amax} or SEL are the point of time in the night, and time since sleep onset. For example, after 7 hours of sleep, noise-induced motility is about 1.3 larger than in the first hour of sleep. Age has only a slight effect on noise-induced motility, with younger and older people showing a lower motility response than persons in the age range of 40–50 years.

3.1.7 BEHAVIOURAL AWAKENING IN ADULTS

Passchier-Vermeer (2003a) published a review of nine studies on awakening by noise. It was found that these studies had different definitions of what constituted an "awakening". In this review, however, all awakening data were collected on "behavioural awakening": these are awakenings that were followed by an action (like pressing a button) from the sleeper. The number of awakenings defined in this manner is much smaller than the number of sleep stage changes which lead to EEG patterns similar to wakefulness.

Data were available for rail traffic noise, ambient (probably road) noise, civil aviation noise and military aviation noise.

The rail traffic noise study is very small (only 20 subject nights), but showed no awakenings. The study states that "there is some evidence, be it very limited, that railway noise events, in the range of SEL_{indoor} considered (up to 80 dB(A)), do not increase [the] probability of awakening".

Ambient noise also showed no effect on the probability of awakening, but as it is uncertain exactly what noise is meant, no firm conclusions could be drawn.

Military aircraft noise showed a very strong effect, but this study is of limited applicability since the few subjects (military) lived near the end of the runway.

For civil aviation noise there were sufficient data to derive a dose-effect relation:

$$\text{Percentage of noise-induced awakenings} = -0.564 + 1.909 * 10^{-4} * (SEL_{inside})^2 \quad [4],$$

where SELinside is the sound exposure level of an aircraft noise event in the bedroom.

This relation is confined to commercial aircraft noise over the intervals $54<SEL<90$ ($37<L_{Amax}<82$) and the number of events per night $1< N< 10$.

With this relation, it is possible to calculate for an individual L_{night} the expected number of noise-induced behavioural awakenings. This requires all single contributions over the year to this L_{night} to be known. Alternatively (if, for instance, a future situation has to be estimated for which no exact data are available) a worst case scenario can be calculated. Fig. 3.1 represents the results of this worst case approach (converted to L_{night}, see Chapter 1, section 1.3.4), and so gives the maximum number of awakenings n_{max} that may be expected.

$$n_{max} = 0.3504 * 10^{(L_{night}-35.2)/10} \quad [5].$$

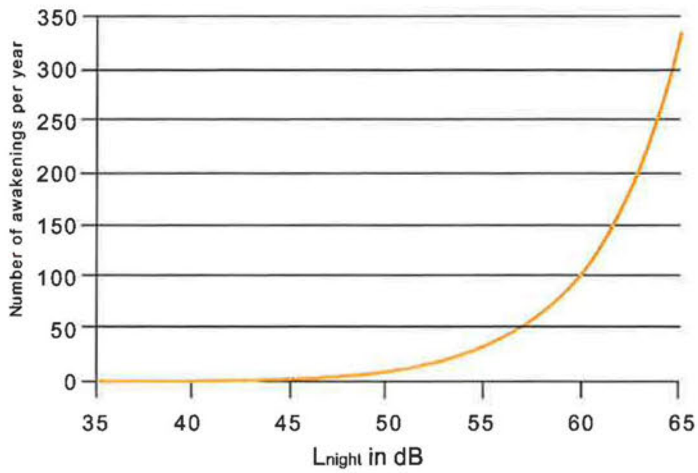

Fig. 3.1
Worst case prediction of noise-induced behavioural awakenings.
L_{night}, converted from inside relation with [3] on page 10.

Source: Miedema, Passchier-Vermeer and Vos, 2003

It can be demonstrated that the number of awakenings reaches a maximum when the SEL_{inside} value is 58.8 dB(A).

It should be noted that, on average, 600 spontaneous awakenings per person are reported per year. This also explains why so many more awakenings are reported than can be attributed directly to aircraft noise. At 55 L_{night}, nearly 100 overflights per night with SEL_{inside} = 58.8, or 1 every 5 minutes are possible. It is, therefore, very likely that an overflight coincides with a spontaneous awakening.

3.1.8 DOSE–EFFECT RELATIONS FOR BODY MOVEMENTS DURING SLEEP

In Passchier-Vermeer et al. (2002) motility is registered in 15-second intervals. A distinction is made between two variables:

- the *presence of motility* in the interval (indicated by m) and
- the onset *of motility*, meaning the presence of motility when there was no motility in the preceding interval (indicated by k).

Relations between a noise-induced increase in motility (m) or a noise-induced increase in the onset of motility (k) in the 15-second interval with the maximum sound level of an overflight, and $L_{Amax,inside}$ or SEL_{inside} have been approximated by quadratic functions with the following format:

$$m = b^*(L_{Amax,inside} - a) + c^*(L_{Amax,inside} - a)^2 \qquad [6].$$

The coefficients a, b and c are given in Table 3.1. The value of a is the value below which m or k is zero. Fig. 3.2 shows the relationship between m and $L_{Amax,inside}$ together with the 95% confidence interval. Relations apply to $L_{Amax,inside}$ and SEL_{inside} values of at most 70 and 80 dB(A), respectively.

Table 3.1.
Coefficients of the quadratic equation (formula [6]) of m and k as a function of $L_{Amax,inside}$ or SEL_{inside} for the 15-second interval in which an indoor maximum sound level of an aircraft noise event occurs. The equations are applicable in the $L_{Amax,inside}$ range from a up to 70 dB(A), or SEL_{inside} range from a up to 80 dB(A). Below a, m and k are zero.

	(Aircraft) noise-induced increase of probability of motility (m)	(Aircraft) noise-induced increase of probability of onset of motility (k)
range	$32 < L_{Amax,inside} < 70$ dB(A) (see Fig. 3.2)	$32 < L_{Amax,inside} < 70$ dB(A)
a	32	32
b	0.000633	0.000415
c	$3.14x10^{-5}$	$8.84x10^{-6}$
range	$38 < SEL_{inside} < 80$ dB(A)	$40 < SEL_{inside} < 80$ dB(A)
a	38	40
b	0,000532	0.000273
c	$2.68x10^{-5}$	$3.57x10^{-6}$

Source: Miedema, Passchier-Vermeer and Vos, 2003.

The study report also gives the upper boundaries for motility, based on the relationship between L_{Amax}, SEL and L_{night} (Fig. 3.3). This figure is mathematically derived from relation [6] as described in Appendix 2.

This area of study is still under development. Miedema, Passchier-Vermeer and Vos (2003) give a detailed account in their study report of the relation between the study used for the data presented here (Passchier-Vermeer et al., 2002), earlier studies like the much quoted Civil Aviation Authority study (Ollerhead et al., 1992; Ollerhead, 1994) and earlier work done in the United States.

3.1.9 INDIVIDUAL SENSITIVITY

Sensitivity to noise may vary greatly from one individual to another. Primary self-evaluation of sensitivity to noise has been used as a factor to evaluate highly sensitive and non-sensitive groups and to compare their reactions to noise exposure during daytime and night-time (Di Nisi et al., 1990). In this study, self-declared highly sensitive individuals had a higher cardiovascular response rate to noise than non-sensitive people during their waking exposure, while there was no difference in sensitivity to noise between these two groups during their night-time exposure while they were asleep.

The physiological sensitivity to noise depends also on the age of the sleeper. Thus, while EEG modifications and awakening thresholds are, on average, 10 dB(A) higher in children than in adults, their cardiovascular sensitivity to noise is similar, if not higher, than the older group (Muzet and Ehrhart, 1980; see also Appendix 4). Elderly people complain much more than younger adults about environmental noise. However, their spontaneous awakenings occurring during night sleep are also much more numerous. Therefore, it is difficult to conclude if elderly people are more sensitive to noise or if they hear noise because they are often awake during the night. This natural fragmentation of their night sleep tends also to lengthen their return to the sleeping state and this accounts for a significant part of their subjective complaints.

Differences in sensitivity to noise have been found between the sexes. Thus, young men seem to complain more about noise-disturbed sleep than young females (Muzet et al., 1973). However, this difference seems to reverse for populations over 30 years of age and then females (often mothers) appear to be more sensitive to noise than males (Lukas, 1972b).

3.1.10 USE OF INSTANTANEOUS EFFECTS IN PREDICTIONS OVER A LONGER TIME PERIOD

It is tempting to use the relations between single exposures and measured effects in long-term predictions. Although this is perhaps possible, a word of caution is appropriate.

In general, the reactions are calculated by looking at a certain time frame around an exposure, usually in the order of a few minutes. The second limitation is that order and follow-up effects are neglected. Time and order effects of identical events on motility have been described by Brink, Wirth and Schierz (2006). Only if the situation that is modelled resembles the one that was used in the single exposure analysis, are no major deviations to be expected. Reactions to noise events are generally not independent from each other. Each event may alter a subject's tendency to awake at the next event, even if no awakening reaction is detected for that particular event. If, for example, each event would additionally increase the probability of awakening at the next event, the total probability of awakening per night would be greater than predicted by mere summation of the single event probabilities. Most likely, this underestimation of probability will occur when events in the real situation follow in close succession, whereas events in the single exposure analysis did not. Such limitations can to some degree be overcome through applying advanced statistical methods such as those put forward by Basner (2006). A third limitation is that an overall increase in the base line could go undetected.

If the situation that is calculated resembles the one that was used in the single exposure analysis, probably no major deviations are to be expected. Care should be taken to extrapolate outside the boundaries given in the number of events or L_{Amax}. Calculations for Amsterdam Schiphol Airport show a good agreement between the number of calculated awakenings per year (based on the actual SEL data) and the self-reported number of awakenings. This number is a factor 2 lower than the worst case scenario presented in section 3.1.7 above.

3.2 CHRONIC EFFECTS: CHRONIC INCREASE OF MOTILITY

Mean motility – all body movements counted together – during sleep is strongly related to age and is also a function of noise exposure during the sleep period. The relationships between mean motility and $L_{night,inside}$ are shown in Fig. 3.4. Mean motility during sleep is lowest at the age of 45 years, and greater at higher and lower ages. The relation between mean motility, $L_{night,inside}$ and age is:

$$\text{Mean motility} = 0.0587 + 0.000192{*}L_{night,inside} - 0.00133{*}age + 0.0000148{*}age^2 \qquad [7].$$

The relation between the increase in mean noise-induced motility, m_{night}, and $L_{night,inside}$ is:

$$m_{night} = 0.000192{*}L_{night,inside} \qquad [8],$$

assuming, as described in Chapter 1, section 1.3.4, that $L_{night,inside} = L_{night}$-21:

$$m_{night} = 0.000192{*}L_{night}-0.004032 \qquad [8a].$$

Source: Miedema, Passchier-Vermeer and Vos, 2003.

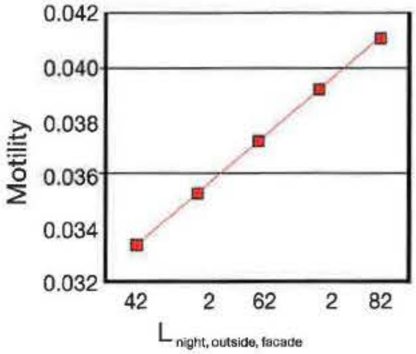

Fig. 3.4
Increase in mean motility (body movements during sleep). Converted from inside relation with [3]

The increase in m_{night} is 22% over the baseline motility (0.03 on average) if indoor $L_{night,inside}$ increases from 0 (absence of aircraft noise) to 35 dB(A) (living close to a runway). This increase is independent of age, although the absolute level varies.

Other chronic effects like the use of sleeping pills, changes in BP and changes in levels of stress hormones are discussed in the next chapter.

3.3 CONCLUSIONS

During sleep the auditory system remains fully functional. Incoming sounds are processed and evaluated and although physiological changes continue to take place, sleep itself is protected because awakening is a relatively rare occurrence. Adaptation to a new noise or to a new sleeping environment (for instance in a sleep laboratory) is rapid, demonstrating this active protection. The physiological reactions do not adapt, as is shown by the heart rate reaction and the increase of average motility with sound level. The autonomous physiological reactions are a normal reaction to these stimuli, but the question is whether prolonged "abuse" of this system leads to adverse consequences for the organism. The next chapter tries to answer that.

CHAPTER 4

EFFECTS OF NIGHT-TIME NOISE ON HEALTH AND WELL-BEING

The sick die here because they can't sleep,

For when does sleep come in rented rooms?
It costs a lot merely to sleep in this city!
That's why everyone's sick: carts clattering
Through the winding streets, curses hurled
At some herd standing still in the middle of the road,
Could rob Claudius or a seal of their sleep!

(Juvenal, 1st century AD)

4.1 INTRODUCTION

In Chapters 2 and 3, sufficient evidence was presented to support the hypothesis for the simplified model presented in Chapter 1: sleep disturbance is connected to health impairment, and noise is an important factor that causes sleep disturbance. The full model (Fig. 2.1, Chapter 2) showed why it is difficult to find evidence for a direct relation between noise exposure at night and health outcomes. Noise is but one of the internal and external factors that cause sleep disturbance and feedback loops obscure the view of the cause and effect chain. In this chapter the evidence for the direct relation is presented.

4.2 SELF-REPORTED (CHRONIC) SLEEP DISTURBANCES

Self-reported sleep disturbance is investigated by means of a questionnaire containing questions regarding sleep disturbance. Often, sleep disturbance is not the main focus of the questionnaires used in studies of self-reported noise effects. This means that considerable effort is needed to harmonize the different response categories. The relationships for self-reported sleep disturbance are based on analyses of the 15 data sets with more than 12 000 individual observations of exposure–response combinations, from 12 field studies (Miedema, 2003; Miedema, Passchier-Vermeer and Vos, 2003).

The curves are based on data in the L_{night} (outside, most exposed facade) range 45–65 dB(A). The polynomial functions are close approximations of the curves in this range and their extrapolations to lower exposure (40–45 dB(A)) and higher exposure (65–70 dB(A)). The formulae of these polynomial approximations are as follows (SD = sleep disturbance; H = high; L = low):

for **road traffic:**

$$\%HSD = 20.8 - 1.05 * L_{night} + 0.01486 * (L_{night})^2 \quad [9]$$

$$\%SD = 13.8 - 0.85 * L_{night} + 0.01670 * (L_{night})^2 \quad [10]$$

$$\%LSD = -8.4 + 0.16 * L_{night} + 0.01081 * (L_{night})^2 \quad [11]$$

for **aircraft:**

$$\%HSD = 18.147 - 0.956 * L_{night} + 0.01482 * (L_{night})^2 \quad [12]$$

$$\%SD = 13.714 - 0.807 * L_{night} + 0.01555 * (L_{night})^2 \quad [13]$$

$$\%LSD = 4.465 - 0.411 * L_{night} + 0.01395 * (L_{night})^2 \quad [14]$$

and for **railways:**

$$\%HSD = 11.3 - 0.55 * L_{night} + 0.00759 * (L_{night})^2 \quad [15]$$

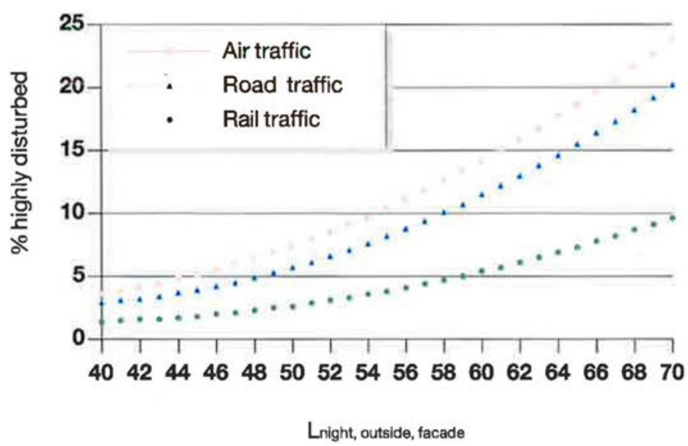
$$\%SD = 12.5 - 0.66 * L_{night} + 0.01121 * (L_{night})^2 \quad [16]$$

$$\%LSD = 4.7 - 0.31 * L_{night} + 0.01125 * (L_{night})^2 \quad [17].$$

The above relations represent the current best estimates of the influences of L_{night} on self-reported sleep disturbance for road traffic noise and for railway noise, when no other factors are taken into account. Fig. 4.1 illustrates the relations [9] [12] and [15] for persons highly disturbed by road, aircraft and rail noise.

Fig. 4.1
High sleep disturbance by noise at night

Source: European Commission, 2004.



With regard to the relations for aircraft noise it should be noted that the variance in the responses is large compared to the variance found for rail and road traffic. This means that the uncertainty regarding the responses for night-time aircraft noise is large, and such responses can be considered as indicative only. Miedema (2003) suggests the following causes.

- The time pattern of noise exposures around different airports varies considerably due to specific night-time regulations.
- The sleep disturbance questions for aircraft noise show a large variation.
- The most recent studies show the highest self-reported sleep disturbance at the same L_{night} level. This suggests a time trend.

For industrial noise there is an almost complete lack of information, although there are some indications (Vos, 2003) that impulse noise may cause considerable disturbance at night.

4.3 COMPLAINTS

According to the Health Council of the Netherlands (2004), the submission of a complaint about noise is symptomatic of reduced well-being.

Complaints about noise are widespread, and night noise seems to cause more complaints than daytime noise at the same level. Hume, Morley and Thomas (2003) found that around Manchester Airport complaints per 1000 aircraft traffic movements rose from an average of 10 in daytime hours to up to 80 in the night. When linking part of the complaints to measured noise levels, they found an increase from an average of 1 complaint at 70 PNLdB (circa 58 L_{Amax}) to 2 at 114 PNLdB (circa 102 L_{Amax}).

Due to differences in complaint cultures and registration practices, it is difficult to make comparisons between complaint registrations. Around Amsterdam Schiphol Airport a relation between complaints and L_{Aeq} was found (Ministerie Verkeer en Waterstaat, 2005). The threshold for complaints is around 45 L_{den}, and increases to 7% of the population at 72 L_{den}. Night-time complaints follow the same pattern, and the threshold for night complaints is 35 L_{night}. In Fig. 4.2 the mean percentage shows a definite relationship with L_{night}. The 95 percentile indicates that the threshold is 35 L_{night}.

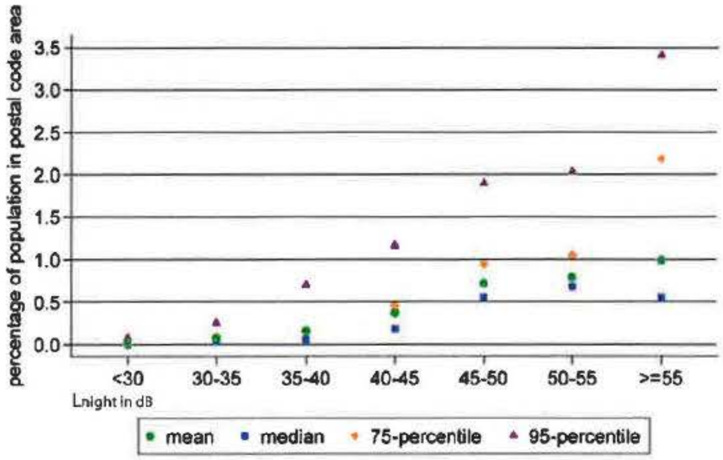


Fig. 4.2
Dose-effect relation for persons having complained at least once during a year between 1994 and 2004

Source: Ministerie Verkeer en Waterstaat (2005).

4.4 NEIGHBOURHOOD NOISE AND NOISE FROM NEIGHBOURS

Inventory studies in the Netherlands indicate that sleep disturbance attributable to the most annoying forms of neighbourhood noise and noise from neighbours (contact noise and human noises in the environment) is on a similar scale to disturbance attributable to the most annoying sources of road traffic noise (mopeds and passenger cars). It is reasonable to assume that chronic sleep disturbance is, in the long term, liable to have consequences for health and well-being. The sound pressure level and other noise characteristics are liable to determine the nature of the influence to some extent, but certain other factors play a more prominent role than is the case with traffic noise. These factors include appreciation of the noise and of the party responsible for the noise, as well as the hearer's personal circumstances. However, scientific understanding of the relative importance of and interaction between acoustic and non-acoustic factors is not sufficient for the committee to draw any definitive conclusions regarding the relationship between, on the one hand, exposure to night-time neighbourhood noise and noise from neighbours and, on the other, health and well-being.

Leidelmeijer and Marsman (1997) carried out an interview-based study of 1242 households in the Netherlands, in which subjects were asked about daytime and night-time noise from neighbours and any associated annoyance. A distinction was made on the basis of the part of the house in which the noises were audible and any associated annoyance was experienced. Subjects proved least tolerant of noise from their neighbours that was audible in the master bedroom. The researchers distinguished five types of noise, which are listed below (Table 4.1), along with the percentage of subjects who indicated hearing the relevant type of noise from a neighbouring dwelling at night in the master bedroom.

Table 4.1 Daytime and night-time noise from neighbours

Type of noise	% subjects hearing noises at night in the bedroom
Contact noise	22%
Noise from sanitary fittings, central heating, etc.	19%
Noise from radio, TV and hi-fi	12%
Do-it-yourself noises	8%
Pets	6%

Source: Leidelmeijer and Marsman, 1997.

Where each of the five investigated types of noise was concerned, roughly 10–15% of subjects indicated that they felt it was unacceptable for the noise to be audible during the day. Overall, nearly 30% of subjects said that sanitary fittings should not be audible at night, while approximately 50% felt each of the other four types of noise was unacceptable at night.

In 1993, Kranendonk, Gerretsen and van Luxemburg produced a synthesis of the research conducted up to that point in time into the annoyance associated with noise from neighbours. Subsequently, in 1998, van Dongen et al. published a report on the relationship between noise from neighbouring dwellings and the airborne and contact noise attenuating indices I_{lu}, $I_{lu;k}$, and I_{co}, drawing on data from a questionnaire-based survey of the residents of 600 dwellings, whose acoustic quality was determined in 202 cases. The results of the two studies are reasonably consistent. Both found that the chief causes of annoyance were loud radios, hi-fis and TVs, audible and sometimes intelligible voices, the slamming of doors and footsteps on floors and staircases. In both cases, it proved that, when Ilu had a value of 0 (the minimum requirement for new homes), 10% of subjects reported high annoyance and 15% reported annoyance caused by noise from neighbouring dwellings. These figures are not specific to night-time noise, but apply to annoyance over a 24-hour period.

On the basis of the findings outlined above, the committee concludes that the standard of inter-dwelling sound attenuation presently required does not provide sufficient protection to prevent annoyance caused by noise from neighbours. Since people are less tolerant of the noise their neighbours make at night-time than of their neighbours' evening or daytime noise, it may be assumed that much of the annoyance associated with noise from neighbours relates to the influence of such noise on sleep.

4.5 CARDIOVASCULAR EFFECTS OF NOISE – FINDINGS FROM EPIDEMIOLOGICAL STUDIES

4.5.1 INTRODUCTION

It is a common experience that noise is unpleasant and affects the quality of life. It disturbs and interferes with activities of the individual including concentration, communication, relaxation and sleep (WHO Regional Office for Europe, 2000; Schwela, 2000). Besides the psychosocial effects of community noise, there is concern about the impact of noise on public health, particularly regarding cardiovascular outcomes (Suter, 1992; Passchier-Vermeer and Passchier, 2000; Stansfeld, Haines and Brown, 2000). Non-auditory health effects of noise have been studied in humans for a couple of decades using laboratory and empirical methods. Biological reaction models have been derived, which are based on the general stress concept (Selye, 1956; Henry and Stephens, 1977; Ising et al., 1980; Lercher, 1996). Amongst other non-auditory health end points, short-term changes in circulation including BP, heart rate, cardiac output and vasoconstriction, as well as stress hormones (epinephrine, norepinephrine and corticosteroids) have been studied in experimental settings for many years (Berglund and Lindvall, 1995; Babisch, 2003). Various studies have shown that classical biological risk factors are higher in subjects who were exposed to high levels of traffic noise (Arguelles et al., 1970; Eiff et al., 1974; Verdun di Cantogno et al., 1976; Algers, Ekesbo and Strömberg, 1978; Knipschild and Sallé, 1979; Manninen and Aro, 1979; Eiff et al., 1981a; Rai et al., 1981; Marth et al., 1988; Babisch and Gallacher, 1990; Babisch et al., 1990; Lercher and Kofler, 1993; Schulte and Otten, 1993; Dugué Leppänen and Gräsbeck, 1994; Yoshida et al., 1997; Goto and Kaneko, 2002). Although controls for other risk factors were not consistent in all these studies, the hypothesis emerged that persistent noise stress increases the risk of cardiovascular disorders including high BP (hypertension) and IHD.

- Sound/noise is a psychosocial stressor that activates the sympathetic and endocrine system.
- Acute noise effects do not only occur at high sound levels in occupational settings, but also at relatively low environmental sound levels when, more importantly, intended activities such as concentration, relaxation or sleep are disturbed.

The following questions need to be answered.

- Do these changes observed in the laboratory habituate or persist under chronic noise exposure?
- If they habituate, what are the physiological costs? If they persist, what are the long-term health effects?

The answers to these questions come from epidemiological noise research. Large-scale epidemiological studies have been carried out for a long time (Babisch, 2000). The studies suggest that transportation noise is associated with adverse cardiovascular effects, in particular IHD. The epidemiological evidence is constantly increasing (Babisch, 2002, 2004a). The biological plausibility of the association derives from the numerous noise experiments that have been carried out in the laboratory. There is no longer any need to prove the noise hypothesis as such. Decision-making and risk management, however, rely on a quantitative risk assessment which requires an established dose–response relationship. Since many of the stress indicators and risk factors that have been investigated in relation to

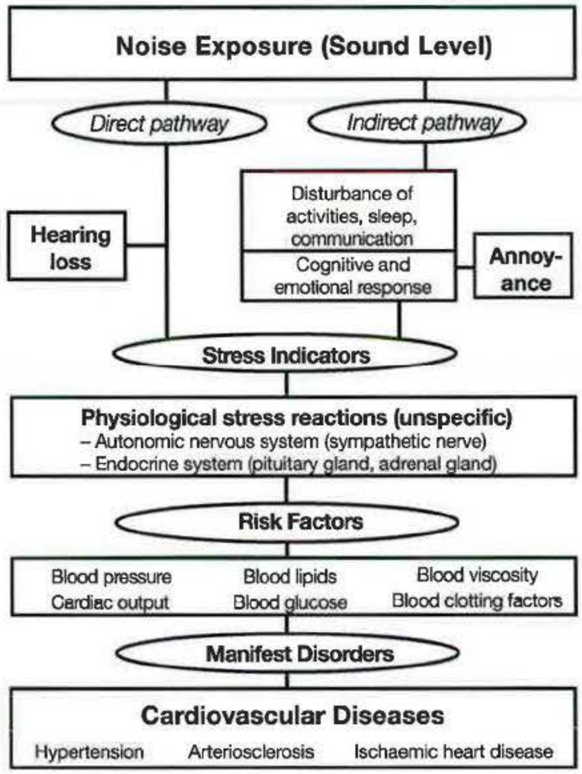

Fig. 4.3 Noise effects reaction scheme

Source: Babisch, 2002.

noise are known to be classical cardiovascular risk factors, the hypothesis has emerged that chronic noise exposure increases the risk of hypertension, arteriosclerosis and IHD. Its relevance for public health comes from the high prevalence of cardiovascular diseases in developed and industrialized countries. It is unclear as to what extent chronically repeated noise-induced sleep disturbance contributes to the development of somatic health disorders. Only a few epidemiological studies address this particular issue. Epidemiological noise research has seldom distinguished between day and night exposures, or between the exposure of the living room and the bedroom. However, some deduction can be made from daytime to night-time exposure.

4.5.2 NOISE AND STRESS-REACTION MODEL

The auditory system is continuously analysing acoustic information, which is filtered and interpreted by different cortical and subcortical brain structures. The limbic system, including the hippocampus and the amygdala, plays an important role in the emotional processing pathways (Spreng, 2000). It has a close connection to the hypothalamus that controls the autonomic nervous system and the hormonal balance of the body. Laboratory studies found changes in blood flow, BP and heart rate in reaction to noise stimuli as well as increases in the release of stress hormones including the catecholamines adrenaline and noradrenaline, and the corticosteroid cortisol (Berglund and Lindvall, 1995; Maschke, Rupp and Hecht, 2000; Babisch, 2003). Such changes also occur during sleep without the involvement of cortical structures. The amygdala has the capacity to learn due to its plasticity, particularly with respect to the meaning of sound stimuli (for example, danger of an approaching lorry) (Spreng, 2000, 2004). Acoustic stimulation may act as an unspecific stressor that arouses the autonomous nervous system and the endocrine system. The generalized psychophysiological concept given by Henry and Stephens can be applied directly to noise-induced stress reaction (Henry, 1992). The stress mechanism as such is genetically determined but it may be modified by experience and environmental factors. Its biological function is to prepare the organism to cope with a demanding stressor. The arousal of the sympathetic and endocrine system is associated with changes in physiological functions and the metabolism of the organism, including BP, cardiac output, blood lipids (cholesterol, triglycerides, free fatty acids, phosphatides), carbohydrates (glucose), electrolytes (magnesium, calcium), blood clotting factors (thrombocyte aggregation, blood viscosity, leukocyte count) and others (Friedman and Rosenman, 1975; Cohen, Kessler and Underwood Gordon, 1995; Lundberg, 1999). In the long term, functional changes and dysregulation may occur, thus increasing the risk of manifest diseases.

Fig. 4.3 shows the principal reaction schema used in epidemiological noise research for hypothesis testing (Babisch, 2002). It simplifies the cause–effect chain, that is: sound – annoyance (noise) – physiological arousal (stress indicators) – (biological) risk factors – disease – and mortality (the latter is not explicitly considered in the graph). The mechanism works "directly" through synaptic nervous interactions and "indirectly" through the emotional and the cognitive perception of the sound. It should be noted that the "direct" pathway is relevant even at low sound levels particularly during sleep, when the organism is at its nadir of arousal. The objective noise exposure (sound level) and the subjective noise "exposure" (annoyance) may serve independently as exposure variables in the statistical analyses of the relationship between noise and health end points.

Principally, the effects of environmental noise cannot directly be extrapolated from results of occupational noise studies. The two noise environments cannot simply be merged into one sound energy-related dose–response model (for example, a simple 24-hour average noise level measured with a dose-meter). Noise effects are not only dependent on the sound intensity but also on the frequency spectrum, the time pattern of the sound and the individuals' activities which are disturbed. Therefore, epidemiological studies carried out under real-life conditions can provide the basis for a quantitative risk assessment provided that there is adequate control over confounding and exposure variables. Other noise sources might act as confounders and/or effect modifiers on the association of interest. The effects of road traffic noise (at home) were shown to be stronger in subjects who were also exposed to high noise levels at work (Babisch et al., 1990).

4.5.3 PREVIOUS REVIEWS ON ENVIRONMENTAL NOISE AND CARDIOVASCULAR RISK

Causality in epidemiology can never be completely proven (Schlesselman, 1987; Christoffel and Teret, 1991; Weed, 2000). It is a gradual term for which evidence is increasing with the increasing number of facts. However, the magnitude of effect, the presence of a dose–response relationship and consistency with other studies in different populations and with different methodology and biological plausibility are commonly accepted arguments for a causal relationship (Bradford Hill, 1965; Evans, 1976; Morabia, 1991; Weed and Hursting, 1998). Classical, systematic and quantitative reviews have been published in the past, summarizing the results of studies that have been carried out up to the end of the last century, and assessing the evidence of the relationship between community noise and cardiovascular disease outcomes (Health Council of the Netherlands, 1994, 1999, 2004; Berglund and Lindvall, 1995; IEH, 1997; Morrell, Taylor and Lyle, 1997; Porter, Flindell and Berry, 1998; Babisch, 2000; Passchier-Vermeer and Passchier, 2000), including a classical review and synthesis report by Babisch (2000) and a systematic review (meta-analysis) by van Kempen et al. (2002).

In a meta-analysis it was concluded that the risk of hypertension due to aircraft noise was 1.26 per increase of 5 dB(A) (95% CI: 1.14–1.39, L_{day} = 55–72 dB(A)) (van Kempen et al., 2002). But, only one study (Knipschild, 1977a) was considered in the meta-analysis. With respect to road traffic noise and hypertension a pooled estimate of 0.95 per 5 dB(A) (95% CI: 0.84–1.08, L_{day} = <55–80 dB(A)) was calculated (van Kempen et al., 2002). Two cross-sectional studies (Knipschild and Sallé, 1979; Knipschild, Meijer and Sallé, 1984) were considered in this calculation. The highest degree of evidence was for the association between community noise and IHD. Across the studies there was not much indication of an increased risk for subjects who lived in areas with a daytime average sound pressure level of less than 60 dB(A). For higher noise categories, however, higher risks were relatively consistently found amongst the studies (Babisch, 2004a). Statistical significance was rarely achieved.

Some studies permit reflections on dose–response relationships. These mostly prospective studies suggest an increase in risk for outdoor noise levels above 65–70 dB(A) during the daytime, the relative risks ranging from 1.1 to 1.5. Noise effects were larger when mediating factors like years in residence, room orientation and window-opening habits were considered in the analyses. In a meta-analysis it was concluded that the risk of IHD increased by 1.09 per 5 dB(A) of the road traffic noise level (95% CI: 1.05–1.13, L_{day} = 51–70 dB(A)) (van Kempen et al., 2002), when two cross-sectional studies (Babisch et al., 1993a) were considered. However, the pooled estimate of two prospective studies (Babisch et al., 1999) was calculated to be 0.97 per 5 dB(A) (95% CI: 0.90–1.04, L_{day} = 51–70 dB(A)) (van Kempen et al., 2002). When the diagnosis of IHD was limited to myocardial infarction, three studies (Babisch et al., 1999, 1994) were considered in this meta-analysis. Then the linear effect estimate was 1.03 per 5 dB(A) increase in road traffic noise level (95% CI: 0.99–1.09, L_{day} = 51–80 dB(A)). New studies have appeared in the meantime which are included in the present updated review (Matsui et al., 2001; Bluhm, Nordling and Berglind, 2001; Evans et al., 2001; Rosenlund et al., 2001; Belojevic and Saric-Tanaskovic, 2002; Goto and Kaneko, 2002; Lercher et al., 2002; Maschke, 2003; Franssen et al., 2004; Matsui et al., 2004; Niemann and Maschke, 2004; Babisch et al., 2005). Others are on their way or have not yet been finalized and published, for instance the pan-European HYENA project (Jarup et al., 2003).

4.5.4 UPDATED REVIEW OF EPIDEMIOLOGICAL STUDIES

Sixty epidemiological studies were recognized as having either objectively or subjectively assessed the relationship between transportation noise and cardiovascular end points. The identification of studies was based on the author's expert knowledge of the topic and respective literature. Details are given in the major report (Babisch, 2006). Information particularly on night-time exposure (L_{night}: 22.00–06.00 or 23.00–07.00) was seldom available. Newer studies used non-weighted or weighted averages of the 24-hour exposure (L_{eq}, L_{dn}, L_{den}). Some aircraft noise studies used national calculation methods (for example, Dutch Kosten Units). For comparisons of study results and the pooling of data (meta-analysis), sound levels were converted on the basis of best guess approximations to L_{day} (Matschat and Müller, 1984; Passchier-Vermeer, 1993; Bite and Bite, 2004; Franssen et al., 2004). It should be noted in this context that doubling/halving of road traffic volume results in a 3 dB(A) higher/lower average sound pressure level. Not all studies allowed dose–response reflections because some of them considered very broad exposure categories. Besides objective noise measurements, subjective measurements of exposure have been used in some epidemiological noise studies, which is in accordance with the noise–stress model. Type of road (for example, busy street, side street, etc.), disturbances and annoyance were rated by the study subjects from given scales.

4.5.5 MEAN BP

Table A2 of the major report (Babisch, 2006) lists the major findings of epidemiological traffic noise studies in which mean BP was considered as the outcome. It indicates mean systolic and diastolic BP differences as obtained from extreme group comparisons of noise exposure. The effects in children and in adults are discussed separately. The findings in children are difficult to interpret with regard to possible health risks in their later life. The effect may be of a temporary nature and may not be relevant to permanent health damage. There is evidence during childhood (Gillman et al., 1992), adolescence (Yong et al., 1993) and adulthood (Tate et al., 1995) that the BP level at an early age is an important predictor of the BP level at a later age. Studies over the full age range are missing (tracking). Growth and body weight are important factors in BP development. The impact of body size was not adequately considered in some of the studies. A crude hint regarding reversible effects on BP came from one study (Morrell et al., 2000). Results of the Munich intervention study on the effects of a reduction of aircraft noise have only been reported regarding cognitive performance but not with respect to change of BP (Hygge, Evans and Bullinger, 2002). It was concluded from the available data on the length of exposure that children do not seem to adapt to high levels of road traffic noise but to some extent to aircraft noise (Passchier-Vermeer, 2000; Bistrup et al., 2001). However, the database appears to be too poor to draw final conclusions. Aircraft noise studies focused on exposure at school, while road traffic noise studies mostly considered noise exposure at home. The conclusions given by Evans and Lepore (1993) seem still to hold true:

> "We know essentially nothing about the long-term consequences of early noise exposure on developing cardiovascular systems. The degree of blood pressure elevations is small. The clinical significance of such changes in childhood blood pressure is difficult to determine. The ranges of blood pressure among noise-exposed children are within the normal levels and do not suggest hypertension. The extent of BP elevations found from chronic exposure are probably not significant for children during their youth, but could portend elevations later in life that might be health damaging."

Regarding mean BP, no consistent findings in the relationship between traffic noise level and mean systolic or diastolic BP can be seen in adults across the studies. In longitudinal studies, problems arose from migration of subjects, which had a considerable impact on sample size. The latter problem also applies to cross-sectional studies, in general. Sensitive subjects may tend to move out of the polluted areas, which dilutes the effect of interest. Medication due to high BP may affect the BP readings. However, the exclusion of subjects with hypertension or hypertension treatment dilutes the true effect on BP differences, if the hypothesis (noise causes high BP) is true. In principle, hypotension – a fall in BP – can also be a stress reaction. All this makes it more reasonable to look at manifest hypertension (defined by a cut-off criterion) as a clinical outcome rather than at mean BP readings (Ising, 1983; Winkleby, Ragland and Syme, 1988). To date, there is no evidence from epidemiological data that community noise increases mean BP readings in the adult population. However, this does not discard the noise hypothesis as such. Studies suffered from insufficient power, narrow exposure range or other difficulties in the study design.

4.5.6 HYPERTENSION

Table A3 of the major report (Babisch, 2006) gives the results of epidemiological traffic noise studies on the relationship between community noise level and the prevalence or incidence of hypertension. Hypertension in these studies was either defined by WHO criteria (WHO-ISH Guidelines Subcommittee, 1999), similar criteria based on measurements of systolic and diastolic BP, from information which was obtained from a clinical interview, or a social survey questionnaire about hypertension diagnosed by a doctor. Most studies refer to road traffic noise. However, in recent years some new aircraft noise studies entered the database. The subjects studied were the adult male and female population, sometimes restricted to certain age ranges. With regard to the association between community noise and hypertension, the picture is heterogeneous. With respect to aircraft noise and hypertension, studies consistently show higher risks in higher exposed areas. The evidence has improved since a previous review (Babisch, 2000). The relative risks found in four significantly positive studies range between 1.4 and 2.1 for subjects who live in high exposed areas, with approximate daytime average sound pressure level in the range of 60–70 dB(A) or more. Swedish studies found a relative risk of 1.6 at even lower levels >55 dB(A). With respect to road traffic noise, the picture remains unclear. New studies, more than older studies, tend to suggest a higher risk of hypertension in subjects exposed to high levels of road traffic noise, showing relative risks between 1.5 and 3.0. However, the earlier studies cannot be neglected in the overall judgement process. Across all studies no consistent pattern of the relationship between community noise and prevalence of hypertension can be seen. Dose–response relationships were considered in new studies. Subjective ratings of noise or disturbances due to traffic noise seem to consistently show a positive association with prevalence of hypertension. The relative risks found here range from 0.8 to 2.3. These studies, however, are of lower validity due to principal methodological issues regarding overreporting (Babisch et al., 2003).

4.5.7 IHD

Table A5 of the major report (Babisch, 2006) gives the results of cross-sectional epidemiological traffic noise studies on the relationship between noise level and prevalence of IHD. Table A6 of the major report gives the results of case-control and cohort studies on the association between noise level and incidence of IHD. In cross-sectional studies, IHD prevalence was assessed by clinical symptoms of angina pectoris, myocardial infarction, ECG abnormalities as defined by WHO criteria (Rose and Blackburn, 1968), or from self-reported questionnaires regarding doctor-diagnosed heart attack. In longitudinal studies, IHD incidence was assessed by clinical myocardial infarction as obtained from hospital records, ECG measurements or clinical interviews. The majority of studies refer to road traffic noise. With regard to IHD, the evidence of an association between community noise and IHD risk has increased since a previous review (Babisch, 2000). There is not much indication of a higher IHD risk for subjects who live in areas with a daytime average sound pressure level of less than 60 dB(A) across the studies. For higher noise categories, a higher IHD risk was relatively consistently found amongst the studies. Statistical significance was rarely achieved. Some studies permit reflections on dose–response relationships. These mostly prospective studies suggest an increase in IHD risk at noise levels above 65–70 dB(A), the relative risks ranging from 1.1 to 1.5 when the higher exposure categories were grouped together. Noise effects were larger when mediating factors like residence time, room orientation and window-opening habits were considered in the analyses. This accounts for an induction period (Rose, 2005) and improves exposure assessment. The results appear as consistent when subjective responses of disturbance and annoyance are considered, showing relative risks ranging from 0.8 to 2.7 in highly annoyed/disturbed/affected subjects. However, these findings may be of lower validity due to methodological issues.

4.5.8 MEDICATION AND DRUG CONSUMPTION

Table A8 of the major report (Babisch, 2006) gives the results of studies on the relationship between drug consumption and community noise. Medication was primarily investigated with respect to aircraft noise. A significant prevalence ratio for medication with cardiovascular drugs of 1.4 was found in the sample of Amsterdam Schiphol Airport (Knipschild, 1977a). The results of the "drug survey", where the annual data of the pharmacies regarding the purchase of cardiovascular drugs were analysed (repeated cross-sectional survey), supported this finding. An increase in drug purchase over time in the exposed areas and not in the less exposed was found. This refers to the purchase of cardiovascular and antihypertensive drugs, as well as the purchase of hypnotics, sedatives and antacids (Knipschild and Oudshoorn, 1977). Furthermore a dependency with changes in night flight regulations was found (decrease after reduction of night flights). A large recent study around Amsterdam Schiphol Airport found only a slightly higher risk of self-reported medication with cardiovascular drugs, including antihypertensive drugs (relative risk 1.2), in subjects exposed to aircraft noise where the noise level L_{den} exceeded 50 dB(A) (Franssen et al., 2004). Dose–response relationships across noise levels (L_{den} = <50–65 dB(A)) with respect to prescribed and non-prescribed sedatives/sleeping pills were found (relative risk 1.5 and 2.0, respectively) in the highest noise category of L_{den} = 61–65 dB(A). The preliminary results of an ongoing aircraft noise study from Sweden carried out around Stockholm's airport are in line with the Dutch studies (Bluhm et al., 2004). A significant relative risk of 1.6 for the use of antihypertensive drugs was found in male subjects, where the noise level according to the Swedish calculation standard exceeded FBM = 55 dB(A). The road traffic noise studies, where medication/purchase of drugs was investigated also tend to show a higher use in higher exposed subjects (Eiff and Neus, 1980; Schulze et al., 1983; Lercher, 1992). The relative risk for cardiovascular drugs was 1.3 in the Bonn study and 5.0 in the Erfurt study. The results for other drugs including sleeping pills, sedatives, tranquillizers and hypnotics ranged between 1.2 and 3.8 in these studies. All in all, the studies on the relationship between the use of medication or purchase of drugs and community noise support the general hypothesis of an increase in sleep disturbance and cardiovascular risk in noise-exposed subjects.

4.5.9 EVALUATION OF STUDIES

This section refers only to studies where the prevalence or the incidence of manifest cardiovascular diseases was considered as a potential health outcome of chronic exposure to environmental noise. The focus here is on a quantitative risk assessment with respect to manifest diseases. Furthermore, studies on the effects of low-altitude jet-fighter noise are also excluded, because this type of noise includes other dimensions of stress (for instance, fear). Thirty-seven studies have assessed the prevalence or incidence of manifest diseases, including hypertension and IHD (angina pectoris, myocardial infarction, ECG abnormalities).

4.5.9.1 Criteria

Epidemiological reasoning is largely based on the magnitude of effect estimates, dose–response relationships, consistency of findings, biological plausibility of the effects and exclusion of possible bias. Internal (the role of chance) and external validity (absence of bias and confounding) are important issues in the evaluation of studies (Bradford Hill, 1965). Analytic studies (for example, cohort or case-control studies) are usually considered as having a higher validity and credibility than descriptive studies (for example, cross-sectional or ecological studies) (Hennekens and Buring, 1987), although many of the reservations against cross-sectional studies seem to be of minor importance when considering noise. For example, it does not appear to be very likely that diseased subjects tend to move differentially more often into exposed areas. Rather the opposite may be true, if noise stress is recognized as a potential cause of the individual's health problem. Thus, a cross-sectional study design may act conservatively on the results. The presence of a dose–response relationship is not a necessary criterion of causality. Non-linear relationships, including "u-" or "j-" shaped, saturation and threshold effects may reflect true associations (Calabrese and Baldwin, 2003; Rockhill, 2005). With respect to the derivation of guideline values in public health policy, the assessment of a dose–response relationship enables a quantitative risk assessment on the basis of continuous or semi-continuous (for instance 5 dB(A) categories) exposure data. Dichotomous exposure data, on the other hand, that refer to a cut-off criterion which splits the entire exposure range into two halves, can be used to evaluate the hypothesis of an association (qualitative interpretation), but not a quantitative assessment. The objective or subjective assessment of exposure and/or health outcomes is an important issue when judging the validity of a study (Malmström, Sundquist and Johansson, 1999; Cartwright and Flindell, 2000; Hatfield et al., 2001). The objective prevalence of hypertension was found to be higher in a population sample than the subjective prevalence of hypertension (Schulte and Otten, 1993). In a telephone survey more than half of the hypertensives classified themselves as normotensive (sensitivity 40% for men and 46% for women) (Bowlin et al., 1993). In a representative health survey, the validity of the self-reported assessment of morbidity (subjective morbidity) was found to be "low" with respect to hypercholesterolaemia, "intermediate" with respect to angina pectoris, hypertension and stroke and "high" with respect to myocardial infarction (Bormann et al., 1990). Myocardial infarction is a very definite and severe health outcome which subjects would clearly know about if they had experienced it. Its assessment by questionnaire tends to be more credible than that regarding hypertension. Test–retest reliability was found to be good with respect to "harder" outcomes, including high BP and heart attack (Lundberg and Manderbacka, 1996; Lipworth et al., 2001). Over-reporting, on the other hand, may be a source of potential bias, particularly when both exposure and outcome are assessed on a subjective basis (Winkleby, Ragland and Syme, 1988; Babisch et al., 2003). The subjects may be more prone to blame their environment for their health problems, or may even tend to exaggerate adverse effects or exposure in order to influence noise policy. Therefore, a higher credibility and ranking was given to studies where exposure and outcome were assessed objectively (for example sound level versus subjective ratings, and measurement of BP or a clinical interview versus self-reported hypertension in a self-administered questionnaire). This means that the sound level must have been measured or calculated on the basis of the traffic counts, and clinical interviews or measurements must have been carried out by medically trained personnel (no self-administered questionnaire data) to give a study a high ranking. Studies which have been adequately controlled (for instance stratification, model adjustment (regression), matching) for a reasonable set of confounding variables in the statistical analyses, besides age and sex, were given a high ranking.

4.5.9.2 Assessment

The evaluation concerning the epidemiological studies was made with respect to the identification of good quality studies that can be feasibly considered for the derivation of guideline values. These studies can either be used for a statistical meta-analysis, for a combined interpretation (synthesis) or for singular interpretations. All the studies were evaluated with respect to the following criteria for inclusion or exclusion in the synthesis process. Necessary criteria were: (1) peer-reviewed in the international literature; (2) reasonable control of possible confounding; (3) objective assessment of exposure; (4) objective assessment of outcome; (5) type of study; and (6) dose–response assessment. All six criteria were fulfilled by the two prospective cohort studies carried out in Caerphilly and Speedwell (Babisch et al., 1999; Babisch, Ising and Gallacher, 2003), the two prospective case-control studies carried out in the western part of Berlin ("Berlin I" and "Berlin II") (Babisch et al., 1992, 1994), and the new prospective case-control study carried out in the whole of Berlin ("NaRoMI" = "Berlin III") (Babisch, 2004b; Babisch et al., 2005). The studies refer to road traffic noise and the incidence of myocardial infarction. They were also the only ones considered in an earlier meta-analysis on this issue (van Kempen et al., 2002), with the exception of the "NaRoMI" study, which was not available at that time. All these studies are observational analytic studies (Hennekens and Buring, 1987). If descriptive studies on individuals – namely cross-sectional studies – are allowed, another two studies from Caerphilly and Speedwell on the association between road traffic noise and the prevalence of IHD, myocardial infarction and angina pectoris can be taken into account (Babisch et al., 1988, 1993a, 1993b). These studies were also considered in the meta-analysis by van Kempen et al. (2002). However, the results of the Berlin study on the prevalence of myocardial infarction (Babisch et al., 1994) – which was also considered in that meta-analysis – are not considered here, because the outcome was assessed subjectively with a self-administered questionnaire (an exclusion criterion). All the studies suggest an increase in IHD, in particular myocardial infarction. These studies are used for a new meta-analysis (section 4.5.10).

Regarding aircraft noise, the cross-sectional Okinawa study (Matsui et al., 2001; Matsui et al., 2004) on the association between aircraft noise and hypertension fulfils the inclusion criteria. When studies are included that did not assess dose–response relationships but only compared dichotomous categories of exposure in the analyses, two more studies appear on the list. The studies were carried out in the vicinity of Amsterdam Schiphol Airport. They suggest a higher risk of cardiovascular diseases in general (Knipschild, 1977b), and – specifically – for hypertension and IHD (angina pectoris, ECG abnormalities, heart trouble) (Knipschild, 1977a) in subjects from areas exposed to high aircraft noise. These studies were considered in the meta-analysis by van Kempen et al. (2002). However, they do not fulfil the strict criteria set here. Finally, if the inclusion criteria are widened to include peer-reviewed studies that assessed dose–response relationships between objective indicators of exposure and the subjective (self-reported) prevalence of diseases, a further two studies can be considered. These are the cross-sectional study carried out in Stockholm regarding the association between aircraft noise and hypertension (Rosenlund et al., 2001), and the cross-sectional part of the study in Berlin regarding the association between road traffic noise and myocardial infarction (Babisch et al., 1994). Fig. 4.4 shows the results of the three aircraft noise studies carried out in Amsterdam, Okinawa and Stockholm (Knipschild, 1977a; Rosenlund et al., 2001; Matsui et al., 2004). The graph clearly indicates that the results are too heterogeneous to derive a pooled dose–response curve. However, all three studies show an increase in risk with increasing noise level.

Studies that are not given a high ranking according to the above mentioned criteria, however, may serve as additional sources of information to support the evidence of the conclusions being made on the basis of this review. This is illustrated in Fig. 4.5. The entries are relative risks (centre of the bars) with 95% confidence intervals (the bars) for dichotomous comparisons of noise exposure (extreme groups or high vs. low). A relative consistent shift of the bars to relative risks greater than 1 can be seen. The dark-shaded bars in the diagram refer to studies where the noise exposure was determined objectively (noise levels), the

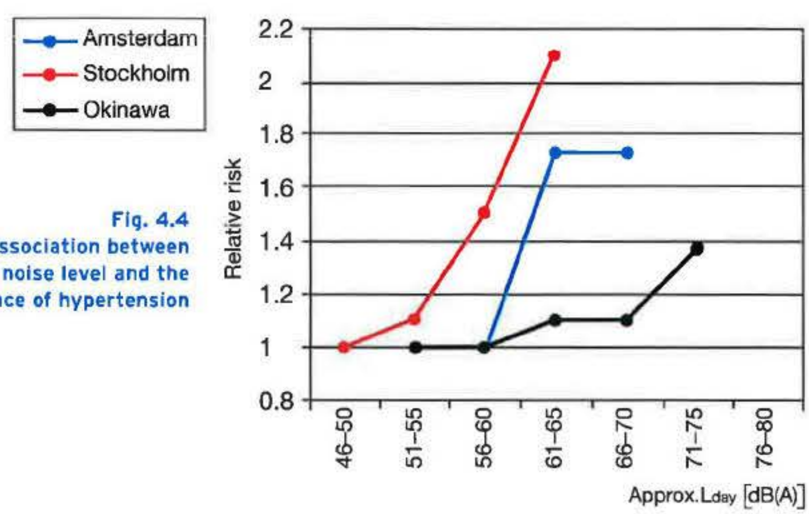

Fig. 4.4
Association between aircraft noise level and the prevalence of hypertension

light-shaded bars where it was determined subjectively (annoyance). Road traffic and aircraft noise studies are here viewed together. No corresponding results are available for rail traffic studies. If different subgroups of the population (males/females) or different health end points were taken into account, specific studies appear more than once in the illustration.

4.5.10 DOSE-RESPONSE CURVE: META-ANALYSIS

For a quantitative risk assessment and the derivation of guidelines for public health noise policy a common dose–response curve is required. The risk estimates obtained from different noise studies can be summarized using the statistical approach of a meta-analysis. Based on the judgement criteria discussed in section 4.5.9.2, five analytic and two descriptive studies emerged that can be used to derive a common dose–response curve for the association between road traffic noise and the risk of myocardial infarction. Two separate meta-analyses were made by considering the analytic studies that were carried out in Caerphilly and Speedwell (cohort studies) and Berlin (case-control studies) on the one hand, and the descriptive studies that were carried out in Caerphilly and Speedwell (cross-sectional studies) on the other hand. It turned out, as a result of the evaluation, that all these studies referred to road traffic noise during the day (L_{day}: 06.00–22.00) and the incidence or prevalence of myocardial infarction as the outcome. Study subjects were men. In all analytic studies the orientation of rooms was considered for the exposure assessment (facing the street or not). With respect to the Caerphilly and Speedwell studies, the six years of pooled follow-up data provided the respective information. In all descriptive studies the traffic noise level referred to the facades that were facing the street and did not consider the orientation of rooms/windows. All individual effect estimates were adjusted for the covariates considered in each of the studies. Different sets of covariates were considered in each study. However, this pragmatic approach accounts best for possible confounding in each study and provides the most reliable effect estimates derived from each study. The concept of meta-analysis was used to aggregate and summarize the findings of the different studies (Olkin, 1995; Blettner et al., 1999). The program "meta" was downloaded from the "STATA" web site for use in the statistical package STATA (version 8.0), and for calculating the pooled random effect estimates.

Table 4.2
Single and pooled (meta-analysis) effect estimates (odds ratios and 95% confidence intervals) of descriptive and analytic studies on the relationship between road traffic noise level (L_{day}) and the incidence/prevalence of myocardial infarction

	Road traffic noise level - L_{day} [dB(A)]					
Descriptive studies	**51-55**	**56-60**	**61-65**	**66-70**		**N**
Caerphilly	1.00	1.00 (0.58-1.71), [13.29]	0.90 (0.56-1.44), [17.23]	1.22 (0.63-2.35), [8.98]		2512
Speedwell	1.00	1.02 (0.57-1.83), [11.19]	1.22 (0.70-2.21), [12.62]	1.07 (0.59-1.94), [10.94]		2348

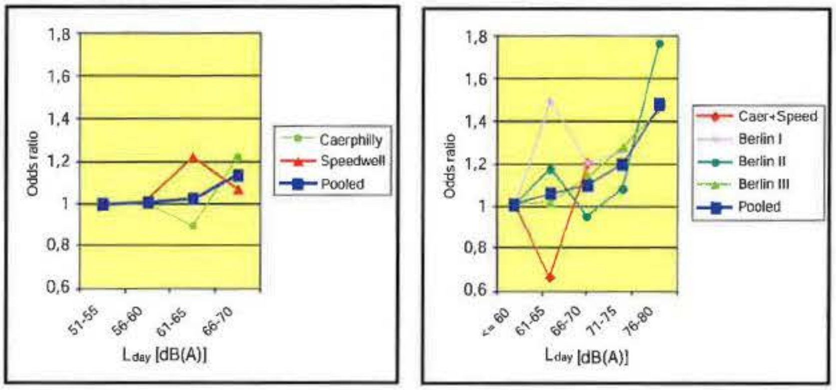
Table 4.2 shows individual and pooled effect estimates with confidence intervals (rounded brackets), statistical weights (square brackets) for the individual studies, and the Q-test of heterogeneity between studies. According to the Q-test, the nil hypothesis of non-heterogeneity was never discarded. Figs 4.6 and 4.7 show odds ratios of individual studies and the pooled estimates for the descriptive and analytic studies.

Fig. 4.6 and Fig. 4.7
Single and pooled effect estimates (odds ratios) for the descriptive and analytic studies of the association between road traffic noise level and the prevalence (left graph) and incidence (right graph), respectively, of myocardial infarction



4.5.11 EFFECT MODIFICATION

Support for any noise–effect relationship may come from subgroup analyses that are in line with the noise hypothesis. This refers to effect modification with respect to residence time, window-opening behaviour and other determinants that affect the noise exposure and cumulative noise dose. In the Amsterdam aircraft noise studies, a steady increase in the purchase of cardiovascular and antihypertensive drugs at local pharmacies was found over the period of eight years in a community newly exposed to aircraft noise. No such increase was found in a control community that was not exposed to aircraft noise (Knipschild and Oudshoorn, 1977). Positive associations between the prevalence of cardiovascular diseases and residence time in exposed areas (but not in unexposed) were also found in the road traffic noise studies carried out in Bonn with respect to hypertension (Eiff and Neus, 1980; Neus et al., 1983) and in Caerphilly and Speedwell with respect to IHD (Babisch et al., 1999; Babisch, Ising and Gallacher, 2003). When the analyses of the road traffic noise studies carried out in Berlin, Caerphilly and Speedwell were restricted to subjects who had not moved within a retrospective period of 10–15 years, the effect estimates turned out to be larger than for the total samples of each study (Babisch et al., 1994, 1999, 2005). Similarly, a larger effect was found in the study in Sollentuna with respect to hypertension (Bluhm, Nordling and Berglind, 2001). No such effect was found in the Lübeck study (Hense, Herbold and Honig, 1989; Herbold, Hense and Keil, 1989). The cross-sectional data of the study carried out in Los Angeles on children regarding mean BP indicated some habituation to aircraft noise (Cohen et al., 1980). The longer the children were enrolled in the school, the smaller was the difference in BP between exposed and non-exposed children.

However, the follow-up study suggested that this may also be an effect of attrition (Cohen et al., 1981). The longer the families experienced the noise, the more likely that they moved away from the exposed areas (selection bias). In contradiction to this, BP differences between children exposed and not exposed to road traffic noise increased with school grade (Karsdorf and Klappach, 1968). Intervention studies were conducted with respect to changes in BP and changes in air traffic operation (for example the opening/closing of airports or runways). In the Munich study, a larger increase in BP was found in children from a noisy area (Evans, Bullinger and Hygge, 1998). Other studies suggested reversible effects on BP when the exposure was lowered (Wölke et al., 1990; Morrell et al., 1998, 2000). In the Tyrol study, significantly lower BP readings were found in subjects who kept the windows closed throughout the night (Lercher and Kofler, 1993, 1996). When the subjects lived close to the highway (within a distance of approximately 500 metres), the prevalence of hypertension was higher in subjects whose bedroom was facing the main road than in those whose bedroom was not facing the main road. The orientation of rooms and window opening was also found to be an effect modifier of the association between road traffic noise and IHD in the Caerphilly and Speedwell studies (Babisch et al., 1999). The relative risk with respect to the noise level was slightly higher in subjects with rooms facing the street and subjects keeping the windows usually open when spending time in the room. A much greater relative risk of hypertension was found in subjects who slept with open bedroom windows in the Spandau Health Survey (Maschke, 2003; Maschke, Wolf and Leitmann, 2003). Hearing impairment was found to be an effect modifier on the association between aircraft noise and hypertension (Rosenlund et al., 2001). Amongst the exposed subjects, a higher risk associated with the noise was only found in subjects without hearing loss.

4.5.12 EXPOSURE DURING THE NIGHT

Unfortunately, epidemiological noise research provides nearly no information regarding the particular impact of noise exposure during the night on cardiovascular health outcomes. The Spandau Health Survey explicitly distinguished between the exposure of the living room (during the day) and the exposure of the bedroom (during the night). There, a slightly higher relative risk of hypertension was found with respect to the traffic noise level during the night (relative risk 1.9 vs. 1.5) compared with the noise level during the day (Maschke, 2003; Maschke, Wolf and Leitmann, 2003). Furthermore, sleeping with open bedroom windows was associated with a large increase in risk. However, due to the small sample size, the confidence intervals were very large. In the drug survey of the Amsterdam aircraft noise studies, a steady increase in purchase of hypnotics (sleeping pills) and sedatives was found (Knipschild and Oudshoorn, 1977). This trend decreased considerably when night flights were largely banned. Such a decrease was not found regarding cardiovascular drugs for which the purchase also increased over time. However, this may partly be due to the fact that atherosclerotic manifestations of high BP were less reversible (in contrast to vasoconstriction, which is more related to acute or semi-acute effects, for instance in children). It was mentioned in the previous section that closing the windows had a protective effect on BP readings in the Tyrol study (Lercher and Kofler, 1993). This was only found regarding closing the windows during the night and not during the day. Furthermore, subjects who had switched the bedroom and the living room because of the noise had a significantly lower BP than those who did not do so. The findings are discussed in a broader context of coping strategies (Lercher, 1996). When subjective responses to community noise were considered, higher relative risks of cardiovascular diseases were found for noise-related disturbances of sleep and relaxation, rather than for other disturbances or subjective descriptors of noise exposure, which did not refer to the night-time. This was found in the Caerphilly and Speedwell studies (Babisch, Ising and Gallacher, 2003), the NaRoMI study (Babisch et al., 2005), the Spandau Health Survey (Maschke, Wolf and Leitmann, 2003) and a general population sample of Germany (Bellach et al., 1995). The LARES study (Niemann and Maschke, 2004), in which noise-induced sleep disturbance was assessed, did not show a higher relative risk compared with the general annoyance.

4.5.13 RISK GROUPS

Most epidemiological noise studies looked at the cardiovascular effects of community noise in men. This may simply be due to the fact that the prevalence of cardiovascular diseases in middle-aged subjects is higher in men than in women. Statistical power is an important issue for the design of a study. Furthermore, in noise experiments, physiological reactions controlled by the autonomic nervous system were less pronounced in females than in males (Neus et al., 1980; Ising and Braun, 2000). Improper control for possible differential effects of the intake of sex hormones, including contraceptives, which may prevent or promote adverse (noise) stress effects, may act conservatively on the results (Cairns et al., 1985; Eiff, 1993; Farley et al., 1998). The studies carried out in Lübeck (Hense, Herbold and Honig, 1989; Herbold, Hense and Keil, 1989), Pancevo (Belojevic and Saric-Tanaskovic, 2002), Berlin (Babisch et al., 2005), Stockholm (Rosenlund et al., 2001), a German population sample (Bellach et al., 1995), Bonn (residence time) (Eiff and Neus, 1980; Eiff et al., 1981b) and in Amsterdam (angina pectoris) (Knipschild, 1977a) found higher prevalences of hypertension, IHD and the use of cardiovascular drugs in noise-exposed men than in women. The studies carried out in Bonn (sound level) (Eiff and Neus, 1980; Eiff et al., 1981b), Sollentuna and Amsterdam (heart trouble) (Knipschild, 1977a; Bluhm, Nordling and Berglind, 2001) found the opposite. In the studies carried out in the former Soviet Union, it was reported that noise effects on the cardiovascular system were more pronounced in young and middle-aged subjects (Karagodina et al., 1969). Swedish noise studies (Bluhm, Nordling and Berglind, 2001, 2004) and the LARES study (Niemann and Maschke, 2004) found similar results. The opposite (larger effects in elderly subjects) was reported from the Amsterdam study (Knipschild, 1977a) and the Stockholm study (Rosenlund et al., 2001). The available database on cardiovascular effects of noise in children is poor. No data are available that refer, in particular, to noise and sleep. The quantitative impact of transportation noise on the cardiovascular system is still a matter of research. A quantitative health risk assessment for children cannot be made at the moment.

Based on the available information from noise studies, it must be concluded that children do not appear to be a particular risk group with respect to cardiovascular outcomes, especially BP. This does not mean that the literature does not suggest higher BP readings in children. It only means that the effect in children does not appear to be different than that in adults. However, children may be exposed longer to noise throughout their lifetime than the adults that have been studied. No long-term follow-up studies are known that focus on noise exposure. Most studies on children considered noise in schools rather than noise at home, which implies different mechanisms about how noise could contribute to a rise in BP (raised effort in learning/speech perception vs. disturbed relaxation/sleep). The prospective part of the Caerphilly and Speedwell studies gave a small hint that health status could be a modifying factor. In subjects with prevalent chronic diseases, road traffic noise was associated with a slightly larger increase in the incidence (new cases) of IHD than in subjects without prevalent diseases – when the objective noise level was considered (Babisch et al., 2003). Surprisingly, when annoyance and disturbances due to traffic noise were considered for exposure, the opposite was found. Noise effects were only seen in subjects without prevalent diseases. This was discussed with respect to reporting bias.

4.5.14 RISK EVALUATION

The process of risk assessment (risk evaluation) comprises hazard identification ("Which health outcome is relevant for the exposure?"), exposure assessment ("How many are affected?") and dose–response assessment ("threshold of effect"). This information is summarized in "risk characterization" ("health hazard characterization"). It involves the interpretation of the available evidence from the available data and other scientific disciplines, and is subject to discussion of the uncertainties. These include chance, bias and validity of studies as well as transparency, replicability and comprehensiveness of reviews. As a result of the risk evaluation process, a quantitative estimate about the likelihood that the hazard will affect exposed people will be derived. Usually, attributable risk percentages are calculated (Walter, 1998). This will serve as key information for any kind of risk management including regulatory options (Jasanoff, 1993). The term "adverse" is essential in this context of environmental standard setting. Risk management should ensure that "adverse" health effects do not occur. The fact that an organism responds to noise does not have to be per se "adverse". The severity of a health outcome is an important determinant of the adversity of an effect and implies variable action levels for public health policy (Babisch, 2002, 2004a; Griefahn et al., 2002; Health Council of the Netherlands, 2003). Since considerable parts of the population are exposed to high noise levels (EEA, 2004), noise policy can have a significant impact on public health (Neus and Boikat, 2000). Due to the increasing number of people affected with the decreasing severity of the effect, even small individual risks and less severe health outcomes can be relevant for public health and decision-making. It has been shown that moderate noise exposures implying a small individual risk may cause more noise-induced cases of health-impaired subjects than higher noise exposures. Franssen et al. (2004) pointed out that the number of people suffering from poor health due to aircraft noise is dominated by the larger number of people that is exposed to relatively moderate-to-low noise levels and not by those exposed to high noise levels. This means that more emphasis should be put on the reduction of noise in moderately exposed areas. However, public health policy cannot only consider population attributable risks (risk percentages), but must also consider individual risks (lifetime risk).

In practice, it seems to be reasonable that noise policy should reduce noise, beginning with the highest exposures and ending with the lowest ones. Decision-making will have to find common standards of acceptable risks, which may vary according to the cost–benefit considerations within and between communities and countries. Such practical standards may, however, vary due to economic development and abilities, cost–benefit considerations and priority settings of a community or country. Health quality targets derived from scientific research are usually intended to minimize risks; decision-making in the political process is only partly scientifically based due to economic limitations and concurring interests (Nijland et al., 2003). Different health outcomes or indicators of well-being and quality of life imply different action levels. Environment and health policy must determine acceptable noise standards that consider the whole spectrum from subjective well-being to somatic health (for example annoyance, physiological arousal, health risk). The evidence for a causal relationship between community or transportation noise and cardiovascular risk appears to have increased over recent years due to new studies that accomplish the database.

4.5.15 CONCLUSIONS

The evaluation process used in this paper considered the "necessary" criteria: peer-reviewed publication in an international journal, reasonable quantitative control of possible confounding, objective assessment of exposure and outcome, type of study (analytic vs. descriptive), and dose–response assessment (not only dichotomous "high" vs. "low"). The approach differs from that of an earlier meta-analysis (van Kempen et al., 2002) in that there regression coefficients were calculated for the entire dose–response curve within a single study (for instance the increase in risk per 5 dB(A)), which were then pooled between studies. Since higher exposure categories usually consist of smaller numbers of subjects than the lower categories, regression coefficients across noise levels tend to be influenced by the lower categories. This may lead to an underestimation of the risk in higher noise categories. The approach presented here pooled the effect estimates of single studies within each noise category, thus giving more weight to the higher noise categories and accounting for possible non-linear associations.

Fig. 4.8 and Fig. 4.9

Pooled effect estimates (meta analysis) of descriptive and analytic noise studies of the association between road traffic noise level and the prevalence (left graph) and incidence (right graph), respectively, of myocardial infarction (odds ratio ± 95% confidence interval).

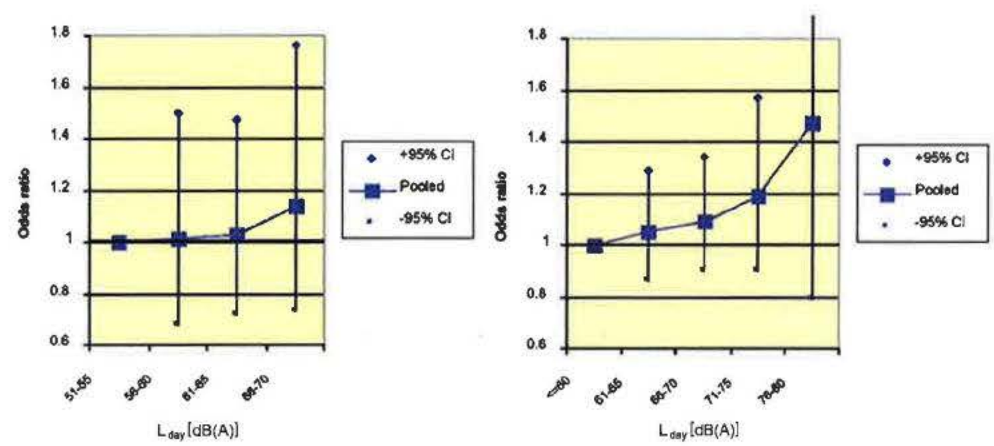


Fig. 4.8 and Fig. 4.9 show the two risk curves for descriptive and analytic studies (Hennekens and Buring, 1987). The graphs show the pooled effect estimates (odds ratios) and the 95% confidence intervals for each noise category. Whereas the cross-sectional studies (Fig. 4.9) cover the sound level range of L_{day} from >50 to 70 dB(A), the cohort and case-control studies (Fig. 4.8) cover the range from ≤60 to 80 dB(A). Both curves together can serve as a basis for a quantitative risk assessment. From Fig. 4.8 it can be seen that below 60 dB(A) for L_{day} no noticeable increase in risk of myocardial infarction is to be detected. Therefore for the time being, L_{day} = 60 dB(A) can be seen as NOAEL (no observed adverse effect level) for the relationship between road traffic noise and myocardial infarction (Babisch, 2002). For noise levels greater than 60 dB(A), the risk of myocardial infarction increases continuously, and is greater than 1.2 for noise levels of 70 dB(A). This can be seen in Fig. 4.9. It should be mentioned that the risk estimates, in general, were found to be higher in subjects that had lived in the exposed areas for a longer time (Babisch et al., 1994, 1999, 2005). This is in accordance with the noise hypothesis and the effects of chronic noise stress (Lercher and Kofler, 1996; Thompson, 1997). However, for the calculation of population attributable risks the figures for the whole population are relevant due to unknown information about residence time.

No particular risk groups could be identified on the basis of epidemiological research on cardiovascular effects of community noise. The assessment of dose-effect relationships sometimes suggested a cut-off level, above which the risk tends to increase. From a biological point of view, one would expect a continuous increase in risk with increasing noise level. However, adaptation, habituation and coping may be reasons for an empirical threshold of effect. Decisions with respect to guideline values usually refer to a quantitative risk assessment of populations (for example population attributable risk percentage). However, prevention strategies – for ethical reasons – should not ignore the individual risks of highly exposed subjects, even if their number may be small.

With respect to night noise exposure, nearly no information is available from epidemiological studies on the cardiovascular effects of long-term noise exposure of the bedroom during the night. Only one study distinguished between the exposures of the bedroom and the living room in the statistical analyses (Maschke, Wolf and Leitmann, 2003). The results suggested slightly higher effect estimates for the prevalence of hypertension with respect to the noise exposure of the bedroom (during the night) compared with the exposure of the living room (during the day). However, the difference was small (odds ration 1.9 vs. 1.5), which means that it still remains an open question whether the night exposure or the overall exposure throughout the whole day is the driving force. The study has some methodological limitations that were addressed in the summary of the major technical report and in a recent advisory report of the Health Council of the Netherlands (2004). They are mainly concerned with the fact that the study population consisted of a selected, predominantly older and health conscious group of persons that might have already suffered from regular health problems (risk group). A few studies that looked at the association between subjective responses to community noise and cardiovascular outcomes suggest a closer relationship with sleep-related annoyance/disturbance reaction rather than with non-sleep-related annoyance/disturbance (Bellach et al., 1995; Babisch et al., 1999, 2005; Maschke, Wolf and Leitmann, 2003; Niemann and Maschke, 2004). Closing the bedroom window or, vice versa, sleeping with the bedroom window open, was associated with a lower or higher risk, respectively (Lercher, 1996). The same was found with respect to changing the bedroom to the living room because of noise. These findings may indicate that night-time noise may be more a determinant of noise-induced cardiovascular effects than daytime exposure. However, daytime activity patterns and expectations of the individuals are much more inhomogeneous than during the night, which tends to dilute the statistical association of true effects with the day noise exposure.

Given the situation that only a few data are available from epidemiological studies with respect to effects on sleep (exposure of the bedroom during the night), there does not seem to be any other way of reasoning than inferring night noise recommendations or guidelines from the results of studies that refer to noise exposure during the daytime period (L_{day}) or the whole day (L_{dn}, L_{24h}). L_{den}, in this context, appears to be a useful noise indicator for decision-making and regulatory purposes. Penalties of 5 dB(A) and 10 dB(A) are usually given to the evening period and the night period, respectively. It can be used for noise mapping and refers normally to the most exposed facade, which incorporates a certain degree of exposure misclassification regarding cause–effect relationships. This weighted indicator was introduced to assess the relationship between sound level and noise annoyance (European Commission, 2002a). However, it may not be adequate for research into (somatic) health-related noise effects. Non-weighted separate exposure indicators, such as L_{day}, $L_{evening}$ or L_{night}, may be more appropriate when assessing physiological responses to the noise. In urban settings, night-time average noise levels (22.00–06.00) for road traffic tend to be approximately 7–10 dB(A) lower than daytime average noise levels – relatively independent (no freeways) of the traffic volume of the street (Utley, 1985; Ullrich, 1998; Evans et al., 2001). In such cases, L_{den} is approximately 2–3 dB(A) higher than L_{day} (Bite and Bite, 2004). Therefore, in epidemiological studies in which the relative effects of road traffic noise are studied, the sound emission during the daytime can as well be viewed as an approximate relative measure of the overall sound emission including the night. This seems to be further justified because existing noise regulations usually consider a 10 dB(A) difference between the day and the night. The NOAEL of 60 dB(A) for L_{day} corresponds, in this respect, with 50 dB(A) for L_{night}. This approximation can only be made with respect to road traffic noise.

Aircraft noise has been less intensively studied in noise epidemiology. The studies focused on high BP. Dose–response curves were hardly considered. A large European study on the association between aircraft noise and road traffic noise on BP is currently being conducted (Jarup et al., 2003). Regarding aircraft noise – and particularly the ongoing debate on night flight restrictions in the vicinity of busy airports – no other alternative exists at present than to take the myocardial infarction risk curves derived from road traffic noise studies as an approximate for aircraft noise. Since aircraft noise acts on all sides of a building, that is, different to road traffic noise, the suspicion exists that the effects induced by aircraft noise could be greater than those induced by road traffic (Ortscheid and Wende, 2000; Babisch, 2004a). This may be due to the lack of evasive possibilities within the home and the greater annoyance reactions to aircraft noise, which are usually expressed in social surveys (Miedema and Vos, 1998). More research is needed regarding the association between aircraft noise and cardiovascular end points.

This section is clearly focused on ill health as an outcome of the adverse effect of noise. A common dose-effect curve for the relationship between road traffic noise (outdoors) and the risk of myocardial infarction was developed. This curve can be used for a quantitative risk assessment and the calculation of attributable cases in a community. However, decisions regarding limit values have to be made within the spectrum between discomfort (annoyance) and ill health (disease) (Lindström, 1992; Babisch, 2002). Whereas quality targets at the lower end of the effects scale may be more flexible, quality targets at the upper end may be more obligatory. For example, for ethical reasons (equality principle) it does not seem to be justified if (ill) health-based limit values are varied according to the type of living area as expressed in land development plans (for example residential, mixed or commercial).

4.6 INSOMNIA

A group of Japanese researchers carried out a questionnaire-based survey of 3600 adult Japanese women (aged between 20 and 80) to gather information about the factors that contribute to insomnia (Kageyama et al., 1997). Some 11% of subjects were found to be affected by insomnia (as defined on the basis of WHO's International Statistical Classification and Related Health Problems, 10th revision – ICD10). Analysis of the survey data took account of various distorting variables, such as age, number of (small) children in the family, social status, receipt of medical treatment, regularity of bedtimes, apnoea-like problems and serious unpleasant experiences in the six months prior to completing the questionnaire. When the percentage of insomniacs in each of the three areas with the highest exposures was compared with the percentage in the low-exposure areas, the ratios worked out at, respectively, 1.4 (2100 vehicles per hour, L_{night} of around 65 dB(A)), 2.1 (2400 vehicles per hour, L_{night} of around 67 dB(A)) and 2.8 (6000 vehicles per hour, L_{night} of around 70 dB(A)). The most frequently reported problem was difficulty getting to sleep.

Research into the effects of exposure to air and road traffic noise has shown that increases in night-time noise exposure or in noise exposure during the sleep latency period have a statistically significant adverse impact on subjects' ability to get off to sleep and on sleep inception periods.

4.7 EFFECTS ON PERFORMANCE

4.7.1 COGNITION AND SWS

Jan Born and co-workers at the University of Lübeck (Wagner, Gais and Born, 2001; Benedict et al., 2004; Born and Wagner, 2004; Gais and Born, 2004; Drosopoulos, Wagner and Born, 2005) have reported interesting research and put forward intriguing hypotheses on the relation between noise exposure, sleep loss and subsequent cognitive performance. They conclude that declarative memory benefits mainly from sleep periods dominated by SWS, while there is no consistent benefit for this memory from periods rich in REM sleep. This points to the importance of SWS for declarative memory.

Since sleep in the early night is dominated by SWS, in contrast to late night when REM sleep dominates, this would imply that noise in the early night, for example aircraft noise before midnight, would be particularly damaging to memory and related cognitive functions. However, this implication has not yet been explicitly tested. That is, there seems to be a certain risk for impoverished memory due to noise in the early night, but there is as yet no graded quantification about whether ordinary pre-midnight noise levels around large airports are sufficient to make a difference to SWS. We also lack graded quantification about the relationship between impoverished SWS and the resulting effect on different aspects of declarative memory.

Thus, in terms of Fig. 1.1 we have evidence for the arrow marked (b), but we do not have enough information to say whether the strength of arrow (a) is sufficient to cause reduced SWS in field settings.

Furthermore, since children's memory systems pass through developmental changes and are not structured in the same way as for adults, it would be interesting to know to what extent the Born group results are also valid for children, and whether the depth of children's sleep counteracts or enhances SWS dominance in the early night.

4.7.2 COMPARING DAYTIME AND NIGHT-TIME NOISE EXPOSURE

As implied by Fig. 1.1, the relation between noise exposure and resulting effects on cognition should be analysed somewhat differently depending on whether the noise exposure takes place during the day or night. Analysing the cognitive effects of daytime noise exposure is fairly straightforward. For night-time noise exposure, however, any effects on cognition can either be a more or less direct effect of the noise exposure, or an indirect effect mediated by reduced sleep or sleep quality.

Also, comparing, for example, memory and learning functions when exposed to night-time noise, in contrast to daytime noise, shifts the focus of analysis away from encoding (in memory) or acquisition (in learning) while experiencing noise, to a focus on storing the material to be remembered or learnt while asleep (compare to daytime noise effects on cognition as reported by Hygge, Evans and Bullinger, 2002; Stansfeld et al., 2005). Thus, assuming that people are mainly asleep at night, all cognitive work that relies on the intake of information, listening or reading is not relevant. In all, this suggests that studies of daytime noise levels cannot be used much to give rough estimates of the effects of night-time exposure.

4.7.3 COMPARING CHILDREN AND ADULTS

How far can effects of daytime noise levels on children be generalized to give a rough estimate of the effects on adults? Are children more sensitive? Judging from earlier daytime studies of children and adults doing the same cognitive tasks while exposed to noise, children are not more sensitive than adults to noise (Boman, Enmarker and Hygge, 2004), but they perform at a lower level than the adults both in noisy and in quiet environments. Thus, it could be said that children are not more vulnerable to (daytime) noise in relation to cognitive performance, but since so much more cognitive work is expected from children while in school, their learning environment and their cognitive tasks can be said to be more noise vulnerable than corresponding environments for adults.

4.7.4 NOISE AND AFTER-EFFECTS

An argument can be made for noise as a stressor leading to reduced motivation (Glass and Singer, 1972), which in turn may act as a mediator of impaired cognitive performance. Along this line of reasoning, night-time noise may be more potent in inducing reduced motivation than daytime noise, but for the time being this is only a conjecture and has not been tested.

4.7.4.1 The role of restoration

Noise can be viewed both as a source of stressful demands and as a constraint on restoration. Noise levels and noise sources that are not by themselves particularly demanding during the waking hours of the day, may nevertheless be quite effective in blocking and constraining when they appear in periods meant to be restorative, such as sleep (Hartig, 2004). To what extent this idea is applicable to night-time noise exposure has not yet been explored.

4.7.4.2 Noise and communication

Some of the difficulties with children's responses to noise are related to problems in speech perception. A metric that weights night-time exposure more heavily is, in fact, less useful since children's auditory processing with parents and teachers is obviously more critical during waking hours.

4.8 EFFECTS ON PSYCHIC DISORDERS

Noise exposure at night may be more disturbing than daytime noise because it interferes with rest and sleep at a time when people want to relax. It seems plausible that night-time noise might have a particular effect on mental health. However, there is little direct research into night-time noise and mental health and it is first necessary to consider the evidence for environmental noise and mental health in general. The association between noise and mental health has been examined using a variety of outcomes including (at the simplest level) individual symptoms, as well as psychiatric hospital admission rates, use of health services and psychotropic medication, and community surveys.

4.8.1 TRANSPORTATION NOISE AND MENTAL HEALTH

Sources of transportation noise that have been studied in relation to mental health include road traffic noise and aircraft noise. Studies relating to each type of noise will be considered in turn.

4.8.1.1 Road traffic noise

The association between road traffic noise exposure and psychological distress has been studied in the small town of Caerphilly, South Wales. In the cross-sectional results, no association was found between the initial level of road traffic noise based on traffic noise maps, in terms of L_{eq} referring to the period 06.00–22.00, and minor psychological distress, measured by the General Health Questionnaire (GHQ), a screening questionnaire for depression and anxiety, even after adjustment for sociodemographic factors (Stansfeld et al, 1993). In longitudinal analyses in the Caerphilly Study, no association was found between road traffic noise and psychological distress, even after adjustment for sociodemographic factors and baseline psychological distress, although there was a small non-linear association of noise with increased anxiety scores (Stansfeld et al, 1996).

The disadvantage of the Caerphilly study is that it relied on one location with not very high levels of traffic noise. In a secondary analysis of a large British road traffic noise study, which took into account multiple noise exposure sites, the noise level in dB(A) exceeded for 10% of the time was weakly associated with a mental health symptoms scale of five items adjusting for age, sex, income and length of residence (Halpern, 1995). Weaker associations between traffic density and the mental health symptoms scale may relate to the skewed distribution of this traffic density variable. It seemed that traffic noise was more important than traffic flow. The scale used included some clear mental health items but also some that were less obviously related to mental health. It may be questioned whether the reported association between noise level and mental health symptoms was actually due to noise exposure; adjustment for the amount of "noise heard" reduced the association very little, suggesting no causal association with noise, but it is likely that there was a good deal of error in the measurement of this variable, reducing its validity.

It may be that the peak noise level is a better indicator of environmental noise heard indoors than noise measures averaged over time and that peak levels are a crucial indicator for mental health. Furthermore, in a road traffic noise study in Belgrade, 253 residents exposed to road traffic noise levels of >65dB(A), with high levels both day and night (L_{eq} 76.5 in the day, 69.5 at night in the noise-exposed area), experienced significantly more fatigue, depression, nervousness and headaches, compared to residents exposed to <55dB(A) (Belojevic and Jakovljevic, 1997). Sleep quality was also found to be worse among the inhabitants of noisy streets, compared to inhabitants of quiet streets, and those living in noisy streets had more difficulties falling asleep, more night awakenings and more pronounced tiredness after sleep. However, there were no differences in time taken to fall asleep or to go back to sleep, duration of sleep or consumption of sleeping pills between noise-exposed and non-exposed residents. A great methodological advantage of this study was that the high and low noise exposure areas were homogenous for age, sex, employment and subjective noise sensitivity. A community study in 366 Japanese women suggests that road traffic noise only has effects on depression, fatigue and irritability above a threshold of 70 dB(A) (Yoshida et al., 1997). However, it is difficult to be confident of the results of these analyses as they were unadjusted for age or social deprivation. Milder psychological states such as health functioning and well-being have also been examined in the first stage of an intervention study on the effect of introducing a bypass to relieve traffic congestion in a small town in North Wales (Stansfeld, Haines and Brown, 2000). Health functioning was measured by the SF-36 General Health Survey (Ware and Sherbourne, 1992), including dimensions of general health status, physical functioning, general mental health and social functioning. Ninety-eight respondents were studied who lived on a busy high street with traffic noise levels varying between 72 and 75 dBA outdoor L_{eq}. These respondents were compared with 239 control subjects living in adjacent quieter streets (noise level 55–63 dB(A) outdoor L_{eq}). Although subjects were well-matched on age, sex, housing insulation, car ownership and employment status, they were not so well-matched on proportion of manual workers, household crowding, deprivation and home ownership. There was no evidence that respondents exposed to higher levels of road traffic noise had worse health functioning than those exposed to lower levels of the noise, adjusting for levels of deprivation.

Another method of assessing mental health effects related to noise exposure is to use an indirect indicator such as medication use. In five rural Austrian communities exposed to road traffic noise, noise levels above 55 dB(A), including increasing night-time exposure to noise from trucks, were associated with increased risk of taking sleeping tablets (OR = 2.22 [CI: 1.13–4.38]) and overall prescriptions (OR = 3.65 [CI: 2.13–6.26]) relative to road traffic noise exposure less than 55 dB(A) (Lercher, 1996). This suggested effects at fairly low noise levels. In this case mental ill health may be secondary to sleep disturbance, which is likely to occur at lower nocturnal noise levels than mental health symptoms resulting from daytime noise exposure. As this occurred in a rural setting where road traffic was the predominant source of noise it would be interesting to replicate these findings in other settings.

4.8.1.2 Road traffic noise and mental health in children

Noise exposure and mental health has also been studied in children where child self-reported mental health on a standard scale and teacher ratings of classroom adjustment in response to motorway, road and rail noise were measured in a large sample of 8–11-year-old Austrian primary school children and in a second stage sample of extreme noise-exposed groups. Noise exposure was significantly associated with classroom adjustment scores but, intriguingly, child self-reported mental ill health was only impaired in noisy settings for children of low birth weight and preterm birth (Lercher et al., 2002).

4.8.1.3 Aircraft noise

Community surveys have found that high percentages of people reported "headaches", "restless nights", and "being tense and edgy" in high aircraft noise areas (Kokokusha, 1973; Finke et al., 1974; Öhrström, 1989). An explicit link between aircraft noise and symptoms emerging in such studies raises the possibility of a bias towards over-reporting of symptoms (Barker and Tarnopolsky, 1978). Notably, a study around three Swiss airports (Grandjean et al., 1973), did not mention that it was related to aircraft noise and did not find any association between the level of exposure to aircraft noise and symptoms. In the West London Survey, "tinnitus", "burns, cuts and minor accidents", "ear problems" and "skin troubles" were all more common in areas of high noise exposure (Tarnopolsky, Watkins and Hand, 1980). Acute symptoms such as "depression", "irritability", "difficulty getting off to sleep", "night waking", "skin troubles", "swollen ankles" and "burns, cuts and minor accidents" were particularly common in high noise areas. However, apart from "ear problems" and "tinnitus", 20 out of 23 chronic symptoms were more common in low noise environments. Symptoms did not increase with increasing levels of noise. This is possibly related both to more social disadvantage and associated ill health among residents in low aircraft noise exposure areas and the possible unwillingness of chronically unhealthy individuals to move into potentially stressful high noise exposure areas. Nevertheless, it would not exclude an effect of noise in causing some acute psychological symptoms. As the majority of aircraft noise exposure is during the day, daytime exposure is likely to have greater effects than nighttime exposure. Many of the effects of noise in industrial and teaching settings may be related primarily to disturbances in communication.

4.8.2 NOISE EXPOSURE AND MENTAL HOSPITAL ADMISSION RATES

Much of the concern with the possible effects of noise on mental health began with the study of admissions to psychiatric hospitals from noisy areas. Early studies found associations between the level of aircraft noise and psychiatric hospital admissions, both in London (Abey Wickrama et al., 1969) and Los Angeles (Meecham and Smith, 1977). These results have been criticized on methodological grounds (Chowns, 1970; Frerichs, Beeman and Coulson, 1980) and a replication study by Gattoni and Tarnopolsky (1973) failed to confirm these findings. Jenkins et al., (1979) found that age-standardized admission rates to a London psychiatric hospital over four years were higher as the level of noise of an area decreased, but lower noise areas were also central urban districts, where high admission rates would be expected. In a further extensive study of three hospitals (Jenkins, Tarnopolsky and Hand, 1981), high aircraft noise was associated with higher admission rates in two hospitals, but in all three of them, admission rates seemed to follow non-noise factors more closely; the effect of noise, if any, could only be moderating that of other causal variables but not overriding them. Kryter (1990), in a re-analysis of the data, found "a more consistently positive relation between level of exposure to aircraft noise and admissions rates". Undoubtedly, the route to hospital admission is influenced by many psychosocial variables that are more potent than exposure to noise. Therefore, whether or not noise causes psychiatric disorder is more suitably answered by studying a community sample.

4.8.3 NOISE EXPOSURE AND PSYCHIATRIC MORBIDITY IN THE COMMUNITY

In a community pilot study carried out in West London, Tarnopolsky et al. (1978) found no association between aircraft noise exposure and either GHQ scores (Goldberg, 1972) (dichotomized 4/5, low scorers/high scorers) or estimated psychiatric cases (Goldberg et al., 1970). This was the case even when exposure to road traffic noise was controlled, except in three subgroups: persons "aged 15–44 of high education" (41%, 14% $p<0.05$), "women aged 15–44" (30%, 13% n.s.), and those in "professional or managerial occupations". The authors expressed the guarded opinion that noise might have an effect in causing morbidity within certain vulnerable subgroups. In the subsequent West London Survey of Psychiatric Morbidity (Tarnopolsky, Morton-Williams and Barker, 1980), 5885 adults were randomly selected from within four aircraft noise zones, according to the Noise and Number Index. No overall relationship was found between aircraft noise and the prevalence of psychiatric morbidity either for GHQ scores or for estimated numbers of psychiatric cases, using various indices of noise exposure. However, there was an association between noise and psychiatric morbidity in two subgroups: "finished full-time education at age 19 years +", and "professionals". These two categories, which had a strong association with each other, were combined and then showed a significant association between noise and psychiatric morbidity ($X2 = 8.18$, df 3 $p<0.05$), but only for the proportion of high GHQ scorers. Tarnopolsky, Morton-Williams and Barker (1980) concluded that their results "show so far that noise per se in the community at large, does not seem to be a frequent, severe, pathogenic factor in causing mental illness but that it is associated with symptomatic response in selected subgroups of the population".

More recent studies have examined the effects of higher levels of military aircraft noise. Exposure to higher levels of military aircraft noise around the busy Kadena military airport in Japan was related in an exposure–effect association to depressiveness and nervousness measured by questionnaire using the Todai Health Index, based on the Cornell Medical Index (Ito et al., 1994; Hiramatsu et al., 1997). Mental health subscales included in this study measured depressiveness, nervousness, neurosis, and mental instability. Noise level was expressed as WECPNL (the power average of the maximum perceived noise exposure level in dB(A)) from 75–79, 80–84, 85–89, 90–94 and over 95). In unadjusted analyses, statistically significant differences were found in scores of depressiveness, nervousness and neurosis between the non-noise exposed control group and the pooled group exposed to 75–95 WECPNL. In multivariate analysis adjusting for age, sex, marital status, type of house and length of residence, noise exposure greater than 95 WECPNL was associated with higher scores on depressiveness and neurosis (Hiramatsu et al., 1997). Clear exposure–effect relationships were not found between scale scores and noise exposure, as expressed in five unit steps. However, using more broadly defined groups, an exposure–effect association was evident. This highlighted differences between the highest noise exposure group and lower exposure groups and indicated a threshold effect rather than a linear relationship – that mental health effects are more likely to be found at higher noise levels. In general, psychological rather than somatic symptoms were more related to noise in this study. Further analyses of the Japanese studies suggest that high levels of military aircraft noise may have effects on mental health. In a cross-sectional study of 5963 inhabitants around two air bases in Okinawa, those exposed to noise levels of L_{dn} 70 or above had higher rates of "mental instability" and depressiveness (Hiramatsu et al., 2000). Those who were more annoyed showed a higher risk of mental or somatic symptoms. A further survey using similar methodology on 6486 respondents found exposure–effect associations between aircraft noise exposure, nervousness and mental health (Miyakita et al., 1998). These are important studies because of the opportunity to examine the effect of high noise-exposure levels and the probability that vulnerable people migrating out of noisy areas and thus biasing the sample was small.

The use of health services has also been taken as a measure of the relationship between noise and psychiatric disorder. Grandjean et al. (1973) reported that the proportion of the Swiss population taking drugs was higher in areas with high levels of aircraft noise and Knipschild and Oudshoorn (1977) found that the purchase of sleeping pills, antacids, sedatives and antihypertensive drugs all increased in a village newly exposed to aircraft noise, but not in a "control" village where the noise level remained unchanged. In both studies, there was also an association between the rate of contact with general practitioners and level of noise exposure. In the Heathrow study (Watkins, Tarnopolsky and Jenkins, 1981), various health care indicators were used – use of drugs, particularly psychiatric or self-prescribed, visits to the GP, attendance at hospital, and contact with various community services – but none of these showed any clear trend in relation to levels of noise. A recent study found that the use of sleeping tablets and sedatives was elevated with increasing night-time noise exposure, especially in the elderly (Passchier-Vermeer et al., 2002). This has been judged to be "sufficient" evidence of a noise effect (Health Council of the Netherlands, 2004).

4.8.4 AIRCRAFT NOISE EXPOSURE AND MENTAL HEALTH IN CHILDREN

Poustka, Eckermann and Schmeck (1992) studied the psychiatric and psychosomatic health of 1636 children aged 4–16 in two geographical regions that differed according to the noise made by jet fighters frequently exercising at low altitude. Psychological and neurological outcomes were not related to noise exposure. They found that associations between noise exposure and depression and anxiety could be demonstrated, but only beneath the threshold of clinical significance. These results are less convincing because the areas differed socioeconomically and the results were not adjusted for these factors and also because of lack of precision of the measures of noise exposure. However, in Munich, children living in areas exposed to high aircraft noise had lower levels of psychological well-being than children living in quieter environments (Evans, Hygge and Bullinger, 1995). The longitudinal data from around Munich showed that after the inauguration of the new airport, the newly noise-exposed communities demonstrated a significant decline in self-reported quality of life measured on the Kindl scale, after being exposed to the increased aircraft noise for 18 months (third wave of testing), compared with a control sample (Evans, Bullinger and Hygge, 1998). Impairment of "quality of life" is a less severe disturbance than impairment of mental health. Further studies have examined the effects of noise on child psychiatric disorders.

Chronic aircraft noise exposure was not associated with anxiety and depression (measured with psychometrically valid scales), after adjustment for socioeconomic factors, in the Schools Health and Environment Study around Heathrow Airport (Haines et al., 2001a). In a further larger study of children's health around Heathrow Airport – the West London Schools Study (Haines et al., 2001b) – an association was found between aircraft noise exposure level and increased hyperactivity scores on the hyperactivity subscale of the Strength and Difficulties Questionnaire (Goodman, 1997). These studies suggest that noise influences child mental health in terms of hyperactivity and that it may affect child stress responses and sense of well-being.

4.8.5 NEIGHBOURHOOD NOISE AND MENTAL HEALTH

Noise from neighbours is the commonest source of noise complaints to local authorities in the United Kingdom (Chartered Institute of Environmental Health, 1999). Noise which is continuous, apparently indefinite, of uncertain cause or source, emotive or frightening or apparently due to thoughtlessness or lack of consideration is most likely to elicit an adverse reaction (Grimwood, 1993). In the 1991 BRE survey, people most objected to barking dogs, banging doors, noise from radio, television, or hi-fi and human voices (Grimwood, 1993). In this survey, two types of emotional response to noise were observed: outwardly directed aggression, characterized by feelings of annoyance, aggravation, bitterness and anger towards the source of the noise, and a more emotional response of tension, anxiety and feelings of pressure. These responses are reminiscent of the distinction between internalizing and externalizing disorders. Whether noise from neighbours can induce psychiatric disorder has been little studied in community research, but this is an area that deserves further study (Stansfeld, Haines and Brown, 2000).

Undoubtedly, prolonged exposure to noise can be very upsetting, intrusive and interfering for sleep and everyday activities. In poorly built dwellings, especially apartments, even low intensity noises may be clearly audible through walls, floors, or ceilings (Raw and Oseland, 1991). In this situation, noise is destructive of privacy, especially for those living alone, and may be associated with perceptions of threat or increase a sense of isolation. This may be especially the case among people who are chronically anxious and likely to complain of sensitivity to noise; prolonged noise exposure may make them more anxious and unhappy. Often, this leads to arguments with neighbours, leading to a breakdown of neighbourly relationships and further isolation which may well in itself have a bad effect on mental health. Occasionally, this may be a sign of feelings of persecution associated with psychotic illness in which noise exposure is just an external trigger of an internally generated condition.

4.8.6 MECHANISMS FOR CAUSAL LINKS BETWEEN NOISE AND MENTAL HEALTH

What might the mechanism be for the effects of noise on mental health? One way to approach this is through the effects of noise on cognitive performance where the laboratory evidence of effects is fairly robust (Smith and Broadbent, 1992). Effects of noise on mental health might be expected because there is evidence that noise impairs other aspects of human functioning, such as performance (Loeb, 1986) and sleep, that are important in maintaining normal functioning, and that noise causes adverse emotional reactions such as annoyance. In general, it seems that noise exposure increases arousal, and decreases attention through distraction (Broadbent, 1953), increases the need for focusing attention to cut out irrelevant stimuli (Cohen and Spacapan, 1978), as well as altering choice of task strategy (Smith and Broadbent, 1981). Even relatively low levels of noise may have subtle ill effects, and in this respect, the state of the person at the time of performance may be as important as the noise itself (Broadbent, 1983). Individuals' perception of their degree of control over noise may also influence whether it impairs memory (Willner and Neiva, 1986) while perception of lack of control over environmental conditions may be an important mediator of health effects.

Additionally, noise may also affect social performance as: (1) a stressor causing unwanted aversive changes in affective state; (2) by masking speech and impairing communication; and (3) by distracting attention from relevant cues in the immediate social environment (Jones, Chapman and Auburn, 1981). It may be that people whose performance strategies are already limited for other reasons (for instance through high anxiety) and who are faced with multiple tasks may be more vulnerable to the masking and distracting effects of noise.

The mechanism for the effects of noise on health is generally conceptualized as fitting the stress–diathesis model, in which noise exposure increases arousal, and chronic exposure leads to chronic physiological change and subsequent health effects. It is not clear, however, whether this model is appropriate for mental health effects. A more sophisticated model (Biesiot, Pulles and Stewart, 1989; Passchier-Vermeer, 1993) incorporates the interaction between the person and their environment. In this model, the person readjusts their behaviour in noisy conditions to reduce exposure. An important addition is the inclusion of the appraisal of noise (in terms of danger, loss of quality, meaning of the noise, challenges for environmental control, etc.) and coping (the ability to alter behaviour to deal with the stressor). This model emphasizes that dealing with noise is an active not a passive process.

4.8.7 HABITUATION TO NOISE AND MENTAL HEALTH

It is likely that mental health effects arise from persistent exposure to noise over a long period of time. But do people habituate or adapt to noise over time? In some studies people do seem to adapt to noise and no longer notice noise that they are frequently exposed to. On the other hand, in some studies of annoyance there seems to be little evidence of adaptation (Cohen and Weinstein, 1981). It may be that, as in physiological studies, a failure of adaptation occurs if the stimulus is novel, salient or implies threat. The development of mental health symptoms implies a failure to habituate to noise, or at least to adapt to noise. In some studies control over noise or active coping with noise rather than passive emotion-focused coping is related to lower levels of symptom (van Kamp, 1990). Habituation has not been formally studied in relation to noise and mental health.

4.8.8 RISK GROUPS FOR MENTAL HEALTH EFFECTS FROM NOISE

One way to look at susceptibility to noise is to think about groups in the population who may be more susceptible to noise, for instance people with existing physical or mental illness tend to be more highly annoyed by noise and potentially could be vulnerable to mental health effects. Similarly, people with hearing impairment may be vulnerable to communication difficulties in noisy environments that could increase the risk of mental health symptoms. People who report that they are sensitive to noise tend to be more prone to noise annoyance and may be more at risk for common mental disorders (Stansfeld et al., 2002).

4.8.9 POPULATION GROUPS AT RISK FOR MENTAL HEALTH EFFECTS FROM NOISE

There is some evidence that children are more vulnerable to the mental health effects of noise than adults in terms of prematurity, low birth weight and through scoring higher on hyperactivity. There is no consistent evidence of age, social class, ethnic or gender differences in susceptibility to mental health effects from environmental noise.

4.8.10 NOISE SENSITIVITY

Noise sensitivity, based on attitudes to noise in general (Anderson, 1971; Stansfeld, 1992), is an intervening variable which explains much of the variance between exposure and individual annoyance responses (Weinstein, 1978; Langdon, Buller and

Scholes, 1981; Fields, 1993). Individuals who are noise-sensitive are also likely to be sensitive to other aspects of the environment (Broadbent, 1972; Weinstein, 1978; Thomas and Jones, 1982; Stansfeld et al., 1985a). This raises the question as to whether noise-sensitive individuals are simply those who complain more about their environment. Certainly, there is an association between noise sensitivity and neuroticism (Thomas and Jones, 1982; Öhrström, Bjorkman and Rylander, 1988; Jelinkova, 1988; Belojevic and Jakovljevic, 1997; Smith, 2003), although it has not been found in all studies (Broadbent, 1972). On the other hand, Weinstein (1980) hypothesized that noise sensitivity is part of a critical/uncritical dimension, showing the same association as noise sensitivity to measures of noise, privacy, air pollution and neighbourhood reactions. He suggested that the most critical subjects, including noise-sensitive people are not uniformly negative about their environment, but more discriminating than the uncritical group, who comment uniformly on their environment.

Noise sensitivity has also been related to current psychiatric disorder (Bennett, 1945; Tarnopolsky, Morton-Williams and Barker, 1980; Iwata, 1984). Stansfeld et al. (1985) found that high noise sensitivity was particularly associated with phobic disorders and neurotic depression, measured by the Present State Examination (Wing, Cooper and Sartorius, 1974). Similar to this association with phobic symptoms, noise sensitivity has also been linked to a coping style based on avoidance, which may have adverse health consequences (Pulles, Biesiot and Stewart, 1988) and a tendency to report health complaints rather than take a more active coping approach to noise (Lercher and Kofler, 1996). Noise sensitivity may be partly secondary to psychiatric disorder: depressed patients followed over four months became less noise-sensitive as they recovered (Stansfeld, 1992). These "subjective" psychological measurements were complemented by an "objective" psychophysiological laboratory investigation of reactions to noise in a subsample of depressed patients. Noise-sensitive people tended to have higher levels of tonic physiological arousal, more phobic and defence/startle responses and slower habituation to noise (Stansfeld, 1992). Thus, noise-sensitive people attend more to noises, discriminate more between noises, find noises more threatening and out of their control, and adapt to noises more slowly than people who are less sensitive. Through its association with greater perception of environmental threat and its links with negative affectivity and physiological arousal, noise sensitivity may be an indicator of vulnerability to minor psychiatric disorder, although not necessarily psychiatric disorder caused by noise (Stansfeld, 1992).

In analysis of a subset of noise-sensitive women, compared to less sensitive women in the West London survey, there was no evidence that aircraft noise exposure predicted psychiatric disorder in the sensitive women (Stansfeld et al., 1985). In the Caerphilly study, noise sensitivity predicted psychological distress at follow-up after adjusting for baseline psychological distress, but did not interact with the noise level, suggesting that noise sensitivity does not specifically moderate the effect of noise on psychological distress (Stansfeld et al., 1993). However, in further analyses, a statistically significant association between road traffic noise exposure and psychological distress, measured by the General Health Questionnaire (GHQ), was found in noise-sensitive men, that was not found in men of low noise sensitivity (Stansfeld et al., 2002). In the original analyses, after adjusting for trait anxiety at baseline, the effect of noise sensitivity was no longer statistically significant. This suggests that much of the association between noise sensitivity and psychological distress may be accounted for by the confounding association with trait anxiety. Constitutionally anxious people may be both more aware of threatening aspects of their environment and more prone to future psychiatric disorder. It seems possible that these traits might be linked.

In a United Kingdom community study, associations were examined between noise exposure, noise sensitivity, subjective symptoms and sleep disturbance in a random sample of 543 adults (Smith, 2003). Perceived noise exposure was related to subjective health, but this association became non-significant after adjustment for negative affectivity. In a similar way, adjustment for negative affectivity eliminated the association between noise sensitivity and subjective health. Thus, it was suggested that noise sensitivity was merely a proxy measure of negative affectivity or neuroticism. However, although this means that noise sensitivity is not specific to noise, the more recent analyses suggest that high levels of trait anxiety or neuroticism may be an indicator of vulnerability to noise effects and could put people at risk of adverse psychological effects from noise, even if they do not increase the risk of physical ill health.

4.8.11 MENTAL HEALTH CONSEQUENCES OF INSOMNIA

Transient insomnia is usually accompanied by reports of daytime sleepiness and performance impairment the next day. Chronic insomnia is generally associated with poorer emotional and physical health. Several large-scale epidemiological studies of the general adult population have shown that between one third and one half of people who complain of chronic insomnia are also diagnosable with primary psychiatric disorders, mostly anxiety and mood disorders. Mellinger, Balter and Uhlenhuth (1985) found that 17% of adults reported "a lot" of trouble falling asleep or staying asleep over the past year; 47% of them had high levels of psychological distress, with symptom complexes suggestive of depression and anxiety disorders. In contrast, only 11% of individuals with no history of insomnia showed elevated levels of psychiatric symptoms. In a survey of almost 8000 individuals, Ford and Kamerow (1989) reported that 10% had suffered from significant insomnia for at least a two-week period during the previous six months; 40% of the insomniacs met criteria for psychiatric disorders, with the majority being anxiety disorders and depression; only 16% of those with no sleep complaints had psychiatric illness.

Breslau et al. (1996) found a strong correlation between lifetime prevalence of sleep problems and psychiatric disorders, with anxiety, depression, and substance abuse disorders being the most common. Similar results have been found by Vollrath, Wicki and Angst (1989), Chang et al. (1997) and Dryman and Eaton (1991). In a large-scale European population-based study (Ohayon and Roth, 2003), it was found that insomnia more often precedes rather than follows incident cases of mood disorders.

Insomniacs not only have higher rates of psychiatric disorders, but they also have increased rates of various kinds of psychological symptoms: patients with insomnia reported increased psychological stress and/or decreased ability to cope with stress according to surveys of the American (Roth and Ancoli-Israel, 1999) and Japanese (Kim et al., 2000) population. Almost 80% of insomniacs had a significant increase on one or more clinical scales on the Minnesota Multiphasic Personality Inventory (MMPI) (Kalogjera-Sackellares and Cartwright, 1997). Even people whose insomnia was due to identified medical factors showed elevation on the MMPI, suggesting a possible causal relationship or specific association between insomnia and psychiatric symptomatology. Compared to good sleepers, severe insomniacs reported more medical problems, had more GP office visits, were hospitalized twice as often and used more medication. Severe insomniacs had a higher rate of absenteeism, missing work twice as often as did good sleepers. They also had more problems at work (including decreased concentration, difficulty performing duties and more work-related accidents) (Leger et al., 2002).

4.8.12 INSOMNIA AS A MENTAL HEALTH SYMPTOM

Insomnia is a symptom of many psychiatric disorders, especially depression and anxiety. In studies of depressed patients compared to control subjects, there was prolonged latency to sleep, increased wakefulness during sleep, early morning wakening, decreased sleep efficiency and reduced total sleep time. There is also evidence that insomnia may be a risk factor for developing depression (Riemann, Berger and Voderholzer, 2001; Roberts, Roberts and Chen, 2002). This raises the question as to whether prolonged noise exposure leading to insomnia provokes the onset of depression in susceptible people? This seems theoretically possible, but there is little evidence to support it. In a longitudinal study of adolescents, it was the other way round – that depressive symptoms preceded the onset of insomnia (Patton et al, 2000). Delayed sleep latency in children has been linked to increased externalizing symptoms including aggressive behaviour, and impaired attention and social problems (Aronen et al., 2000). In this cross-sectional study, the direction of association was uncertain, but it seems most plausible that the sleep disturbance is a feature of the behavioural disturbance rather than a cause of it. Three criteria have been suggested for sleep disturbance to be environmentally determined: (1) the sleep problem is temporally associated with the introduction of a physically measurable stimulus or definable set of environmental circumstances; (2) the physical rather than the psychological properties of the environmental factors are the critical causative elements; and (3) removal of the responsible factors results in an immediate or gradual return to normal sleep and wakefulness (Kraenz et al., 2004). Most studies do not fulfil these criteria. In a German school-based study of 5–6-year-old children, sleep disturbance by noise, largely from road traffic, was reported "sometimes" in 10% by parents of children and 2% "often". Children's reports were slightly higher: "sometimes" in 12% and 3% "often" (Kraenz et al., 2004). Further longitudinal research is needed to ascertain whether noise-induced insomnia leads on to overt psychiatric disorder.

In summary, population as well as clinic-based studies have demonstrated a high rate of psychiatric morbidities in patients with chronic insomnia. It has traditionally been assumed that insomnia is secondary to the psychiatric disorders; however, it is possible that in some cases the insomnia preceded the psychiatric disorder.

4.8.13 DEPRESSIVE EPISODE AND ANXIETY DISORDERS

A mild depressive episode is diagnosed by clinical interview. The criteria for a mild depressive episode include two or more symptoms of depressed mood, loss of interest or fatigue lasting at least two weeks, with two or three symptoms such as reduced concentration, reduced self-esteem, ideas of guilt, pessimism about the future, suicidal ideas or acts, disturbed sleep, diminished appetite and social impairment, and fewer than four symptoms including lack of normal pleasure/interest, loss of normal emotional reactivity, waking =>2 hours early, loss of libido, diurnal variation in mood, diminished appetite, loss of =>5% body weight, psychomotor agitation or psychomotor retardation.

Anxiety disorders are similarly diagnosed by clinical interview. The criteria for "generalized anxiety disorders" include duration of at least six months of free-floating anxiety and autonomic overactivity.

4.8.14 ASSOCIATIONS BETWEEN INSOMNIA AND PSYCHIATRIC DISORDERS

At the present time, exposure–effect associations have not been established between parameters of sleep disturbance (number of behavioural awakenings, body movements or EEG awakenings) and the onset of depressive and anxiety disorders, although there is some evidence that insomnia is a risk factor for developing depression (Riemann, Berger and Voderholzer, 2001; Roberts, Roberts and Chen, 2002). A number of longitudinal prospective studies in different age groups have found associations between self-reports of insomnia and the subsequent onset of psychiatric disorder, in particular major depression. A selection of the most important studies and their findings are outlined in Table 4.3 below.

Table 4.3 Insomnia as a predictor of psychiatric disorder

Study	Sample size	Sample	Follow-up interval	Depression measure	Results
Ford and Kamerow, 1989	7954	Community sample	1 year	Diagnostic interview schedule	Risk of developing new depression for insomnia on two occasions: [OR=39.8, 95% CI 19.8-80.0]
Breslau et al., 1996	1200	21–30 years members of health maintenance organization	3 years	Diagnostic interview schedule	RR for new onset major depression associated with baseline insomnia [RR=4.0, 95% CI 1.5-5.6]
Chang et al., 1997	1053	Male medical students	34 years (median)	Clinical depression	RR for clinical depression for those who reported insomnia at medical school [RR= 2.0, 95% CI 1.2-3.3]
Roberts, Roberts and Chen, 2002	3136	11–17 years from managed care rosters	1 year	Diagnostic interview schedule for children major depression module	Fully adjusted OR for insomnia in waves 1 and 2 for depression at follow-up [OR=1.92, 95% CI 1.30-2.82]

4.8.15 CONCLUSIONS: ASSOCIATIONS BETWEEN NOISE AND PSYCHIATRIC DISORDERS

The effects of noise are strongest for those outcomes that, like annoyance, can be classified under "quality of life" rather than illness. What they lack in severity is made up for in numbers of people affected, as these responses are very widespread.

Current evidence does seem to suggest that environmental noise exposure, especially at higher levels, is related to mental health symptoms and possibly raised anxiety and consumption of sedative medication, but there is little evidence that it has more serious effects. Further research is needed on mental health effects at very high noise levels. Existing studies may be confounded either by prior selection of subjects out of (or into) noisy areas as a result of noise exposure, or by confounding between noise exposure, socioeconomic deprivation, and psychiatric disorder. It is also possible that people underestimate or minimize the effects of noise on health through optimism bias (Hatfield and Soames Job, 2001) and that this is particularly protective for mental health.

The evidence is not strong for the association between noise exposure and mental ill health. What evidence there is suggests that noise exposure may be responsible for psychological symptoms above 70 dB(A) L_{eq}. Almost all studies have only examined the effects of daytime noise on mental health, but it is possible that night-time noise, during sleep time, may have effects on mental health at lower levels than daytime noise.

The most powerful evidence of noise on mental health comes from studies of military aircraft noise. There is also some evidence that intense road traffic noise may lead to psychological symptoms. There is no evidence of any effects of railway noise on mental health.

4.9 THE SEVERITY OF SELF-REPORTED SLEEP DISTURBANCE

4.9.1 INTRODUCTION

In section 2.1.2 of Chapter 2 of this report, it is stated that sleep disturbance caused by noise may either be diagnosed (Environmental Sleep Disorder: ICSD 780-52-6) or self-reported. Although self-reported sleep disturbance is subjective by definition, its observed occurrence correlates with noise levels as well as with important diagnostic criteria for ICSD 780-52-6. It appears justified to consider self-reported sleep disturbance as an impairment of health, especially if indicated by representative population samples in social surveys. Furthermore, section 4.1 of Chapter 4 of this report gives a quantitative relationship between noise level L_{night} and the percentage of population that reports a disturbed sleep of high, medium or low disturbance intensity.

But an open question concerns severity: even if night-time noise causes large percentages of the population to declare themselves as highly sleep-disturbed, this could nevertheless represent an almost negligible loss of health, if the mean severity of self-reported sleep disturbance were negligible in comparison with commonly accepted diseases. Attempts have been made to give an answer to this important question, using WHO's concept of disability weights (Murray et al., 1996) as a basis for severity comparisons.

4.9.2 AN ASSESSMENT OF DISABILITY WEIGHTS

A Swiss study (Müller-Wenk, 2002) aimed at determining a disability weight for sleep disturbance due to road traffic noise. For this purpose, a description of road-noise-related sleep disturbance was set up: essentially, this state of health was assumed to be present if a person indicated that, due to traffic noise, he or she, almost every night, had problems with falling asleep, with continuing sleep during the night or with early or non-restorative waking in the morning. In addition, a list was established with already available disability weights (Murray et al., 1996; Stouthard et al., 1997) for a selection of 28 diseases of various types, covering a range from very light severity to high severity (Müller-Wenk 2002:65–66). All 64 members of the medical staff of the Swiss Accident Insurance Institute (SUVA) were then asked in a written questionnaire to determine the hitherto unknown disability weight of sleep disturbance by interpolation, that is, by inserting sleep disturbance at the appropriate place between the presented 28 diseases that were sorted according to ascending disability weight. These participants were chosen because the physicians of the SUVA, besides being medical doctors, have a particularly high professional know-how in comparing the severity of different types of disability. Forty-two questionnaires were completed, of which 41 were usable.

From these questionnaires, an arithmetical mean of 0.055 of the disability weight for sleep disturbance could be calculated, with a 95% confidence limit of 0.039 at the low end and 0.071 at the high end. This result can be illustrated by mentioning diseases from the catalogues of Murray et al. (1996) or Stouthard et al. (1997) with the same disability weight: hence the disability weight of the road-noise-related sleep disturbance is roughly the same as the disability weight of "chronic hepatitis B infection without active viral replication", the latter having a mean disability weight of 0.06 and a 95% confidence interval from 0.034 to 0.087. The low-end estimate of 0.039 for sleep disturbance severity would correspond to the mean disability weight of "benign prostatic hypertrophy (symptomatic cases)", whilst the high estimate of 0.071 would correspond to the mean disability weight of "uncomplicated diabetes mellitus". The conclusion is that the mean disability weight of road-noise-related sleep disturbance is not smaller (= less severe) than the disability weight of health impairments commonly recognized as diseases, and there is a strong overlap amongst the probability distributions of these disability weights. On the basis of the chosen disability weight 0.055 for self-reported sleep disturbance, and taking into account the current traffic noise levels during the night in many European states, it is justified to consider noise-related sleep disturbance as a substantial loss of public health.

4.9.3 COMPARISON BETWEEN INSOMNIA AND SELF-REPORTED SLEEP DISTURBANCE

The original list of disability weights (Murray et al., 1996) did not contain any kind of non-normal sleep. In the meantime, WHO has published an extended list (Mathers et al., 2003, Annex Table 5a) containing a disability weight of 0.100 for insomnia (diagnostic code 307.42). This has opened a way to recheck the disability weight of 0.055 (Müller-Wenk, 2002), by asking a panel of medical professionals to compare, on the basis of disability weights, the mean severity of self-declared sleep disturbance due to road noise at night with the mean severity of insomnia. It may be debated whether it is more straightforward to compare two types of sleep anomalies with similar symptoms, or to compare self-declared sleep disturbance with various types of completely different diseases. But it makes sense anyway to use the comparison with insomnia as a second approach for determining the disability weight of self-reported sleep disturbance.

This severity comparison between different sleep anomalies was made in 2005 by structured oral interviews, executed by a medical staff member of the sleep clinic of Kantonsspital St. Gallen (Switzerland), with 14 GPs selected at random from all GPs who had admitted patients to the sleep clinic during the nine preceding months. These patients were mainly suffering from OSAS. The question was as follows:

> "Could you please give us your opinion on the relative severity of three different cases of insomnia:
>
> 1. (primary) insomnia, in our region usually called psychophysiological insomnia
> 2. Obstructive Sleep Apnoea Syndrome (OSAS)
> 3. traffic-noise-related sleep disturbance, that may occur with persons who are forced to sleep along through roads with nocturnal motor traffic.
>
> Your opinion should be based on the patients you have seen in your office lately, or on other persons of your social environment. When comparing the severity of the health impairment, the focus should be above all on the person's condition during the day after the sleep-disturbed night. The absolute value of the severity is less important for the current study than the relative severity amongst the three cases of insomnia. The opinion of the severity may be expressed on a linear scale from 0 (no impairment at all) to 10 (impairment almost unsupportable). On the scale from 0 to 10, you may give us your mean value of the severity, or you may give us a span from a low to a high for the severity."

All of the interviewed GPs gave their opinions, and the result is presented in Table 4.4.

Table 4.4
Severity ratings (10 = almost insupportably disturbing, 0 = not in the least disturbing) by 14 GPs selected at random

	Primary insomnia				OSAS (sleep apnoea)				Sleep disturb.(noise)				Ratio noise/	Noise/
No	Max	Min	Mean	Rank	Max	Min	Mean	Rank	Max	Min	Mean	Rank	priminsomnia	OSAS
10	6	4	5	3	8	6	7	1	8	6	7	1	1.40	1.00
11	5	3	4	3	9	7	8	1	8	4	6	2	1.50	0.75
12			5	3			10	1	7	8	7.5	2	1.50	0.75
13	2	3	2.5	2	4	5	4.5	1	1	2	1.5	3	0.60	0.33
14			3	2			6	1	1	2	1.5	3	0.50	0.25
15			8	2			9	1			6	3	0.75	0.67
16			8	1			7	2			4	3	0.50	0.57
17			5	1			5	1			3	3	0.60	0.60
18	2	3	2.5	2			6	1	1	2	1.5	3	0.60	0.25
19			8	1			3	2			2	3	0.25	0.67
20			6	2			7	1			4	3	0.67	0.57
21			7	2			8	1			0	3	0.00	0.00
22			4	3			5	2			6	1	1.50	1.20
23			4	3	6	7	6.5	2	8	9	8.5	1	2.13	1.31
Mean			5.143	2.143			6.57	1.286			4.18	2.429	0.89	0.64
Sigma													0.60	
Median													0.63	
Upper value 95% C.I. for mean													1.20	
Lower value 95% C.I. for mean													0.58	

Clearly, the severity judgements vary widely between the participating GPs. Apart from the differences in personal judgement, this variation is certainly influenced by the mix of patients visiting a particular GP. For instance, GP number 15 could have encountered one or two very serious cases of OSAS, whilst his/her experience with noise-related sleep disturbance might refer to persons that were only moderately disturbed by night-time noise in their bedroom. On the other hand, number 22 could have had experience with persons suffering very much from sleep disturbance due to high traffic noise exposure, whilst his/her OSAS or primary insomnia patients happened to be light cases. One must accept that even GPs have a limited experience with the whole range of cases of each of the three types of insomnia, so that their opinion on the mean severity of noise-related sleep disturbance, compared to the mean severity of OSAS or insomnia, is influenced by the randomness of their patient mix.

Nevertheless, the table supports the following statements.

- With respect to severity, the majority of GPs rank noise-related sleep disturbance lower than insomnia and OSAS, while three of them put noise-related sleep disturbance in the first rank. Only one of the participants (number 21) considers noise-related sleep disturbance as a fully negligible disturbance.
- The severity ratio between noise-related sleep disturbance and insomnia varies between 0 and 2.1. Seven of the fourteen GPs indicate a severity ratio between 0.5 and 0.75, that is to say that half the participants are of the opinion that the severity of noise-related sleep disturbance amounts to 50–75% of the severity of insomnia.
- The mean of this severity ratio is 0.89, with a standard deviation (sigma) of 0.60. The confidence interval (CI) for the mean goes from 0.58 to 1.20. The median of the severity ratio is 0.63. The distribution is skewed to the right.

The severity ratio developed above can be used as a proportionality factor between the known disability weight for insomnia and the required disability weight for self-reported sleep disturbance. Bearing in mind that the already existing WHO disability weight for insomnia is 0.10, a best guess for the mean disability weight for self-reported sleep disturbance due to road traffic noise at night is therefore 0.089, with a CI from 0.058 to 0.12.

4.9.4 CONCLUSIONS

According to the two groups of interviewed medical professionals, persons that declare themselves to be chronically deprived of normal sleep by road traffic noise have a health state whose mean disability weight is comparable to "chronic hepatitis B infection without active viral replication" or higher. Irrespective of the question whether self-reported sleep disturbance is formally recognized as a disease or not, its severity is comparable to commonly accepted diseases.

The best estimate for a mean disability weight for self-reported sleep disturbance due to road traffic noise was 0.055 (CI: 0.039; 0.071) according to Müller-Wenk (2002), whilst our recheck based on a comparison with insomnia resulted in a disability weight of 0.09 (CI: 0.06; 0.12). The higher disability weight according to the second approach might be caused by the fact that in this second approach, there was a stronger focus on "the person's condition during the day after the sleep-disturbed night".

The above figures compare reasonably with a study published by van Kempen (1998), cited in Knol and Staatsen (2005:46), where a severity weight of 0.10 for severe sleep disturbance was found, based on the judgement of 13 medical experts according to the protocol of Stouthard et al. (1997).

In conclusion, a mean disability weight of 0.07 is proposed for self-reported sleep disturbance due to road noise or similar ambient noise. This disability weight can be used in connection with the equations of section 4.1 of this chapter for highly sleep-disturbed persons.

4.10 DISCUSSION: CAN CHRONIC SHORT-TERM EFFECTS CAUSE LONG-TERM EFFECTS ON HEALTH?

EEG modifications, cardiovascular responses, body movements and awakenings due to noise occur within a few seconds after the stimulus. In addition to the instantaneous effects related to single events, large field studies on aircraft (Passchier-Vermeer et al., 2002) and road traffic noise exposure during night-time (Griefahn et al., 2000; Passchier-Vermeer et al., 2004) show that also sleep latency and average motility during the sleep period increased monotonously as a function of the noise exposure level. The increase in average motility was substantially higher than would be expected on the basis of the instantaneous extra motility at the times of the noise events (Passchier-Vermeer et al., 2002) suggesting persistent arousal during the sleep related to aircraft noise. Furthermore, an international field study (Jurriëns et al., 1983) found slightly reduced REM sleep, increased time being awake according to the EEG, increased average heart rate, and reduced performance on a reaction time test in people when exposed during the night to higher road traffic noise levels.

The relationship between instantaneous effects and more global modifications of one night sleep, as well as chronic changes, is not simple, as illustrated by the findings concerning motility. An increase in average motility that is substantially higher than would be expected on the basis of the instantaneous extra motility at the times of the noise events (Passchier-Vermeer et al., 2002) suggests a persistent arousal during sleep related in a dose-dependent way to the aircraft noise.

Since EEG arousal and instantaneous motility are correlated, this finding suggests that also the number of (micro-)arousals may increase during noise exposure more than by the sum of the instantaneous (micro-)arousals that occur contingent upon a noise event.

For overall motility during sleep, clear indications have been found of associations with further effects, although the causal direction is not in all cases clear. Mean (onset of) motility during sleep is associated with the following variables based on questionnaires and diaries (Passchier-Vermeer et al., 2002):

- frequency of conscious awakening during the sleep period: the increase is 0.8 conscious;
- awakenings per night, if motility increases from low to high;
- frequency of awakening remembered next morning: the increase is 0.5 remembered;
- awakenings per night, if motility increases from low to high;
- long-term frequency of awakening attributed to specific noise sources assessed with a questionnaire;
- sleep quality reported in a morning diary;
- long-term sleep quality assessed with a questionnaire;

- number of sleep complaints assessed with a questionnaire;
- number of general health complaints assessed with a questionnaire.

The associations of mean motility with these variables are stronger than the corresponding associations of mean onset of motility.

For evaluating the adverseness of the instantaneous effects, it is important to consider whether they bring the body into a more persistent state of higher arousal or not, although this is not the only criterion. Those effects which are progressively disappearing with the repetition of the stimulus may be less harmful than those which do persist over long exposure time, provided that the suppression of the effects do not require costs in another form. For example, short-term cardiovascular effects that appear not to habituate could lead to permanent cardiovascular system impairment (Carter, 1996, 1998).

The relations presented for motility and conscious awakening imply that motility is sensitive to noise and has a relatively low threshold, while conscious awakening, the strongest instantaneous interference of noise with sleep, has the highest threshold of the instantaneous effects considered.

In one of the most sophisticated field studies (Passchier-Vermeer et al., 2002), increased probability of instantaneous motility was found for events with a maximum sound level $L_{Amax} > 32$ dB(A), while in a meta-analysis conscious awakening was found for events with $L_{Amax} > 42$ dB(A) (Passchier-Vermeer, 2003a). Above their threshold, these effects were found to increase monotonously as a function of the maximum sound level during a noise event (aircraft noise). It is important to note that in another recent sophisticated field study (Basner et al., 2004), the threshold found for EEG awakening was $L_{Amax} = 35$ dB(A), that is, only a little higher than the 32 dB(A) found for noise-induced awakenings. This strengthens the evidence that noise starts to induce arousals at L_{Amax} values in the range 30–35 dB(A). Given the night-time noise levels to which people are exposed, these results imply that instantaneous effects are common. Although most studies concerned aircraft noise, the instantaneous effects can be assumed to occur at similar levels for different types of transportation.

The above observations can be used as a basis for setting limits with respect to night-time transportation noise. For transparency, it is useful to distinguish two steps in choosing actual limits: the first step is the derivation of a health-based limit; the second step is the derivation of an actual limit that takes into account the health-based limit as well as feasibility arguments. Here the concern is with the first step.

When deriving a health-based limit, two points need to be considered: the dose-dependent effects of a single noise event, and the number of events. With respect to the dose-dependent effects of a single event, adverse effects can be distinguished from effects that by themselves need not be adverse but can contribute to an adverse state. It is proposed to classify conscious awakenings as an adverse effect. Conscious awakenings have been estimated to occur at a baseline rate of 1.8 awakening per night. A substantial increment of conscious awakenings over this baseline is thought to be adverse. Since, in general, falling asleep after conscious awakening takes some time, and this latency is longer after noise-induced conscious awakening that will often also induce an emotional reaction (anger, fear), it will also reduce the time asleep and may affect mood and functioning next day. Although additional, more sophisticated analyses could be performed to refine this estimate, we propose L_{Amax}

= 42 dB(A) is proposed as the currently best estimate of the threshold for conscious awakening by transportation noise. This would mean that the no observed effect level ($NOEL_{Amax}$) for transportation noise events is at most 42 dB(A).The most sensitive instantaneous effect that has been studied extensively in field studies is motility. A single interval with (onset of) noise-induced motility by itself cannot be considered to be adverse.

However, noise-induced motility is a sign of arousal, and frequent (micro-)arousal and accompanying sleep fragmentation can affect mood and functioning next day and lead to a lower rating of the sleep quality. Therefore, motility is relevant for adverse health effects, but more than a few intervals with noise-induced motility are needed for inducing such effects. Although additional, more sophisticated analyses could be performed to refine this estimate, we propose L_{Amax} = 32 dB(A) as the currently best estimate of the threshold for motility induced by transportation noise. The threshold found for EEG awakening was L_{Amax} = 35 dB(A), that is, only a little higher than the 32 dB(A) found for noise-induced awakenings. This would mean that the $NOEL_{Amax}$ for transportation noise events is most likely at most 32 dB(A), and definitely not higher than 35 dB(A). It is important to note that the above given $NOEL_{Amax}$ ~ 32 dB(A) and $NOEL_{Amax}$ ~ 42 dB(A) are indoor levels, in the sleeping room. Although events below 32 dB(A) are audible, and, hence, further research may show more sensitive effects than motility, on the basis of the present available evidence we propose to assume that $NOEL_{Amax}$ = 32 dB(A) and set a health-based night-time noise limit that is tolerant for transportation noise events with L_{Amax} ~ 32 dB(A). On the other hand, since adverse health effects need to be prevented by health-based limits and even though vulnerable groups may require lower limits, on the basis of the present available evidence we propose to assume that $NOAEL_{Amax}$ = 42 dB(A) and set a health-based night-time noise limit that does not tolerate transportation noise events with L_{Amax} > 42 dB(A).

On the basis of the above proposal, it would be possible to derive a night-time noise guideline value in terms of L_{night}. Such a guideline value would indicate the level below which no short-term effects are to be expected that would lead to temporary reduced health or chronic disease. Such a guideline value needs to be compared with guideline values derived directly with a view to preventing temporary reduced health and chronic diseases. In particular, for self-reported sleep disturbance, which is an expression of reduced well-being and may be an indication of effects that could contribute to cardiovascular disease, exposure–effect relationships have been derived on the basis of an extensive set of original data from studies from various countries (Miedema, Passchier-Vermeer and Vos, 2003; Miedema, 2004). The percentage of people reporting high noise-induced sleep disturbance (%HS) levels off at 45 dB(A) but at a non-zero effect level. The remaining effect may be caused by events not incorporated in the exposure assessment and it appears that if all noise contributions would be incorporated in the exposure metric, high noise-induced sleep disturbance would vanish between 40 dB(A) and 45 dB(A), say at 42 dB(A). Since values found for other temporary reduced health effects or chronic diseases, in particular cardiovascular diseases, will be higher, and considering self-reported sleep disturbance as an adverse effect, this would suggest L_{night} = 42 dB(A) as the NOAEL to be compared with the value derived from the short-term effects. Note that this is an outdoor level, which would, assuming partly opened windows and an actual insulation of 15 dB(A), correspond to an indoor equivalent night-time sound level of 27 dB(A). The above discussion is based on motility, EEG awakenings, and conscious awakening. In addition, EEG micro-/minor arousals, and autonomic reactions have been discussed above.

Furthermore, there are potential instantaneous effects, such as effects on memory consolidation or restoration of the immune system, for which the information on a possible relation with noise exposure is so limited that they were not considered here. In order to acquire more insight into these effects, more field research is needed. Field research is needed because earlier studies have shown that estimates of effects on the basis of laboratory studies are much higher than estimates from field studies. Methodological differences between the different approaches certainly cannot be the only possible explanation. Research allowing the introduction of some specific but light laboratory technique into the sleeper's own bedroom, should be encouraged, as, for example, used in the Swiss Noise Study 2000 (Brink, Müller, and Schierz, 2006). The key to better insight into effects of night-time noise, leading to mechanistic models describing the relationships between noise exposure, instantaneous effects, effects at the level of a 24-hour period and chronic effects, appears to be epidemiological studies at home with well-designed instrumentation.

The relationships between noise exposure, instantaneous effects, effects at the level of a single 24-hour period and chronic effects is complex because the effects at a smaller time scale do not simply add up to effects at a larger time scale. For example, the noise-related increase in night-time average motility was substantially higher than would be expected on the basis of the instantaneous extra motility at the times of the noise events (Passchier-Vermeer et al., 2002), suggesting persistent arousal during sleep related to aircraft noise. It is likely that such shifts in the basic state are more important for the development of chronic effects than the instantaneous effects per se. A further complication is that some effects habituate. Habituation in some effect parameters can occur in a few days or weeks, but the habituation is not always complete. The measured modifications of the cardiovascular functions remain unchanged over long periods of exposure time (Muzet and Ehrhart, 1980; Vallet et al., 1983). Most striking is that none of the cardiovascular responses show habituation to noise after a prolonged exposure, while subjective habituation occurs within a few days. It appears plausible that, in particular non-habituating effects lead to the development of chronic effects, but also the disappearance of effects with continuing exposure may come at a cost associated with suppressing the effects. A third complication is that daytime noise exposure may contribute to the effects found in relation to night-time noise. Large epidemiological studies are needed that compare populations exposed to similar daytime noise and differ in their night-time noise exposure only. A specific challenge for mechanistic models on the effects of noise on sleep is the identification of factors that make subjects vulnerable to night-time noise. The following groups may be hypothesized to be more vulnerable to noise during sleep: old people, ill people, people with chronic insomnia, shift workers and people resting during daytime, people with a tendency to depression, light sleepers, pregnant women, people with high anxiety and high stress levels. Furthermore, children need attention because of their relatively high exposure during sleep, and because they are in a phase of neurocognitive development for which undisturbed sleep may be particularly important.

CHAPTER 5

GUIDELINES AND RECOMMENDATIONS

5.1 ASSESSMENT

In Chapter 1 the need for a guideline document for night-time exposure to noise was defended on the basis of the lack of existing guidance, the signs that a substantial part of the population could be exposed to levels of noise that might risk their health and well-being and the EU activities that compel the public and authorities to take notice when noise maps showing L_{night} levels are made public.

Where sufficient direct evidence concerning the effects of night-time noise on health could not be collected, indirect evidence was looked at: the effects of noise on sleep (quality) and the relations between sleep and health.

In Chapter 2 the evidence was presented that sleep is a biological necessity and disturbed sleep is associated with a number of health outcomes. Studies of sleep disturbance in children and in shift workers clearly show the adverse effects. Unravelling the relations between sleep and health (Fig. 2.1) shows that sleep is an essential feature of the organism, so that simple direct relations can hardly be expected.

In Chapter 3 it was shown beyond doubt that noise disturbs sleep through a number of direct and indirect pathways. Even at very low levels physiological reactions (heart rate, body movement and arousals) can be reliably measured. It was also shown that awakening reactions are relatively rare, occurring at a much higher level.

Chapter 4 summarized the known evidence for the direct effects of night-time noise on health. The working group agreed that there is sufficient evidence that night noise is related to self-reported sleep disturbance, use of pharmaceuticals, self-reported health problems and insomnia-like symptoms. These effects can lead to a considerable burden of disease in the population. For other effects (hypertension, myocardial infarctions, depression and others), limited evidence was found: although the studies were few or not conclusive, a biologically plausible pathway could be constructed from the evidence.

An example of a health effect with limited evidence is myocardial infarction. Although evidence for increased risk of myocardial infarction related to L_{day} is sufficient according to an updated meta-analysis, the evidence in relation to $L_{night, outside}$ was considered limited. This is because $L_{night, outside}$ is a relatively new exposure indicator, and few field studies have focused on night noise when considering cardiovascular outcomes. Nevertheless, there is evidence from animal and human studies supporting a hypothesis that night noise exposure might be more strongly associated with cardiovascular effects than daytime exposure, highlighting the need for future epidemiological studies on this topic.

The review of available evidence leads to the following conclusions.

- Sleep is a biological necessity and disturbed sleep is associated with a number of health outcomes.

- There is sufficient evidence for biological effects of noise during sleep: increase in heart rate, arousals, sleep stage changes and awakening.
- There is sufficient evidence that night noise exposure causes self-reported sleep disturbance, increase in medicine use, increase in body movements and (environmental) insomnia.
- While noise-induced sleep disturbance is viewed as a health problem in itself (environmental insomnia), it also leads to further consequences for health and well-being.
- There is limited evidence that disturbed sleep causes fatigue, accidents and reduced performance.
- There is limited evidence that noise at night causes hormone level changes and clinical conditions such as cardiovascular illness, depression and other mental illness. It should be stressed that a plausible biological model is available with sufficient evidence for the elements of the causal chain.

In the next section threshold levels are presented for the effects, where these can be derived.

5.2 THRESHOLDS FOR OBSERVED EFFECTS

The NOAEL is a concept from toxicology, and is defined as the greatest concentration which causes no detectable adverse alteration of morphology, functional capacity, growth, development or lifespan of the target organism. For the topic of night-time noise (where the adversity of effects is not always clear) this concept is less useful. Instead, the observed effect thresholds are provided: the level above which an effect starts to occur or shows itself to be dependent on the dose. This can also be an adverse effect (such as myocardial infarcts) or a potentially dangerous increase in a naturally occurring effect such as motility.

Threshold levels are important milestones in the process of evaluating the health consequences of environmental exposure. The threshold levels also delimit the study area, which may lead to a better insight into overall consequences. In Tables 5.1 and 5.2 all effects are summarized for which sufficient or limited evidence exists (see Table 1.2 in Chapter 1 for a definition). For the effects with sufficient evidence the threshold levels are usually well known, and for some the dose-effect relations over a range of exposures could also be established.

5.3 RELATIONS WITH $L_{NIGHT,OUTSIDE}$

Over the next few years, the END will require that night exposures are reported in $L_{night,outside}$. It is therefore interesting to look into the relation between $L_{night,outside}$ and the effects from night-time noise. The relation between the effects listed in Tables 5.1 and 5.2 and $L_{night,outside}$ is, however, not straightforward. Short-term effects are mainly related to maximum levels per event inside the bedroom: $L_{Amax,inside}$. In order to express the (expected) effects in relation to the single EU indicator, some calculation needs to be done.

Table 5.1
Summary of effects and threshold levels for effects where sufficient evidence is available

Effect		Indicator	Threshold, dB	Reference (chapter, section)
Biological effects	Change in cardiovascular activity	*	*	3.1.5
	EEG awakening	$L_{Amax,inside}$	35	4.10
	Motility, onset of motility	$L_{Amax,inside}$	32	3.1.8, dose–effect relation for aircraft
	Changes in duration of various stages of sleep, in sleep structure and fragmentation of sleep	$L_{Amax,inside}$	35	3.1
Sleep quality	Waking up in the night and/or too early in the morning	$L_{Amax,inside}$	42	3.1.7, dose–effect relation for aircraft
	Prolongation of the sleep inception period, difficulty getting to sleep	*	*	3.1
	Sleep fragmentation, reduced sleeping time	*	*	3.1
	Increased average motility when sleeping	$L_{night,outside}$	42	3.2, dose–effect relation for aircraft
Well-being	Self-reported sleep disturbance	$L_{night,outside}$	42	4.2, dose–effect relation for aircraft/road/rail
	Use of somnifacient drugs and sedatives	$L_{night,outside}$	40	4.5.8
Medical conditions	Environmental insomnia**	$L_{night,outside}$	42	3.1; 4.1; 4.2

* *Although the effect has been shown to occur or a plausible biological pathway could be constructed, indicators or threshold levels could not be determined.*

** *Note that "environmental insomnia" is the result of diagnosis by a medical professional whilst "self-reported sleep disturbance" is essentially the same, but reported in the context of a social survey. Number of questions and exact wording may differ.*

Table 5.2
Summary of effects and threshold levels for effects where limited evidence is available+

Effect		Indicator	Estimated, threshold dB	Reference (chapter, section)
Biological effects	Changes in (stress) hormone levels	*	*	2.5
	Drowsiness/tiredness during the day and evening	*	*	2.2.3
	Increased daytime irritability	*	*	2.2.3
Well-being	Impaired social contacts	*	*	2.2.3
	Complaints	$L_{night,outside}$	35	4.3
	Impaired cognitive performance	*	*	2.2.3
	Insomnia	*	*	4.6
	Hypertension	$L_{night,outside}$	50	2.2.3; 4.5.6
	Obesity	*	*	2.2.3
	Depression (in women)	*	*	4.8
	Myocardial infarction	$L_{night,outside}$	50	4.5.15
	Reduction in life expectancy (premature mortality)	*	*	2.2.3; 2.5
	Psychiatric disorders	$L_{night,outside}$	60	4.8.15
	(Occupational) accidents	*	*	2.2.3; 2.4

+ *Note that as the evidence for the effects in this table is limited, the threshold levels also have a limited weight. In general they are based on expert judgement of the evidence.*

* *Although the effect has been shown to occur or a plausible biological pathway could be constructed, indicators or threshold levels could not be determined.*

The calculation for the total number of effects from reaction data on events (arousals, body movements and awakenings) needs a number of assumptions. The first that needs to be made is independence: although there is evidence (Brink, Müller and Schierz, 2006) that the order of events of different loudness strongly influences the reactions, the calculation is nearly impossible to carry out if this is taken into consideration.

Secondly, the reactions per event are known in relation to levels at the ear of the sleeper, so an assumption for an average insulation value must be made. In this report a value of 21 dB (see Chapter 1, sections 1.3.4 and 1.3.5) has been selected. This value is, however, subject to national and cultural differences. One thing that stands out is the desire of a large part of the population to sleep with windows (slightly) open. The relatively low value of 21 dB already takes this into account. If noise levels increase, people do indeed close their windows, but obviously reluctantly, as then complaints about bad air increase and sleep disturbance remains high. This was already pointed out in the WHO guidelines on community noise (WHO, 1999).

From source to source the number of separate events varies considerably. Road traffic noise is characterized by relatively low levels per event and high numbers, while air and rail traffic are characterized by high levels per event and low numbers. For two typical situations estimates are made and presented in graphical form. The first is an average urban road (600 motor vehicles per night, which corresponds roughly to a 24-hour use of 8000 motor vehicles, or 3 million per year, the lower boundary the END sets) and the second case is for an average situation of air traffic exposure (8 flights per night, nearly 3000 per year).

Fig. 5.1 shows how effects increase with an increase of $L_{night,outside}$ values for the typical road traffic situation (urban road). A large number of events lead to high levels of awakening once the threshold of $L_{Amax,inside}$ is exceeded. To illustrate this in practical terms: values over 60 dB $L_{night,outside}$ occur at less then 5 metres from the centre of the road.

In Fig. 5.2 the same graph is presented for the typical airport situation. Due to a lower number of events there are fewer awakenings than in the road traffic case (Fig. 5.1), but the same or more health effects.

In these examples the worst case figures can be factors higher: the maximum number of awakenings for an $L_{night,outside}$ of 60–65 dB is around 300 per year.

A recent study suggests that high background levels (from motorways) with low numbers of separate events can cause high levels of average motility (Passchier-Vermeer, to be published). In Table 5.3 the full details are summarized.

5.4 DEALING WITH SITUATIONS EXCEEDING THE THRESHOLDS

Noise exposure data demonstrate that a large part of the population is over the no-effect levels. It is expected that this will extend into the future for quite some time. This means that circumstances may require that a risk assessment must be made. It is then recommended to apply the method laid out in Chapter 1, using the values given in Tables 5.1 and 5.2 and the dose–effect relations given in Chapter 4.

Typical actions requiring risk assessment are:

- new infrastructure projects (if an environmental impact statement is required)
- improvement programmes

- policy evaluation
- national or international setting of limit values.

In the EU *Position Paper* (European Commission, 2002a) an overview of national night-time noise regulations can be found.

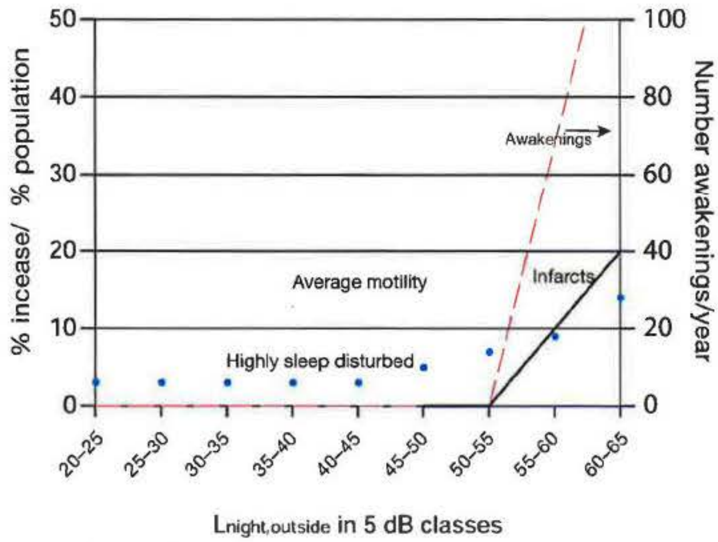

Fig. 5.1
Effects of road traffic noise at night*

Source: European Commission, 2002 a

* *Average motility and infarcts are expressed in percent increase (compared to baseline number); the number of highly sleep disturbed people is expressed as a percent of the population; awakenings are expressed in number of additional awakenings per year.*

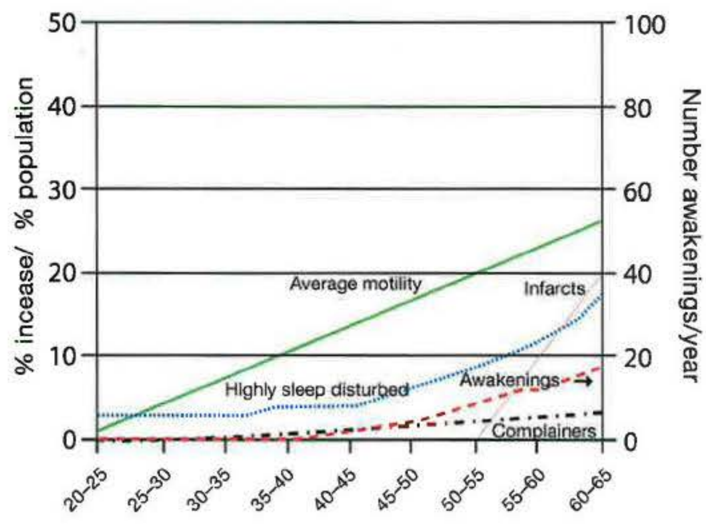

Fig. 5.2
Effects of aircraft noise at night*

Source: European Commission, 2002 a

* *Average motility and infarcts are expressed in percent increase (compared to baseline number); the number of highly sleep disturbed people is expressed as percent of the population; complainers are expressed as a percent of the neighbourhood population; awakenings are expressed in number of additional awakenings per year.*

Table 5.3
Effects (yearly, additional with respect to the normal except odd ratio) 0=below threshold, +=increase)

$L_{night, outside}$	Arousals		Body movements related to single exposures (15 sec intervals)		Average body movements (without single exposures)	Awakenings		% sleep disturbed (% highly sleep disturbed)			Myocardial infarcts

5.5 PROTECTION MEASURES AND CONTROL

What is the best strategy to reduce sleep disturbance? The first thought should always be to reduce the impact, either by reducing the number of events or by reducing the sound levels, or both. For some effects reducing the number of events may seem to be more effective (although that depends on the exact composition). Other effects are reduced by lowering overall noise level by either the number of events, the levels per event or by any combination.

In combination with other measures, sound insulation of bedroom windows is an option, but care must be taken to avoid negative impact on inside air quality. Even then, many people may want to sleep with their windows open, thereby making the insulation ineffective. Although good instruction may go some way to helping to overcome this, it is still a matter well worth taking into account. In warmer climates, in particular, insulation is not a serious option for residential purposes and excessive exposure must be avoided either by removing the people exposed or removing the source if source-related measures fail.

Although air conditioning of houses (or just bedrooms) is not commonplace in the EU, there are indications that its use is increasing, especially in the warmer parts of the Region. Although this still leaves the possibility that people may sleep with their windows open outside the summer season, it is something to consider when discussing measures.

Exposed areas could be a good choice for uses such as offices, where there will be no people at night, or where it is a physical impossibility to sleep with the windows open (fully air-conditioned buildings, for example hotels and sometimes hospitals).

A simple measure is the orientation of noise-sensitive rooms on the quiet side of the dwelling (this applies to road and rail traffic noise).

Zoning is an instrument that may assist planning authorities in keeping noise-sensitive land uses away from noisy areas. In the densely populated areas of the EU this solution must often compete, however, with other planning requirements or a simple lack of suitable space.

5.6 RECOMMENDATIONS FOR HEALTH PROTECTION

Sleep is an essential part of healthy life and is recognized as a fundamental right under the European Convention on Human Rights[1](European Court of Human Rights, 2003). Based on the systematic review of evidence produced by epidemiological and experimental studies, the relationship between night noise exposure and health effects can be summarized as below. (Table 5.4)

Table 5.4
Effects of different levels of night noise on the population's health[2]

Average night noise level over a year $L_{night,outside}$	Health effects observed in the population
Up to 30 dB	Although individual sensitivities and circumstances may differ, it appears that up to this level no substantial biological effects are observed. $L_{night,outside}$ of 30 dB is equivalent to the NOEL for night noise.
30 to 40 dB	A number of effects on sleep are observed from this range: body movements, awakening, self-reported sleep disturbance, arousals. The intensity of the effect depends on the nature of the source and the number of events. Vulnerable groups (for example children, the chronically ill and the elderly) are more susceptible. However, even in the worst cases the effects seem modest. $L_{night,outside}$ of 40 dB is equivalent to the LOAEL for night noise.
40 to 55 dB	Adverse health effects are observed among the exposed population. Many people have to adapt their lives to cope with the noise at night. Vulnerable groups are more severely affected.
Above 55 dB	The situation is considered increasingly dangerous for public health. Adverse health effects occur frequently, a sizeable proportion of the population is highly annoyed and sleep-disturbed. There is evidence that the risk of cardiovascular disease increases.

[1] "Article 8:1. Everyone has the right to respect for his private and family life, his home and his correspondence." Although in the case against the United Kingdom the Court ruled that the United Kingdom Government was not guilty of the charges, the right to undisturbed sleep was recognized (the Court's consideration 96).

[2] $L_{night,outside}$ in Table 5.4 and 5.5 is the night-time noise indicator (L_{night}) of Directive 2002/49/EC of 25 June 2002: the A-weighted long-term average sound level as defined in ISO 1996-2: 1987, determined over all the night periods of a year; in which: the night is eight hours (usually 23.00 – 07.00 local time), a year is a relevant year as regards the emission of sound and an average year as regards the meteorological circumstances, the incident sound is considered, the assessment point is the same as for L_{den}. See *Official Journal of the European Communities*, 18.7.2002, for more details.

Below the level of 30 dB $L_{night,outside}$, no effects on sleep are observed except for a slight increase in the frequency of body movements during sleep due to night noise. There is no sufficient evidence that the biological effects observed at the level below 40 dB $L_{night,outside}$ are harmful to health. However, adverse health effects are observed at the level above 40 dB$L_{night,outside}$, such as self-reported sleep disturbance, environmental insomnia, and increased use of somnifacient drugs and sedatives. Therefore, 40 dB $L_{night,outside}$ is equivalent to the LOAEL for night noise. Above 55 dB the cardiovascular effects become the major public health concern, which are likely to be less dependent on the nature of the noise. Closer examination of the precise impact will be necessary in the range between 30 dB and 55 dB as much will depend on the detailed circumstances of each case.

A number of instantaneous effects are connected to threshold levels expressed in L_{Amax} (Table 5.1). The health relevance of these effects cannot be easily established. It can be safely assumed, however, that an increase in the number of such events over the baseline may constitute a subclinical adverse health effect by itself leading to significant clinical health outcomes.

Based on the exposure–effects relationship summarized in Table 5.4, the night noise guideline values are recommended for the protection of public health from night noise as below (Table 5.5).

Table 5.5 Recommended night noise guidelines for Europe

Night noise guideline (NNG)	$L_{night,outside}$ = 40 dB
Interim target (IT)	$L_{night,outside}$ = 55 dB

For the primary prevention of subclinical adverse health effects related to night noise in the population, it is recommended that the population should not be exposed to night noise levels greater than 40 dB of $L_{night,outside}$ during the part of the night when most people are in bed. The LOAEL of night noise, 40 dB $L_{night,outside}$, can be considered a health-based limit value of the night noise guidelines (NNG) necessary to protect the public, including most of the vulnerable groups such as children, the chronically ill and the elderly, from the adverse health effects of night noise.

An interim target (IT) of 55 dB $L_{night,outside}$ is recommended in the situations where the achievement of NNG is not feasible in the short run for various reasons. It should be emphasized that IT is not a health-based limit value by itself. Vulnerable groups cannot be protected at this level. Therefore, IT should be considered only as a feasibility-based intermediate target which can be temporarily considered by policy-makers for exceptional local situations.

All Member States are encouraged to gradually reduce the proportion of the population exposed to levels over the IT within the context of meeting wider sustainable development objectives. It is highly recommended to carry out risk assessment and management activities at local and national levels targeting the exposed population, and aiming at reducing night noise to the level below IT or NNG. IT and NNG can be used for health impact assessment of new projects (for example construction of roads, railways, airports or new residential areas) even before the achievement of IT, as well as for the risk assessment of the whole population. In the long run the NNG would be best achieved by control measures aimed at the sources along with other comprehensive approaches.

5.7 RELATION WITH THE GUIDELINES FOR COMMUNITY NOISE (1999)

The *Guidelines for community noise* (WHO, 1999) have been quoted a number of times in this paper, so one could rightfully ask what the relation is between the 1999 guidelines and the present NNG.

Impact of night-time exposure to noise and sleep disturbance is indeed covered in the 1999 guidelines, and this is the full statement (WHO, 1999):

> "If negative effects on sleep are to be avoided the equivalent sound pressure level should not exceed 30 dBA indoors for continuous noise. If the noise is not continuous, sleep disturbance correlates best with L_{Amax} and effects have been observed at 45 dB or less. This is particularly true if the background level is low. Noise events exceeding 45 dBA should therefore be limited if possible. For sensitive people an even lower limit would be preferred. It should be noted that it should be possible to sleep with a bedroom window slightly open (a reduction from outside to inside of 15 dB). To prevent sleep disturbances, one should thus consider the equivalent sound pressure level and the number and level of sound events. Mitigation targeted to the first part of the night is believed to be effective for the ability to fall asleep."

It should be noted that the noise indicators of the 1999 guidelines are L_{Aeq} and L_{Amax}, measured inside for continuous and non-continuous noise, respectively. The present night noise guidelines adopt an harmonized noise indicator as defined by Environmental Noise Directive (2002/49/EC): L_{night} measured outside, averaged over a year.

It should also be borne in mind that the 1999 guidelines are based on studies carried out up to 1995 (and a few meta-analyses some years later). Important new studies (Passchier-Vermeer et al., 2002; Basner et al., 2004) have become available since then, together with new insights into normal and disturbed sleep.

Comparing the above statement with the recommendations, it is clear that new information has made more precise statements possible. The thresholds are now known to be lower than L_{Amax} of 45 dB for a number of effects. The last three sentences still stand: there are good reasons for people to sleep with their windows open, and to prevent sleep disturbances one should consider the equivalent sound pressure level and the number of sound events. The present NNG allow responsible authorities and stakeholders to do this. Viewed in this way, the *Night noise guidelines for Europe* complements the 1999 guidelines. This means that the recommendations on government policy framework on noise management elaborated in the 1999 guidelines should be considered valid and relevant for the Member States to achieve the guideline values of this document.

APPENDIX 1. GLOSSARY OF TERMS AND ACRONYMS

Term/acronym	Definition
Actimetry	The measurement of accelerations associated with the movement of an actimeter
ADHD	Attention-deficit hyperactivity disorder
Behavioural awakening	Awakening that is registered by the subject by means of a conscious action
BP	Blood pressure
CAP	Cyclic alternating patterns
EBD	Environmental burden of disease
END	Environmental Noise Directive (2002/49/EC)
EEG	Electroencephalogram, recording of electric activity in the brain
ECG	Electrocardiogram, recording of electric activity of the heart
EEG awakening	Transition from a state of sleep to a state of consciousness, as determined by a sleep EEG
Heart rate acceleration	A temporary rise in heart rate relative to the average heart rate assessed shortly before a noise event
HPA axis	Hypothalamus-pituitary-adrenal axis
ICSD	International Classification of Sleep Disorders
IHD	Ischaemic heart disease
Insomnia	Sleeping disorder consistent with an internationally accepted definition (see ICSD), which takes account of difficulty falling or staying asleep, the daytime implications and the duration of the problems
$L_{Aeq,T}$	Exposure to noise for the duration of a given time interval T (a 24-hour period, a night, a day, an evening) is expressed as an equivalent sound pressure level (measured in dB(A)) over the interval in question
L_{Amax}	Maximum outdoor sound pressure level associated with an individual noise event
L_{night}	Refers to the EU definition in Directive 2002/49/EC: equivalent outdoor sound pressure level associated with a particular type of noise source during night-time (at least 8 hours), calculated over a period of a year
Motility onset	The presence of movement in a short time interval, following an interval without movement
Mg	Magnesium
Motility	The presence of movement in a short time interval, as recorded on an actigram
OR	Odds ratio: the ratio of the odds of an event occurring in another group, or to a sample-based estimate of that ratio

Term/acronym	Definition
OSAS	Obstructive sleep apnoea syndrome
OTC	Over-the-counter (medicines sold without prescription)
Polysomnography	The measurement during a subject's time in bed of his or her brain activity by means of EEG, EOG and EMG. The technique involves the use of electrodes to record electrical potentials in the brain
REM	Rapid eye movement (sleep phase)
RR	Relative risk: a ratio of the probability of the event occurring in the exposed group vs. the control (non-exposed) group
SEL	Sound exposure level: equivalent outdoor sound pressure level associated with an individual noise event, with the equivalent level standardized at one second
Sleep disturbance	Disturbance of sleep by night-time noise, as perceived by a subject and described in a questionnaire response or journal entry
Sleep EEG	Graph created using data from EEG scanning during a subject's time in bed, showing the various stages of sleep as a function of time
Sleep fragmentation	Within a sleep period, the frequency and duration of intervals of wakefulness recorded on a sleep EEG or intervals of motility recorded on an actigram
Sleep latency	The length of time taken to fall asleep, i.e. the interval between the point at which a person begins trying to go to sleep or allowing him/herself to go to sleep and sleep inception time
Sleep stage change	Change from a deeper stage of sleep to a less deep stage, as determined by a sleep EEG
SMR	Standardized mortality ratios
SROBD	Sleep related obstructive breathing disorders
SWS	Slow-wave sleep (sleep phase)
UARS	Upper airway resistance syndrome

APPENDIX 2. RELATIONS BETWEEN L_{NIGHT} AND INSTANTANEOUS EFFECTS

STATEMENT 1

Let f be a function of SEL that gives the expected number of instantaneous effects caused by a single event. With a given L_{night} and a given number of events N, the expected number of times that an effect occurs in the night, n, is maximal if all events have equal SEL, provided that f°10lg is increasing but negatively accelerated.

STATEMENT 2

If

$$n_{max} = 10^{(L_{night}-SEL+70.2)/10} \cdot f(SEL),$$

has a maximum over SEL and f is the quadratic function $f(SEL) = a\ SEL^2 + b\ SEL + c$, then the maximum occurs irrespective of L_{night} at

$$SEL_0 = 4.34 - A \pm ((A - 4.34)^2 - (c/a) + 8.68A)^{1/2},$$

where $A = b/(2a)$. (Only with + at the place of ± the value will come in the realistic range of SEL)

STATEMENT 3A

If the shape of the time pattern of the sound level has a block form, then $SEL = L_{Amax} + 10lg(T)$, where L_{Amax} is the maximum sound level (integrated over 1-s) and T is the duration of the noise event in seconds.

STATEMENT 3B

If the sound level increases with rate a (in dB(A)/s) and after time point $t = 0$ decreases with rate –a, then $SEL \approx L_{Amax} - 10lg(a) + 9.4$.

APPENDIX 3. ANIMAL STUDIES ON STRESS AND MORTALITY

INTRODUCTION

Is noise a health risk or does it just annoy? This basic question needs to be carefully answered when establishing night noise guidelines. No one will deny that in the case of high noise levels there is a risk of inner ear damage, but what about the moderate levels of environmental noise? To approach this rather difficult question, all available methods must be combined.

1. In animal experiments it is possible to assess the complete causal chain from noise exposure via physiological reactions and biological risk factors to morbidity or even mortality. However, a quantitative application of the results to humans is not possible. Instead, the method is useful in studying the pathomechanisms qualitatively.
2. Experiments on humans are, for ethical reasons, restricted to the study of reversible physiological reactions. But as long as there is no proof that reactions to chronically repeated noise exposures are increasing the risk of specific diseases, the results of such physiological studies are not considered conclusive.
3. Epidemiological studies have the advantage of investigating health effects which are particularly caused by chronic noise exposure although there is no possibility to control all influencing factors. Additionally, epidemiological studies have to be based upon biologically evident hypotheses.

A hypothetical model of noise-induced health effects is shown in Fig. 4.3 in Chapter 4, section 4.5.2 of this report. This model is based on the results of noise experiments with animals and humans. With animal experiments, the whole causal chain from noise exposure to health outcome can be traced as a direct pathway starting with a chronic high level noise exposure which, via endocrine stress reactions, leads, for example, to microcirculatory defects and to manifest hypertension.

Physiological experiments on humans have shown that noise of a moderate level acts via an indirect pathway and has health outcomes similar to those caused by high noise exposures on the direct pathway. The indirect pathway starts with noise-induced disturbances of activities such as communication or sleep. Since we are dealing with night noise guidelines, noise-induced sleep disturbances and any resulting persistent health effects are of primary interest here.

In physiological studies with experimentally changed noise exposure, the increase of arousals and of hormone excretion was studied in sleeping people. If this model is correct then in the cause–effect chain the arousal ought to precede the endocrine reactions. This order was derived from the different reaction times of the effects. While arousals appear within 1 second after a noise stimulus, hormones like catecholamines take several minutes, and cortisol about 10 minutes to be increased. This observation, together with the fact that arousals are evoked by equal or lower noise levels than the corresponding endocrine reactions, confirms the correctness of the model and leads to an important conclusion: noise exposure which does not evoke arousals in sleeping people will not induce adverse health effects.

This conclusion is essential with regard to night noise guidelines. However, the answers to the basic question as to whether certain health risks are connected with environmental noise must be clarified by epidemiological studies based on noise experiments on both humans and animals.

TYPES OF ANIMAL STUDIES

Noise has often been used as a stressor in animal studies. Even Selye (1953), who introduced the psychophysiological stress concept, used noise stimuli in his animal studies. Most of the modern animal studies testing the pharmacological effects of drugs are carried out with and without various stressors. The typical noise exposure is to short and very intensive sounds. One such example is the study of Diao et al. (2003) who exposed guinea pigs to 4 kHz octave band noise at 115 dB for 5 hours. But these experiments are of little value regarding the noise exposure types in question.

The same is true for another type of animal study concerned with the prevention of noise-induced health effects in wild and domestic animals (for review of the former kind see Fletcher, 1983). One example for the latter kind is the study of Geverink et al. (1998) on stress responses of pigs to transport and lairage sounds.

Since the subject of the present paper is noise-induced health effects in humans, the review addresses only those studies in which animals are used as a model for humans.

The animal model for aural effects in humans has been established in great detail, so that even quantitative transference of results from animals to humans is possible. However, inner ear damage generally occurs at much higher noise levels than the environmental levels under discussion in this paper. Therefore interest focuses on animal models with respect to extra-aural noise effects.

LIMITING ASPECTS OF ANIMAL MODELS

Other than in studies on aural effects, the animal model does not allow quantitative comparisons in studies of extra-aural noise effects. It may, however, be used for the qualitative investigation of pathophysiological mechanisms following exposure to acute and very short sounds. But an animal model for long-term noise effects as caused by chronically repeated noise exposures needs careful planning. First it has to be ensured that stress reactions in both humans and animals when activated by noise exposure are qualitatively comparable. Secondly, the stress effects of chronic noise exposure have to be assessed in humans, and the animal models should be designed correspondingly. However, in the animal model, influences from cortical interconnections have to be excluded as a factor in these noise experiments. Naturally, one cannot expect to establish an animal model for indirect environmental noise effects which in humans may, for example, disturb activities such as verbal communication, which in turn may induce stress hormone increases.

STRESS HORMONES IN NOISE-EXPOSED ANIMALS

HABITUATION

In short-term experiments any kind of exposure to loud noise will cause acute increases of stress hormones. Long-term repeated noise exposure, however, will cause a certain habituation in the animal. Periodic repetitions of identical noise bursts lead to almost complete habituation. This was probably the main reason why Borg (1981) found no adverse health effects in rats exposed for their whole lives to periodic noise pulses. Therefore, random series of noise pulses are now applied in most long-term studies.

Selye (1974) had already stated that not all stages of a stress response are noxious, especially in the case of mild or brief exposures. Since environmental noise is a mild stressor, adverse health effects are only to be expected under the condition that repeated noise exposures induce long-term stress hormone changes. According to the Allostatic Load Model (McEwen, 1998), the normal response to an environmental stressor such as noise is the physiological activation of the endocrine system enabling the body to cope with the stressor and, after the stress situation is terminated, to shut off the allostatic response.

J.D. HENRY'S MODEL OF BEHAVIOURAL STRESS EFFECTS

On the basis of the available literature on stress effects in animals and humans, Henry (1992) developed a model with regard to different biological effects and health risks associated with different coping styles. He explains that the neuroendocrine response to various challenges and threats varies according to the type and degree of control a mammal can exert over it. This in turn is strongly determined by the animal's previous experience. In general, the sympathetic adrenomedullary system is preferentially activated when the animal displays an active response to escape from or deal with an environmental challenge. This is the fight/flight mode of stress response. The adrenocortical axis is preferentially activated as the subjects become immobile/passive when no control or threat of its loss is experienced. This is the conservation/withdrawal mode of response.

THE NOISE STRESS MODEL

On the basis of noise effect studies in animals and humans (for review see Ising and Braun, 2000), a noise stress model was developed. It describes a differentiation of prevailing "stress hormones" under noise exposure. Predominantly adrenaline – and to a lesser degree noradrenaline – are released from the adrenal medulla as the normal response to novel noise stimuli of moderate intensity. Following long-term noise exposures of moderate intensity habituation will alter the response mode and predominantly noradrenaline is released. As a response to extremely intensive noise, near the inner ear pain threshold, predominantly cortisol is released from the adrenal cortex induced by increased releases of adrenocorticotropic hormone (ACTH), especially in the case of unexpected noise.

The described differentiation will only be observed under special conditions. Unexpected exposure for three minutes to white noise at 75 dB leads, in dogs that are awake, to increased adrenal secretion of adrenaline and noradrenaline and – following a delayed increase in plasma ACTH – an increase in cortisol secretion (Engeland, Miller and Gann, 1990).

The cortisol response as described is valid for animals and humans in their active phases. During sleep, however, several studies in humans showed cortisol increases under exposure to traffic noise of moderate levels (Maschke, Arndt and Ising, 1995;

Evans et al.2001; Ising and Ising, 2002; Ising et al., 2004). It was hypothesized that noise stimuli signalling a danger, for example the noise of an approaching lorry, will, during sleep, normally generate a defeat reaction, which includes the release of cortisol from the adrenal cortex. Appropriate studies with sleeping animals after conditioning them – for example with a specific noise stimulus followed by pain – should be carried out to test this hypothesis.

Rats were exposed for a period of 12 hours to low-altitude flight noise – reproduced electro-acoustically once per hour on average at stochastically fluctuating intervals (L_{Amax} 125 dB, 10 dB downtime: 1 s, L_{eq}: 89 dB) (Ising et al., 1991; Ising, 1993). Adrenaline and noradrenaline excretions tended to decrease, whereas plasma cortisol increased significantly. Although in rats corticosterone is secreted rather than cortisol, we will simplify this paper by using cortisol for rats all the same. In this experiment, as well as in all others of our group, normally four rats were kept in one stainless steel cage, which was set on a funnel to collect their urine.
These results show that exposure to noise levels approaching or exceeding the pain threshold of the inner ear leads to endocrine reactions qualitatively different from those induced by less intensive noise.

The different endocrine reactions to acute and chronic noise exposure were studied in rats by Gesi et al. (2002b). They were exposed either to a single (6-hour) session of loud (100 dB(A)) noise, or to the same noise stimulus repeatedly every day for 21 consecutive days. Exposure to noise for 6 hours on one day induced parallel increases in dopamine, noradrenaline and adrenaline concentrations in tissue samples of the adrenal medulla. After 21 days of noise exposure, noradrenaline concentration was significantly higher than in controls, and that of adrenaline decreased significantly. Cortisol was not assessed in this study.

In another subchronic noise experiment, rats were exposed to irregular white noise at 90 dB for 3 and 9 hours per day during 18 and 8 days respectively (van Raaij et al., 1997). In rats with 3 hours of exposure per day the blood concentrations of adrenaline, noradrenaline and cortisol did not differ from controls. Exposure for 9 hours per day, however, resulted in significantly increased concentrations of noradrenaline and cortisol. At the end of the experiment all animals were subjected to restraint stress and their endocrine reactions were assessed. The authors sum up their findings as follows: these results indicate that chronic noise exposure at mild intensities induces subtle but significant changes in hormonal regulation.

The results of another experiment with different levels of random white noise pulses during 45 minutes per hour, 12 hours per day for 8 days demonstrate that cortisol responses to subchronic mild noise exposure do not monotonously increase with the noise levels (Bijlsma et al., 2001). While in rats exposed to 95 dB pulses plasma cortisol concentrations were raised twofold against controls, the exposure to 105 dB pulses did not increase cortisol significantly.

The time dependency of cortisol increase in the blood of rats under exposure to white noise (100 dB, 6 hours per day for 21 days) was examined by Gesi et al. (2001). The authors found a progressive increase in cortisol which reached a plateau 9 days from the beginning of exposure.

In summing up the results of these studies we can reach the following conclusions.

- Acute exposure to unexpected and novel noise of moderate intensities leads to activation of both the sympathetic adrenal-medullary system with increased secretion of adrenaline and noradrenaline, and the HPA axis with increased secretion of ACTH and of cortisol from the adrenal cortex.

- Under chronic exposure to unpredictable noise, adrenaline secretion is reduced to normal or subnormal values while noradrenaline and ACTH/cortisol concentrations remain increased.

- Extremely intensive unpredictable noise near the inner ear pain threshold triggers, in mammals that are awake, a defeat reaction with increases of ACTH/cortisol while the catecholamines adrenaline and noradrenaline remain normal or are slightly decreased.

- Chronic noise exposure at mild intensities will induce changes in hormonal regulation, if the individual threshold of allostasis is exceeded. A chronic allostatic load leads to subtle but significant changes in hormonal regulation, which are at present not fully understood.

EFFECTS OF PRENATAL NOISE EXPOSURE ON THE SENSITIVITY TO STRESS

Pregnant rats were subjected to noise and light stress, three times weekly on an unpredictable basis throughout gestation (Weinstock et al., 1998). Blood concentrations of adrenaline, noradrenaline and cortisol at rest and after footshock were assessed. At rest cortisol was significantly increased in offspring of stressed rats in comparison to controls while adrenaline and noradrenaline did not differ in either of the groups. After footshock, noradrenaline was significantly higher in offspring of stressed rats, showing that prenatal stress can induce long-term changes in the sensitivity of the sympathicoadrenal system to stress.

Pregnant monkeys were repeatedly exposed to unpredictable noise during days 90–145 after conception (Clarke et al., 1994). Blood concentration of ACTH and cortisol were measured in offspring of stressed and control monkeys at rest and under four progressively stressful conditions. Prenatally stressed offspring showed higher ACTH than controls in all four stressful conditions while cortisol did not change under stress. These results indicate that prenatal stress may have long-term effects on the HPA axis regulation.

EFFECTS OF NOISE EXPOSURE ON CORTISOL AND THE IMMUNE SYSTEM

The effect of acute noise stress on rats was studied by assessing blood concentrations of cortisol and total as well as differential leukocyte count (Archana and Namasivayam, 1999). A significant increase in cortisol and a significant decrease of total leukocyte counts were found.

Rats were exposed to "rock" music (80dB) for 24 hours (McCarthy, Quimet and Daun, 1992). In vitro stimulation of leukocyte subpopulations revealed several noise effects. Neutrophils and macrophages secreted significantly less superoxide anion and interleukin-1. Such effects may be detrimental to wound healing.

Pregnant rats were from gestation day 15 to day 21 daily exposed to the noise of a fire alarm bell (L_{Amax} = 85–90 dB) delivered randomly for 1 hour (Sobrian et al., 1997). In developing offspring mitogen-specific alterations in lymphoproliferatic activity and reduced immunoglobulin G levels were found at postnatal day 21.
Aguas et al. (1999) exposed a special breed of mice to low frequency noise – a model of noise – for three months as described below (Castelo Branco et al., 2003). These mice spontaneously developed an autoimmune disease at 6 months of age. Chronic low frequency noise exposure accelerated the expression of the autoimmune disease and affected the immune system, which was associated with kidney lesions and increased mortality.

Embryotoxic effects
Geber (1973) exposed pregnant rats day and night for three weeks to constantly changing sound mixtures between 76 and 94 dB for 6 minutes per hour, day and night, and demonstrated embryotoxic effects, notably calcification defects in the embryos.

Pregnant rats on a moderately magnesium deficient diet were exposed to noise during their active phase from 20.00 to 08.00 for three weeks (stochastically applied white noise impulses L_{Amax}: 87 dB, L_{eq}: 77 dB, t: 1 s duration) (Günther et al. 1981).

As compared to controls on the same diet, there was no difference in bone mineralization. The only significant effect was an increased fetal resorption rate.

The noise was changing in Geber's experiment but the noise level was comparable to the noise impulses stochastically applied by Günther et al. (L_{Amax} = 87 dB). Since these impulses were more frequent, their stress effect was at least as strong as the noise exposure employed by Geber. Therefore the major factor that differentiated the two exposure types in causing a reduced mineralization of the rat skeletons (Geber, 1973) must have been the additional noise exposure during sleep.

Castelo Branco et al. (2003) studied Wistar rats born under low frequency noise exposure. The third octave level of the applied broadband noise was > 90 dB for frequencies between 50 and 500 Hz. The broadband level was 109 dB(lin). The exposure schedule was chosen as a model for occupational noise: 8 hours per day, 5 days per week, and weekends in silence. Third generation rats born in low frequency noise environments were observed showing teratogenic malformations including loss of segments.

Morphological alterations in the myocardium caused by acute noise
Gesi et al. (2002a) reviewed the literature and stated that in experimental animals undergoing noise exposure, subcellular myocardial changes have been reported, especially at mitochondrial level; in particular, after 6 hours of exposure only the atrium exhibited significant mitochondrial alterations, whereas after 12 hours as well as subchronic exposure both atrium and ventricle were damaged.

Exposure of rats to 100 dB(A) noise for 12 hours caused a significant increase of DNA damage accompanied by ultrastructural alterations and increased noradrenaline concentrations in the myocardium (Lenzi et al., 2003). In another paper this group described an increase in mitochondrial calcium (Ca) influx caused by the same noise exposure. They described Ca accumulation at myocardial subcellular level. Summing up their results they wrote that: moreover, the present results joined with previous evidence indicate that calcium accumulation is the final common pathway responsible for noise-induced myocardial morphological alterations (Gesi et al., 2000).

Connective tissue proliferation
Hauss, Schmitt and Müller (1971) described a proliferation of connective tissue in the myocardium of rats under acute exposure to noise.

On the basis of these results a noise exposure experiment was carried out of 5 weeks with day and night exposure to stochastically triggered bells (L_{Amax}: 108 dB, t (duration of one signal):1 s, L_{eq}: 91 dB) (Ising, Noack and Lunkenheiner, 1974). We confirmed the results of Hauss, Schmitt and Müller (1971) using an electron microscope to demonstrate fibrosis in the interstitial tissue of the myocardium. Additionally electron dense areas (visible as black spots) located within bundles of collagen in the myocardium were observed. According to Selye (1962), these dark areas were most probably caused by high concentrations of calcium (Ca) carbonate or calcium phosphate deposits. This suggestion is consistent with the results of Gesi et al. (2000).

After publication of these findings, a reservation was correctly voiced that, as the noise exposure had not left intervals for sleep, it was not certain whether the myocardial damage was provoked by the noise stress as such or by a noise-induced lack of sleep. For this reason, all subsequent experiments provided for noise-free intervals of 8 to 12 hours during the rats' inactive phases to enable them to sleep.

Rats were exposed for 28 weeks to a random series of white noise impulses from 16.00 to 08.00 daily with an 8 hour rest in their inactive phase (Ising et al., 1979). The third octave spectrum of the noise was flat between 5 and 25 kHz and had a third octave level of 88 dB (lin) (broadband L_{Amax} = 97 dB(lin). L_{eq} = 87 dB(lin)). The duration of noise impulses was 4 seconds and the noise to pause ratio 1:10 on average. There was a small but significant increase in hydroxyproline as indicator of collagen in the rats' left myocardium. Electron micrographs showed, similar to the earlier experiment, collagen bundles in the otherwise empty interstitial space but no indication of calcium deposits.

Respiratory effects
Castelo Branco et al. (2003) studied respiratory epithelia in Wistar rats born under low frequency noise exposure and further exposed for up to 5403 hours during more than 2.5 years. The third octave level of the applied broadband noise was > 90 dB for frequencies between 50 and 500 Hz. The broadband level was 109 dB(lin). The exposure schedule was chosen as a model for occupational noise: 8 hours per day, 5 days per week and weekends in silence. Rats were gestated and born under the described noise exposure with additional exposures from 145 to 5304 hours. Transmission electron micrographs of the tracheal epithelium of rats exposed for 2438 hours revealed a subepithelial layer of hyperplastic collagen bundles, several of them exhibiting a degenerative pattern. The results indicate an increased proliferation as well as degenerative processes of collagen.

Castelo Branco et al. (2003) observed sheared cilia in the respiratory epithelia of Wistar rats born under and further chronically exposed to low frequency noise. As interpretation of their findings they stated that both mechanical and biochemical events may be responsible for this pattern of trauma.

Electrolytes: Ca/Mg shift
Acute exposure of rats to the fast rising overflight noise of low flying fighter planes

reaching levels of up to 125 dB(A)) (Ising et al., 1991; Ising, 1993) resulted not only in an increase of cortisol but also in a decrease of intracellular magnesium (Mg) and an increase of Mg excretion.
In guinea pigs, acute stress – due to 2 hours of noise exposure (95 dB white noise) or to overcrowding in the cage – caused significant increases of serum Mg and decreases of erythrocyte Mg (Ising et al., 1986).

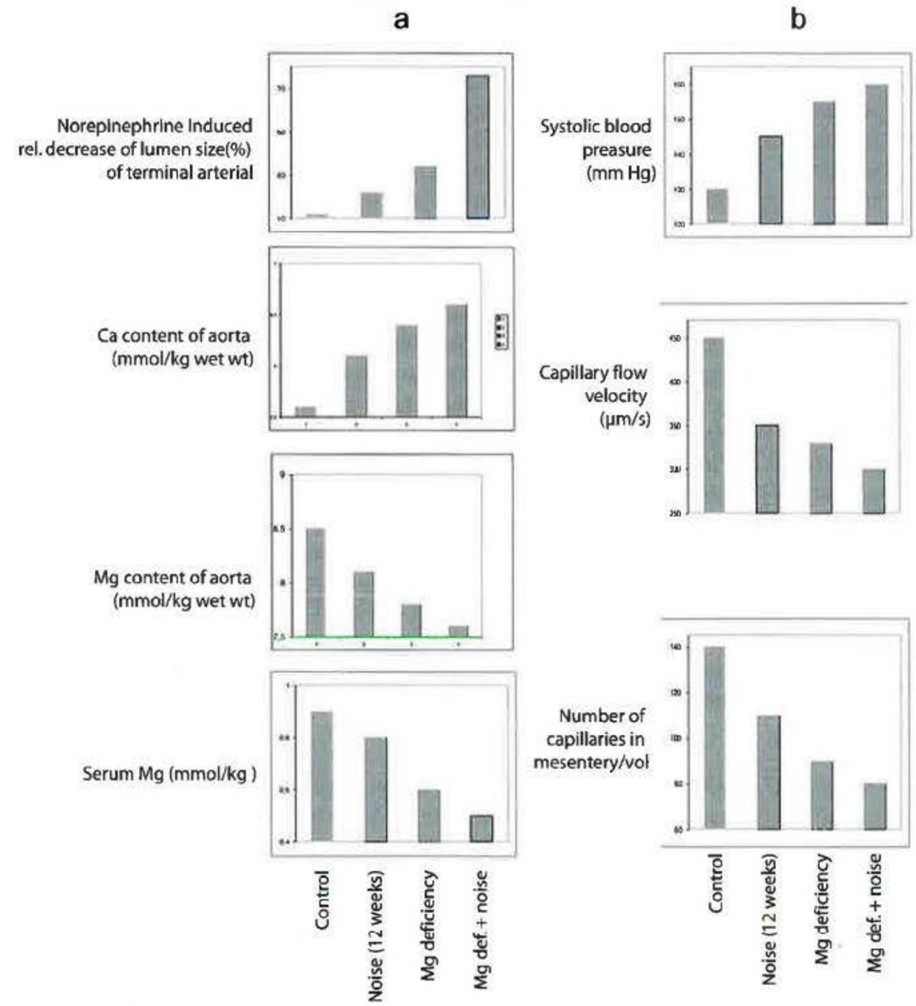
For chronic noise experiments an additional stress factor had been sought which would act synergistically with unwanted noise, since in the above described noise experiment, half a year of exposure led to but relatively mild health effects (Ising et al., 1979). The justification for using two stressors derives from the fact that humans have to cope with a whole range of more or less synergistic stress factors and not with noise alone.

Organic damage as a result of chronic stress is likely to occur only under the condition that the overall exposure to stress exceeds a certain tolerance level during a relatively long period of time (Selye, 1974). For technical reasons, the two options available to supply a suitable additional stress factor were the cold or a magnesium (Mg) deficiency. Both factors, like habitual noise, cause an increased noradrenaline secretion. For practical reasons different degrees of a magnesium-deficient diet were selected as an additional stress factor. Noise exposure was provided by electro-acoustically reproduced traffic noise of L_{Amax}: 86 dB, L_{eq}: 69 dB over 12 hours during the rats' active phase. For one group the noise level was slightly increased (L_{eq}: 75 dB). The experiment lasted 16 weeks (Günther, Ising and Merker, 1978). Magnesium deficiency combined with noise exposure led to dose-dependent increases in adrenaline and noradrenaline, which can be used to quantify the overall stress of the dietary treatment. As stress grew, the hydroxyproline (as an indicator of collagen) and calcium (Ca) content of the myocardium increased while the magnesium content decreased. Long-term stress therefore resulted in an intracellular Ca/Mg shift.

Altura et al. (1992) studied the relationship between microcirculation (measured several days after termination of noise exposure), hypertension and Ca/Mg shifts in vascular walls of noise-stressed rats on Mg deficient diets. Noise exposure during the first 8 weeks was set to an energy equivalent level of 85 dB(A) from 20.00 to 08.00. Noise impulses were randomly switched on at randomized peak levels of 80, 90 and 100 dB(A). During the final 4 weeks the equivalent noise level was elevated to 95 dB(A) and the daily exposure increased to 16 hours with an 8 hour rest during the animals' inactive phase. In aortic and port vein smooth muscle the Ca content increased with rising noise exposure, with decreasing Mg uptake, and with the combination of both together, while the Mg content decreased. Parallel to this the reactivity of terminal arterioles to noradrenaline was increased (Fig.1a).

Stress-induced Ca/Mg shifts in smooth muscle cells have the potential to increase the risk of hypertension and myocardial infarction (Ising, Havestadt and Neus, 1985). Stress increases the membrane permeability of catecholamine-sensitive cells, which in turn raises Ca influx into cells and liberates intracellular Mg. A depression of catecholamine-induced vasoconstriction by stress-dependent hypermagnesemia (excess serum Mg concentration) has been demonstrated experimentally. However, the benefit from this stress-depressing hypermagnesemia is obtained at the expense of increased renal Mg loss. In the long run, chronic stress combined with suboptimal Mg in diet will reduce the Mg release in acute stress situations, causing an increase of vasoconstriction and raising the risk of hypertension.

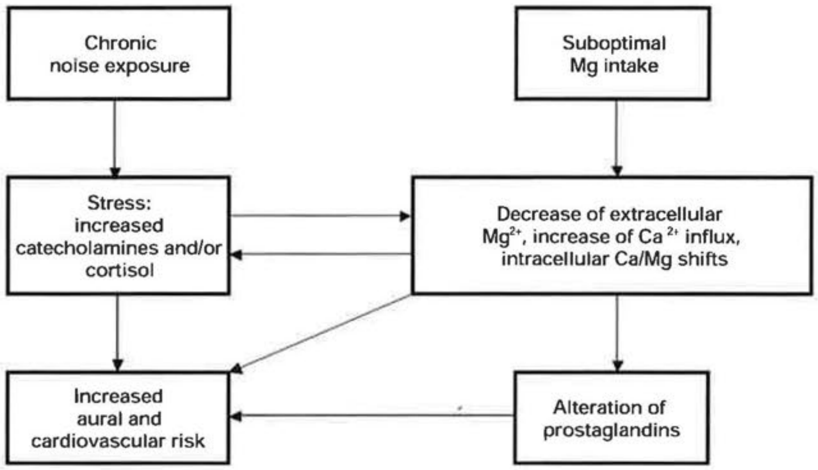
Fig.1
Effects of 12 weeks noise exposure, Mg deficient diet and the combination of both in Wistar rats. (a) Ca/Mg shifts in vascular smooth muscle, Mg concentration in blood and reactivity of arterioles to noradrenaline. (b) Systolic BP, capillary blood flow velocity and numbers of capillaries/volume.



Source: Altura et al., 1992

Further analysis of the experimental results led to an interaction model between chronic stress and intracellular electrolyte shifts (Ising, 1981; Ising et al., 1986) (Fig.2). Chronic stress caused a loss of extracellular and intracellular Mg and an increase in intracellular Ca (Günther, Ising and Merker, 1978). A decrease of Mg was correlated with an increase in physiological noise sensitivity, that is, to more severe noradrenaline releases in animals and humans under noise exposure (Günther, Ising and Merker, 1978; Ising, Havestadt and Neus, 1985; Ising et al., 1986). There was a positive feedback mechanism between stress – caused by noise and other stressors – and intracellular Mg/Ca shifts, which may end in a circulus vitiosus and increase cardiovascular risks.

Fig. 2
Interaction between stress and Ca/Mg shifts and its long term consequences



Hypertension

Rothlin, Cerletti and Emmenegger (1956) exposed rats for 1.5 years, day and night, to 90 dB "audiogenic stress" and observed a raising of systolic BP values from 120 mm Hg to about 150 mm Hg. He used a cross-breed of Albino rats and wild Norwegian rats since Albino rats did not develop hypertension under noise exposure. After termination of exposure the BP returned to normal.

Albino rats were exposed to noise during their whole lifespan (for review see Borg, 1981) to periodic noise impulses of 80 and 100 dB. This periodic exposure had no detrimental health effects, which can be understood on the basis of the work of Glass, Singer and Friedmann (1969). Unpredictable noise presentation was shown to cause lasting cortisol increases in rats in contrast to periodic exposure to 100 dB, which led to adaptation (De Boer, van der Gugten and Slangen, 1989). The unpredictability of a noise is a decisive precondition of long-term stress effects.

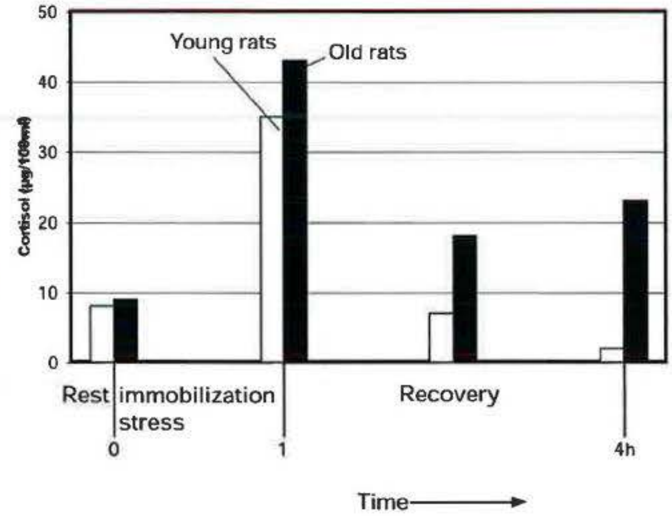
Exposure of primates to traffic noise for 10 hours per day during 9 months led to a significant BP increase, which persisted during 3 weeks after termination of exposure (Peterson et al., 1981). A replication of this experiment with a different species of primates failed to show an increase of their BP (Turkkan, Hienz and Harris, 1983).

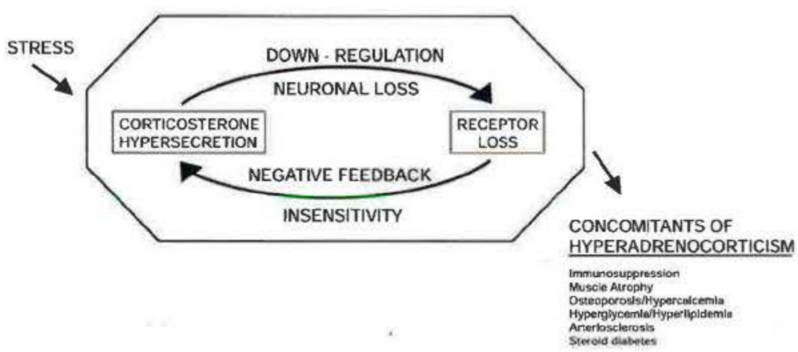
In the above-mentioned experiment of Altura et al. (1992), exposure to unpredictable noise impulses led within 12 weeks to irreversible changes of microcirculation and an increase of systolic BP (Fig. 1b). The observed rarefication of capillaries in the mesentery can be interpreted as an indicator of accelerated ageing of the circulatory system.

Ageing and lifespan

The cortisol response and recovery after immobilization stress was compared in young and old rats. The results are demonstrated in Fig. 3 together with Sapolsky's Glucocorticoid Cascade Model (Sapolsky, Krey and McEwen, 1986). The stress response of young and old rats is more or less the same. However, while the young rats recover immediately after termination the old ones recover only in part.

Fig. 3
Above: Recovery after stress (young and old rats).
Below: Sapolsky´s Glucocorticoid Cascade Model





Therefore, acute stress leads, in old animals, to considerably prolonged cortisol increases. On the other hand, chronically repeated stress activates the HPA axis and can cause cortisol receptor losses even in younger animals, a process generally developing only in old age. Finally, chronic cortisol hypersecretion may occur along with follow-up health defects.

Aguas et al. (1999) exposed a special breed of mice to the above described model of occupational low frequency noise for three months. Chronic low frequency noise exposure accelerated the expression of the autoimmune disease and was associated with kidney lesions and increased mortality.

Chronic noise exposure of animals on a suboptimal Mg diet led to increases of connective tissue and calcium and decreases of Mg in the myocardium (Günther, Ising and Merker, 1978). These changes were correlated with noradrenaline changes. Since they are also correlated with normal ageing, the noise stress induced changes may be interpreted as accelerated ageing (Ising, Nawroth and Günther, 1981). Even the lifespan was reduced in rats on an Mg deficient diet, and was further dose-dependently reduced in combination with noise exposure (see Table 1).

Table 1
Effects of noise exposure combined with dietary Mg-deficiency in rats

Treatment		Effect					
4 months	3 months	Urine		Myocardium			Death rate
Mg in diet	Noise	Noradre-naline	Adre-naline	Hydroxy-proline	Ca	Mg	
	L_{eq}/L_{Amax}	(µg/g Cre)		(mg/g dry wt.)	(mg/g d.w.)	(mg/g d.w.)	
control	ambient	18 ± 4	12 ± 2	3.0 ± 0.1	3.0 ± 0.2	37.5 ± 0.8	0
suboptimal	ambient	23 ± 4	18 ± 2	3.0 ± 0.1	3.5 ± 0.5	38.0 ± 1.7	0
suboptimal	69/86 dB	37 ± 11	16 ± 2	3.0 ± 0.1	4.3 ± 0.2	37.9 ± 1.3	0
deficient	ambient	98 ± 17	20 ± 5	3.9 ± 0.1	6.2 ± 0.7	31.2 ± 1.4	38%
deficient	69/86 dB	129 ± 19	41 ± 10	4.6 ± 0.1	6.7 ± 0.6	29.8 ± 1.8	62%
deficient	75/86 dB	172 ± 26	60 ± 15	5.6 ± 0.9	8.0 ± 0.9	26.8 ± 0.8	75%

Adrenaline and noradrenaline excretion was measured during the fourth week of noise exposure; death rate is related to the 4-month period of Mg treatment; all other parameters were determined at the end of the experiment (mean values ± S.E.). Noise has the potential to cause stress reactions which are enhanced by suboptimal magnesium intake. Chronic noise-induced stress accelerates the ageing of the myocardium and thus increases the risk of myocardial infarction. The involved pathomechanisms include increases of catecholamines and/or cortisol under acute noise exposure and an interaction between endocrine reactions and intracellular Ca/Mg shifts.

WHAT CAN BE LEARNED FROM ANIMAL STUDIES ABOUT NOISE EFFECTS IN HUMANS?

The effects of low frequency noise – the "vibroacoustic disease" – were studied primarily in humans (for review see Castello Branco and Alves-Pereira, 2004).

In this context, the amygdalar contribution to conditioned fear learning, revealed for normal human subjects, has to be mentioned. Longer lasting activation of the HPA axis, especially abnormally increased or repeatedly elevated cortisol levels may lead to disturbances of the hormonal balance and even severe diseases in man (Spreng, 2000).

Catecholamines induce various detrimental effects on the heart (Ceremuzynski, 1981). Additionally, magnesium deficiency causes alterations of serum lipids (Weglicki et al., 1993), cytokines (Rayssiguier, 1990) and prostaglandines (Nigam, Averdunk and Günther, 1986), in particular an increase of thromboxan, which is released from thrombocytes (Neumann and Lang, 1995) and several other cell types and – in turn – thromboxan A2 can aggregate thrombocytes. All these alterations may increase the risk of myocardial infarction.
Beside these cardiovascular stress effects, chronically increased cortisol may induce

neuronal degeneration and thus accelerate the ageing also of the brain (Sapolsky, Krey and McEwen, 1986), not only in rats but in humans as well (Sapolsky, 1994).

The importance of Ca/Mg shifts was confirmed by post mortem studies of hearts from victims of IHD (Elwood et al. 1980). The tissue samples were taken from areas of the myocardium not affected by the infarction and the results were stable after controlling for several confounders. The results are shown in Table 2. With normal ageing Ca increases and Mg decreases in the myocardium. This process is accelerated in myocardial infarction patients, which indicates an accelerated ageing of these peoples' heart muscle under the pathogenic influences that lead to myocardial infarction.

Table 2
Age dependency of myocardial Ca and Mg contents in ischaemic heart disease (IHD)

IHD deaths and non IHD deaths. (Mean Value ± SD, numbers in brackets)

	Group	Age < 45years	45–64 years	≥ 65 years
Ca [µg/g]	Non IHD	43 ± 15 (175)	50 ± 14 (281)	57 ± 22 (155)
	IHD	48 ± 10 (48)	53 ± 17 (389)	58 ± 21 (188)
Mg [µg/g]	Non IHD	183 ± 28	173 ± 34	178 ± 30
	IHD	170 ± 29	157 ± 30	156 ± 27
Ca/Mg	Non IHD	0.24	0.29	0.32
	IHD	0.28	0.34	0.37

Another factor which decreases Mg and increases Ca (Hofecker, Niedermüller and Skalicky, 1991) and collagen (Caspari, Gibson and Harris; 1976, Anversa et al., 1990; Gibbons, Beverly and Snyder, 1991) in the myocard is normal ageing (Ising, Nawroth and Günther, 1981). Therefore, it is plausible that the age-dependent decrease of Mg in hearts of IHD victims was about double of that in age-matched non-IHD deaths. This is therefore an indication that age- and stress-dependent electrolyte changes exist in humans and may be correlated with an increased risk of IHD.

Long-term experiments with Mg-deficient and noise-stressed rats showed that connective tissue and Ca in the myocardium increased with age while Mg decreased. Hence, stress caused by noise or cold is enhanced by suboptimal Mg intake and accelerates the ageing of the heart and decreases the lifespan (Heroux, Peter and Heggtveit, 1977; Ising, Nawroth and Günther, 1981; Günther, 1991).

Since coronary arteriosclerosis increases strongly with age (Lakatta, 1990) a biologically older heart is at a higher risk of IHD and of myocardial infarction. The interaction process described seems to be one of the pathomechanisms by which chronic noise stress increases the risk of myocardial infarction.

Several of the risk factors described in the literature to explain the correlation of work stress with myocardial infarction have been found to be increased under noise-induced stress as well, that is, increases of BP and total cholesterol.

APPENDIX 4. NOISE AND SLEEP IN CHILDREN

FACTORS THAT MODIFY AUDITORY AROUSAL THRESHOLDS IN CHILDREN

By the time that most studies were conducted in infants, it had become progressively evident that arousal and awakening thresholds are influenced by a variety of factors. These significantly modify the response to ambient noise of sleeping infants. Some factors inhibit the arousal response, while others enhance the response.

PRENATAL AND PERINATAL FACTORS

Age of gestation
In 97 healthy infants, auditory awakening thresholds decreased significantly from the 44th to the 60th week after conception (Kahn, Picard and Blum, 1986). Awakening thresholds were defined as the infant opening their eyes and/or crying. Mean awakening thresholds dropped from 98.5+/-11 at the 44th week after conception to 83 dB(A) by the 60th week after conception.

Cigarette smoke
To evaluate the effects of cigarette smoke on polygraphic arousal thresholds, 26 newborns were studied with polygraphic recordings for one night: 13 were born to mothers who did not smoke, and 13 were born to mothers who smoked (over 9 cigarettes per day) (Franco et al., 1999). Another group of infants with a median postnatal age of 12 weeks were also studied: 21 born to non-smoking mothers and 21 born to smoking mothers. The auditory arousal thresholds of the infants of both age groups were measured with the use of auditory challenges of increasing intensity, administered during REM sleep. More intense auditory stimuli were needed to induce arousals in newborns (p=.002) and infants (p=.044) of smokers than in infants of non-smokers (mean value of 84+/-11 dB(A) for smokers and 81.6+/-20 for non-smokers). Behavioural awakening (infants opening their eyes and/or crying) occurred significantly less frequently in the newborns of smokers (p=.002) than of non-smokers.

It was concluded that newborn and infants born to smoking mothers had higher arousal thresholds to auditory challenges than those born to non-smoking mothers. From the present findings, it appeared that the impact of exposure to cigarette smoke occurred mainly before birth.

POSTNATAL FACTORS

The following postnatal factors modify arousal from sleep.

Sleep stage
In infants, auditory stimuli have generally indicated increased responses during active as compared with quiet sleep (Busby, Mercier and Pivik, 1994).

Time of the night

In 31 infants, the arousal thresholds decreased across the night (mean value of 67+/-12.5 dB(A) in the first part of the night, for 51+/-3.5 in the third part of the night; p=.017) (Franco et al., 2001). Similar findings had been reported in adult subjects (Rechtschaffen, Hauri and Zeitlin, 1966).

Body position during sleep

To investigate whether prone or supine sleeping was associated with a different response threshold to environmental stimuli, 25 3-month-old healthy infants with a median age of 9 months were exposed to an auditory challenge while sleeping successively prone or supine (Franco et al., 1998). Three infants were excluded from the study because they awoke while their position was being changed. For the 22 infants included in the analysis, more intense auditory stimuli were needed to arouse the infants in the prone position (median of 70 db(A), range values 50 to more than 100 db(A)) than in the supine position (median of 60 db(A), range values 50–90 db(A)) (p=.011). Arousal thresholds were higher in the prone than in the supine position in 15 infants, unchanged in 4 infants and lower in the prone position in 3 infants (p=.007). It was concluded that infants show higher arousal thresholds to auditory challenges when sleeping in the prone position than when sleeping in the supine position. The findings could not readily be explained. The difference in arousal thresholds could be related to difference in chest wall mechanoreceptor responses, or differences in BP and/or central baroreceptors responses.

Ambient room temperature

Two groups of healthy infants with a median age of 11 weeks were recorded polygraphically during one night: 31 infants were studied at 24°C and 31 infants at 28°C. To determine their arousal thresholds, the infants were exposed to white noises of increasing intensities during REM and non-REM sleep (Franco et al., 2001). The arousal thresholds decreased across the night in the infants sleeping at 24°C (p= .017). The finding was not found for the infants sleeping at 28°C. When analysing the arousal responses according to time of the night, it was found that the auditory thresholds were significantly higher at 28°C (75+/-19 dB(A)) than at 24°C (51+/-3.5 dB(A)) between 03.00 and 06.00 (p=.003). These findings were only seen in REM sleep.

Sleeping with the head covered by bedclothes

To evaluate the influence of covering the face of sleeping infants with a bed sheet, 18 healthy infants with a median of 10.5 weeks (range 8–15 weeks) were recorded polygraphically for one night (Franco et al., 2002). They slept in their usual supine position. During sleep, a bed sheet was gently placed on their face for 60 minutes. With the face free or covered by the sheet, the infants were exposed to white noises of increasing intensities during REM and non-REM sleep. Compared to with their face free, during the periods when their faces were covered, the infants had increases in pericephalic ambient temperature (p<.001), increases in REM sleep (p=.035) and body movements (p=.011) and a decrease in non-REM sleep (p<.001). Respiratory frequency was increased in both REM (p=.001) and non-REM (p<.001) sleep. With their face covered, the infants had higher auditory arousal thresholds (mean of 76+/-23 dB(A)) than with their face free (mean of 58+/-14 dB(A)) (p=.006). The difference was seen in REM sleep only. A positive correlation was found between pericephalic temperature and arousal thresholds in REM sleep (r=.487; p=.003).

Short sleep deprivation

Following short sleep deprivation, a study reported that in infants there was no measurable change in arousal propensity by auditory stimuli (1 kHz pure tone, delivered in the midline of the cot, from 73 dB and increased in 3 dB steps to 100 dB) during quiet sleep (Thomas et al., 1996). Another study was undertaken to evaluate the influence of a brief period of sleep deprivation on sleep and arousal characteristics of healthy infants (Franco et al., submitted). Thirteen healthy infants with a median age of 8 weeks (range 7–18 weeks) were recorded polygraphically during a morning nap and an afternoon nap in a sleep laboratory. They were two hours sleep-deprived, either in the morning or in the afternoon before being allowed to fall asleep. Six infants were sleep-deprived before the morning nap and seven before the afternoon nap. During each nap, the infants were exposed to white noises of increasing intensities in REM sleep to determine their arousal thresholds. Following sleep deprivation, the infants tended to have less gross body movements during sleep (p = .054). They had a significant increase in obstructive sleep apnoeas (p = .012). The infants' auditory arousal thresholds were significantly higher following sleep-deprivation (mean of 76+/-13.5 dB(A)) than during normal sleep (mean of 56+/-8.4 dB(A)) (p = .003) and during REM sleep. It was concluded that short-term sleep deprivation in infants is associated with the development of obstructive sleep apnoeas and a significant increase in arousal thresholds.

Pacifiers and breastfeeding

Fifty-six healthy infants were studied polygraphically during one night: 36 infants used a pacifier regularly during sleep; 20 never used a pacifier (Franco et al., 2000). Thumb users or occasional pacifier users were not included in the study. The infants were recorded at a median age of 10 weeks (range 6–19 weeks). To evaluate their auditory arousal thresholds, the infants were exposed to white noise of increasing intensity during REM sleep. Polygraphic arousals occurred at significantly lower auditory stimuli in pacifier-users than in nonusers (mean of 60+/-11.6 with pacifiers, for 71+/-15.3 without pacifier; p=.010). Compared to non-users, pacifier-users were more frequently bottle-fed than breastfed (p=.036).

Among infants sleeping without a pacifier, breastfed infants had lower auditory thresholds than bottle-fed infants (mean of 67.7+-13.0 breastfed, for 77.7+-17.5 bottle-fed; p=.049). The question of how a pacifier contributes to protect the sleeping infant might be best explained by the observed loss of the pacifier early after sleep onset. This could contribute to disruption of the infant's sleep and favour arousals.

CONCLUSIONS

Various factors modify auditory arousal responses from sleep in healthy infants. Some inhibit arousals while others enhance the response. To evaluate the effect and dose-effect relationship on children therefore requires the careful determination of confounders that may bias studies and lead to conflicting results.

Additional confounders should be added to the list of factors that modify arousal thresholds. These include past experience with the stimulus (Rechtschaffen, Hauri and Zeitlin, 1966), or the presence of meaning in the noise as both of them are of critical importance in determining the persistence of physical reactions to the noise (McLean and Tarnopolsky, 1977). These are the reasons which lead most sleep/wake researchers to use white noises to stimulate the sleeping child.

Knowledge of these variables does little to clarify the physiological determinants of the awakening response, because knowledge of how such variables are related to possible physiological determinants is little better than that of the awakening response itself (Rechtschaffen, Hauri and Zeitlin, 1966).

These findings however, underline the significant dose–response relationship between ambient noise and arousal or awakening from sleep in infants.

NOISE AND SLEEP FOR DIFFERENT STAGES OF DEVELOPMENT

THE FETUS

The human fetus spends most of its time in a state equivalent to sleep, similar to that recorded in newborn infants. The healthy fetus in utero was shown to react to external noises. This is the result of the development of the human cochlea and peripheral sensory end organs. These complete their normal development by 24 weeks of gestation. Sound is well transmitted into the uterine environment. Ultrasonographic observations of blink/startle responses to vibroacoustic stimulation are first elicited at 24–25 weeks of gestation, and are consistently present after 28 weeks, indicating maturation of the auditory pathways of the central nervous system (Committee on Environment Health of the American Academy of Pediatrics, 1997). The fetus reacts to 1–4 seconds of 100–130 dB of 1220–15000 Hz sound. The hearing threshold (the intensity at which one perceives sound) at 27–29 weeks of gestation is approximately 40 dB and decreases to a nearly adult level of 13.5 dB by 42 weeks of gestation, indicating continuing postnatal maturation of these pathways.

Teratogenic effects have been described in animals prenatally exposed to noise (Committee on Environment Health of the American Academy of Pediatrics, 1997). These were associated with higher levels of cortisol and corticotropin hormones in the exposed animals. No such effects could be demonstrated in humans, in whom studies on the relation between exposure to noises during gestation and shortened gestation or lower birth weights were inconclusive or conflicting. It is possible that in these studies, noise could be a marker of other risk factors (Committee on Environment Health of the American Academy of Pediatrics, 1997). In conclusion, most studies on the effects of noise on perinatal health have been criticized as being hampered by serious methodological limitations, both in terms of the measurement of exposure and outcome, and failure to control for other known determinants of the outcomes under investigation. The lack of properly controlled studies makes it difficult to draw conclusions about what effects ambient noise has on perinatal outcomes (Morrell, Taylor and Lyle, 1997).

NEWBORN INFANTS

A large number of investigations have been concerned with the responses of sleeping newborn infants to acoustic signals. Many of the studies arise from a large and general interest in child development as well as from a need for hearing tests for infants (Mills, 1975).

Infant incubators produce continuous noise levels of between 50 and 86 dB(lin) (American Academy of Pediatrics, 1974). Oxygen inlets produced an additional 2 dB (lin). Slamming of incubator doors and infant crying produced 90 to 100 dB(A)

(American Academy of Pediatrics, 1974). It was shown that inside incubators, background noise level is about 50 dBA and can reach 120 dBA (Committee on Environment Health of the American Academy of Pediatrics, 1997). Much of the energy is located below 500 Hz, between 31 and 250 Hz (Mills, 1975).

Ambient noise appears to influence the quantity and quality of the sleep of newborns. Some newborns appear to be particularly responsive to ambient noises. Sleeping premature, anoxic, or brain-damaged infants detect intruding sounds better than sleeping healthy or term babies (Mills, 1975).

Newborn infants spend most of their time sleeping. Some studies have documented hearing loss in children cared for in intensive care units (Committee on Environment Health of the American Academy of Pediatrics, 1997). Noise and some ototoxic drugs act synergistically to produce pathological changes of the inner ears of experimental animals (neomycin, kanamycin, sodium salicylate). The relationship with the infant's clinical condition and associated treatments has, however, not yet been clearly defined. Infants exposed to sound levels of incubators are usually premature, on drugs and in very poor health. Moreover, the exposures are continuous. A weak infant could spend weeks sleeping in such a noise level without rest periods away from noise (Mills, 1975).

High noise levels may be associated with other types of responses. In young infants, sudden loud (of approximately 80 dB) environmental noise induced hypoxaemia.

Noise reduction was associated in neonates with increases in sleep time, in particular in quiet sleep (Committee on Environment Health of the American Academy of Pediatrics, 1997). It also resulted in fewer days of respiratory support and oxygen administration. Premature infants cared for with noise reduction had a better maturation of electroencephalograms.

A Committee on Environmental Health of the American Academy of Pediatrics (1997) concluded that high ambient noise in the neonatal intensive care unit (NICU) changed the behavioural and physiological responses of infants. For all the above observations and considerations, sound in infant intensive care units should be maintained at under 80 dB(A) (Graven, 2000). Among other recommendations, paediatricians were encouraged to monitor sound in the NICU, and within incubators, where a noise level greater than 45 dB is of concern.

INFANTS (1 MONTH TO 1 YEAR OLD)

Some studies of the effect of external noises on the sleep/wake reactions of infants were conducted in their natural home environment. The reactions of babies to aircraft noise were studied by means of electroplethysmography (PLG) and EEG (Ando and Hattori, 1977). The recordings were done in the morning, in the infants' sleeping rooms. The infants were exposed to recorded noise of a Boeing 727 at take-off. The noise was presented at 70, 80 and 90 dB(A) at peak level at the position of the babies' heads. The subjects who had not been awakened by exposure to aircraft noise were exposed to music (Beethoven's Ninth Symphony) at levels of 70, 80 and 90 dB(A). The frequency ranged between 100 Hz and 10 kHz. It was found that the babies whose mothers had moved to the area around the Osaka International Airport before conception (Group I; n=33) or during the first five months of pregnancy (Group II; n=17) showed little or no reaction to aircraft noise. In contrast, babies whose mothers had moved closer to the airport during the second half of the pregnancy or after birth (Group III; n=10 or IV; n=3) and the babies whose mothers lived in a quiet living area (Group V; n=8) reacted to the same auditory stimuli. The babies in groups I and II showed differential responses depending on whether the auditory stimuli were aircraft noise or music. Abnormal PLG and EEG were observed in the majority of babies living in an area where noise levels were over 95 dB(A). It was concluded that the difference in reactivity to aircraft noise may be ascribed to a prenatal difference in time of exposure to aircraft noise. The reactions diminished after the sixth month of life in groups I and II, and the ninth month in groups III to V. This phenomenon may be explained as habituation to aircraft noise after birth. However, in all groups, no habituation occurred for a noise level over 95 dB(A) (Ando and Hattori, 1977). This study was criticized, as the authors did not adjust for several important determinants of birth weight, such as prematurity and the mother's age, weight, smoking status or socioeconomic status (Morrell et al., 1997).

Noise levels may be constantly high in paediatric units. The mean noise levels measured in a centre of a surgical recovery room were 57.2 dB(A), while those measured at the patients' heads were 65.6 dB(A) (American Academy of Pediatrics, 1974). In a medical unit (6-bed wards containing 5 infants between 3 and 17 months) peak sound levels were recorded on the pillow of the cot for 12 min (Keipert, 1985). Infant crying produced 75–90 dB(A) and a beeper around 76–78 dB(A). Peak noise levels recorded at the nurses' station were about 78 dB(A) for telephone, 80 for infant crying, public address system, adult talking, and up to 90 dB(A) for child talking (Keipert, 1985).

In a study conducted on infants exposed to 50–80 dB(lin) in the range of 100–7000 Hz (American Academy of Pediatrics, 1974), a level of 70–75 dB(lin) for 3 minutes led to obvious disturbance or awakening in two thirds of the children. All infants awakened after 75 dB(lin) for 12 minutes.

In other studies conducted on the effects of awakening and arousal, it was shown that white noise intensity was significantly lower when it elicited polygraphically scored arousals than when it induced awakenings (Franco et al., 1998).

TODDLERS PREADOLESCENTS (8–12 YEARS OLD) ADOLESCENTS (13–18 YEARS OLD)

Developmental variations in auditory arousal thresholds during sleep were investigated in four groups of normal male subjects: children (n=6; 5–7 years old), preadolescents (n=10; 8–12 years old), adolescents (n=10; 13–16 years old), and young adults (n=10; 20–24 years old) (Busby, Mercier and Pivik, 1994). Arousal thresholds were determined during non-REM and REM sleep for tones (3-s, 1500 Hz pure tones delivered in an ascending series of increasing intensity, 5 dB increments beginning at 30 dB SPL (sound pressure level) re 0.0002 dynes/cm2 until awakening or maximum intensity of 120 dB) presented via earphone insert on a single night following two adaptation nights of undisturbed sleep. Age-related relationships were observed for both awakening frequency and stimulus intensity required to effect awakening, with awakenings occurring more frequently in response to lower stimulus intensities with increasing age. In children, 43.1% of stimuli induced awakenings, in preadolescents 54.8%, adolescents 72% and adults 100% (X2=60.37; p<.001). Partial arousals (brief EEG desynchronization and/or EMG activity with the subjects returning to sleep) occurred in 9.8% of children, 4.8% of preadolescents, 12.2% of adolescents, 0% of adults. Although stimulus intensities required for awakening were high and statistically equivalent across sleep stages in non-adults, higher intensity stimulus was required in stage 4 relative to stage 2 and REM sleep. Frequency of awakening increased with age, whereas stimulus intensities required to effect these awakenings decreased with age. These relationships were maintained for individual sleep stages. These results confirm previous observations of marked resistance to awakening during sleep in preadolescent children and suggest that processes underlying awakening from sleep undergo systematic modification during ontogenic development. The observed resistance to elicited awakening from sleep extending up to young adulthood implies the presence of an active, developmentally related process that maintains sleep (Busby, Mercier and Pivik, 1994).

In another study, children aged 5–7 years were shown to be 10–15 dB less sensitive to pure tones than adults aged 22–30 (Mills, 1975). Another report on male hyperactive and normal children aged 8–12 showed that these children were awakened with auditory stimulus intensity levels of up to 123 dB SPL, much higher than values reported for adults (range of 50–85 dB) (Busby, Mercier and Pivik, 1994).

In a study on four children (two males), aged 5–8 years old on the effects of simulated sonic booms (68 dB(A) near the subjects' ears), 94.1% of the subjects showed no change, 5.9% had shallower sleep, but none aroused or had behavioural awakening. In general, the frequency of arousal or behavioural awakenings and of sleep stage changes increased with age (up to 75 years) (Lukas, 1975).

In a prospective longitudinal investigation, which employed non-exposed control groups, effects of aircraft noise prior to and subsequent to inauguration of a new airport as well as effects of chronic noise and its reduction at an old airport (6–18 months after relocation), were studied in 326 children aged 9–13 years (Bullinger et al., 1999). The psychological health of children was investigated with a standardized quality of life scale as well as with a motivational measure. In addition, a self-report noise annoyance scale was used. In the children studied at the two airports over three time points, results showed a significant decrease of total quality of life 18 months after aircraft noise exposure as well as motivational deficits demonstrated by fewer attempts to solve insoluble puzzles in the new airport area. Parallel shifts in children's attributions for failure were also noted. At the old airport parallel impairments were present before the airport relocation but subsided thereafter (Bullinger et al., 1999).

In some studies, the effects of ambient noise on autonomic responses could be demonstrated in children. In children aged 6–12 years exposed to intermittent traffic noise during 4 nights (at a rate of 90 noises per hour; peak intensity of the noise, 45, 55 and 65 dB(A) varied semi-randomly) and 2 quiet nights. Heart rate was affected and relatively higher in noise during REM and stage 2 than during delta sleep (Muzet et al., 1980, in Abel, 1990).

CONCLUSIONS

Several studies on the extra-auditory effects of ambient noise on sleeping children were summarized in Table 1. In relation to ambient noise, specific changes were reported in both sleep quality and quantity. Some of the effects were shown to have a dose–response relationship.
Several limitations to the present report should be discussed. Firstly, no one knows

whether the inference that is often made that the effects of noise might develop with a longer exposure time (Abel, 1990) is correct. Serious cardiorespiratory or autonomic changes, such as increases in BP could only develop following a long time exposure starting from childhood. This, in fact, has never been documented, nor has the extent of variability between subjects due to difference in susceptibility. Secondly, there is no information to evaluate whether adaptation to ambient noise could limit the effects observed during short-term experiments. Thirdly, as the existing research data are applicable to generally healthy children, no one knows how the reported findings could be applied to ill children, children receiving medical treatment or very young premature infants. Finally, as most studies were conducted in laboratory controlled environments, no one knows the correlation between these studies and the effects of noise in the home. The multifactorial effects of the environment on sleep and arousal controls could be much more complex than expected. One might predict that, similarly as for adults, the effects of noise on the child's sleep and health are very complicated and depend upon the spectrum and level of the noise, temporal aspects of the noise, psychological responses to the noise and the nature of the evaluation technique. The complexity of the conditions related to sleep/wake controls was illustrated by the review of confounding factors affecting auditory arousal thresholds.

Despite these limitations, it can be concluded that, based on the evidence available, the extra-auditory effects of noise could be pervasive, affecting the children's physical and psychological well-being. Changes in sleep quantity and quality together with autonomic reactions are seen when a child is exposed to ambient noise during sleep. Ambient noise exerts a dose-effect relationship on changes in sleep/wake behaviours. These reflect modifications induced within the brain of the sleeping child. It remains, however, to be determined what pervasive effects long-term exposure to ambient noise has on the child's development, health and well-being. Evidence should also be defined to support an enforcement of strategies for noise reduction at the source as suggested by some studies. Noise-induced health effects on children, a clinical and public health concern, should be evaluated by further studies.

Environmental noise is a threat to public health, having negative impacts on human health and wellbeing. This book reviews the health effects of night time noise exposure, examines dose effects relations, and presents interim and ultimate guideline values of night noise exposure. It offers guidance to policy-makers in reducing the health impacts of night noise, based on expert evaluation of scientific evidence in Europe.

GUIDELINES FOR COMMUNITY NOISE

Edited by

Birgitta Berglund
Thomas Lindvall
Dietrich H Schwela

This WHO document on the *Guidelines for Community Noise* is the outcome of the WHO-expert task force meeting held in London, United Kingdom, in April 1999. It bases on the document entitled "Community Noise" that was prepared for the World Health Organization and published in 1995 by the Stockholm University and Karolinska Institute.

TABLE OF CONTENTS

Foreword

Noise has always been an important environmental problem for man. In ancient Rome, rules existed as to the noise emitted from the ironed wheels of wagons which battered the stones on the pavement, causing disruption of sleep and annoyance to the Romans. In Medieval Europe, horse carriages and horse back riding were not allowed during night time in certain cities to ensure a peaceful sleep for the inhabitants. However, the noise problems of the past are incomparable with those of modern society. An immense number of cars regularly cross our cities and the countryside. There are heavily laden lorries with diesel engines, badly silenced both for engine and exhaust noise, in cities and on highways day and night. Aircraft and trains add to the environmental noise scenario. In industry, machinery emits high noise levels and amusement centres and pleasure vehicles distract leisure time relaxation.

In comparison to other pollutants, the control of environmental noise has been hampered by insufficient knowledge of its effects on humans and of dose-response relationships as well as a lack of defined criteria. While it has been suggested that noise pollution is primarily a "luxury" problem for developed countries, one cannot ignore that the exposure is often higher in developing countries, due to bad planning and poor construction of buildings. The effects of the noise are just as widespread and the long term consequences for health are the same. In this perspective, practical action to limit and control the exposure to environmental noise are essential. Such action must be based upon proper scientific evaluation of available data on effects, and particularly dose-response relationships. The basis for this is the process of risk assessment and risk management.

The extent of the noise problem is large. In the European Union countries about 40 % of the population are exposed to road traffic noise with an equivalent sound pressure level exceeding 55 dB(A) daytime and 20 % are exposed to levels exceeding 65 dB(A). Taking all exposure to transportation noise together about half of the European Union citizens are estimated to live in zones which do not ensure acoustical comfort to residents. More than 30 % are exposed at night to equivalent sound pressure levels exceeding 55 dB(A) which are disturbing to sleep. The noise pollution problem is also severe in cities of developing countries and caused mainly by traffic. Data collected alongside densely travelled roads were found to have equivalent sound pressure levels for 24 hours of 75 to 80 dB(A).

The scope of WHO's effort to derive guidelines for community noise is to consolidate actual scientific knowledge on the health impacts of community noise and to provide guidance to environmental health authorities and professional trying to protect people from the harmful effects of noise in non-industrial environments. Guidance on the health effects of noise exposure of the population has already been given in an early publication of the series of Environmental Health Criteria. The health risk to humans from exposure to environmental noise was evaluated and guidelines values derived. The issue of noise control and health protection was briefly addressed.
At a WHO/EURO Task Force Meeting in Düsseldorf, Germany, in 1992, the health criteria and guideline values were revised and it was agreed upon updated guidelines in consensus. The essentials of the deliberations of the Task Force were published by Stockholm University and

Karolinska Institute in 1995. In an recent Expert Task Force Meeting convened in April 1999 in London, United Kingdom, the Guidelines for Community Noise were extended to provide global coverage and applicability, and the issues of noise assessment and control were addressed in more detail. This document is the outcome of the consensus deliberations of the WHO Expert Task Force.

Preface

Community noise (also called environmental noise, residential noise or domestic noise) is defined as noise emitted from all sources except noise at the industrial workplace. Main sources of community noise include road, rail and air traffic, industries, construction and public work, and the neighbourhood. The main indoor sources of noise are ventilation systems, office machines, home appliances and neighbours. Typical neighbourhood noise comes from premises and installations related to the catering trade (restaurant, cafeterias, discotheques, etc.); from live or recorded music; sport events including motor sports; playgrounds; car parks; and domestic animals such as barking dogs. Many countries have regulated community noise from road and rail traffic, construction machines and industrial plants by applying emission standards, and by regulating the acoustical properties of buildings. In contrast, few countries have regulations on community noise from the neighbourhood, probably due to the lack of methods to define and measure it, and to the difficulty of controlling it. In large cities throughout the world, the general population is increasingly exposed to community due to the sources mentioned above and the health effects of these exposures are considered to be a more and more important public health problem. Specific effects to be considered when setting community noise guidelines include: interference with communication; noise-induced hearing loss; sleep disturbance effects; cardiovascular and psycho-physiological effects; performance reduction effects; annoyance responses; and effects on social behaviour.

Since 1980, the World Health Organization (WHO) has addressed the problem of community noise. Health-based guidelines on community noise can serve as the basis for deriving noise standards within a framework of noise management. Key issues of noise management include abatement options; models for forecasting and for assessing source control action; setting noise emission standards for existing and planned sources; noise exposure assessment; and testing the compliance of noise exposure with noise immission standards. In 1992, the WHO Regional Office for Europe convened a task force meeting which set up guidelines for community noise. A preliminary publication of the Karolinska Institute, Stockholm, on behalf of WHO, appeared in 1995. This publication served as the basis for the globally applicable *Guidelines for Community Noise* presented in this document. An expert task force meeting was convened by WHO in March 1999 in London, United Kingdom, to finalize the guidelines.

The *Guidelines for Community Noise* have been prepared as a practical response to the need for action on community noise at the local level, as well as the need for improved legislation, management and guidance at the national and regional levels. WHO will be pleased to see that these guidelines are used widely. Continuing efforts will be made to improve its content and structure. It would be appreciated if the users of the *Guidelines* provide feedback from its use and their own experiences. Please send your comments and suggestions on the WHO *Guidelines for Community Noise – Guideline document* to the Department of the Protection of the Human Environment, Occupational and Environmental Health, World Health Organization, Geneva, Switzerland (Fax: +41 22-791 4123, e-mail: schwelad@who.int).

Acknowledgements

The World Health Organization thanks all who have contributed to the preparation of this document, *Guidelines for Community Noise.* The international, multidisciplinary group of contributors to, and reviewers of, the *Guidelines* are listed in the "Participant list" in Annex 6. Special thanks are due to the chairpersons and workgroups of the WHO expert task force meeting held in London, United Kingdom, in March 1999: Professor Thomas Lindvall, who acted as the chairperson of the meeting, Professor Birgitta Berglund, Dr John Bradley and Professor Gerd Jansen, who chaired the three workgroups. Special contributions from those who provided the background papers and who contributed to the success of the WHO expert meeting are gratefully acknowledged:

Professor Birgitta Berglund, Stockholm University, Stockholm, Sweden;
Bernard F. Berry, National Physical Laboratory, Teddington, Middlesex, United Kingdom; Dr. Hans Bögli, Bundesamt für Umwelt, Wald und Landschaft, Bern, Switzerland;
Dr. John S. Bradley, National Research Council Canada, Ottawa, Canada;
Dr. Ming Chen, Fujian Provincial Hospital, People's Republic of China;
Lawrence S. Finegold, Air Force Research Laboratory, AFRL/HECA, Wright-Patterson AFB, OH, USA;
Mr Dominique Francois, WHO Regional Office for Europe, Copenhague, Denmark;
Professor Guillermo L. Fuchs, Córdoba, Argentina;
Mr Etienne Grond, Messina, South Africa;
Professor Andrew Hede, University of the Sunshine Coast, Maroochydore South, Qld., Australia;

Dr. Michinori Kabuto, National Institute for Environmental Studies, Tsukuba, Ibaraki, Japan;
Professor Thomas Lindvall, National Institute of Environmental Medicine and Karolinska Institute, Stockholm, Sweden;
Dr. Amanda Niskar, CDC/NCEH, Atlanta, Georgia, USA;
Dr Sudhakar B. Ogale, Medical College and KEM Hospital, Parel, Mumbai, India;
Mrs. Willy Passchier-Vermeer, TNO Prevention and Health, Leiden, The Netherlands;
Dr. Dieter Schwela, World Health Organization, Geneva 27, Switzerland;
Dr. Michinki So, Nihon University, Tokyo, Japan;Professor Shirley Thompson, University of South Carolina, Columbia, USA;
Max Thorne, National Environmental Noise Service, Rotorua, New Zealand;
Frits van den Berg, Science Shop for Physics, University of Groningen, Groningen, The Netherlands;
Professor Peter Williams, Director MARC, King's College London, UK;
Professor Shabih Haider Zaidi, Dow Medical College, Karachi , Pakistan;

Particular thanks are due to the Ministry of Environment of Germany, which provided the funding to convene the WHO expert task force meeting in London, United Kingdom, in March 1999 to produce the Guidelines for Community Noise.

Executive Summary

1. Introduction

Community noise (also called environmental noise, residential noise or domestic noise) is defined as noise emitted from all sources except noise at the industrial workplace. Main sources of community noise include road, rail and air traffic; industries; construction and public work; and the neighbourhood. The main indoor noise sources are ventilation systems, office machines, home appliances and neighbours.

In the European Union about 40% of the population is exposed to road traffic noise with an equivalent sound pressure level exceeding 55 dB(A) daytime, and 20% are exposed to levels exceeding 65 dB(A). When all transportation noise is considered, more than half of all European Union citizens is estimated to live in zones that do not ensure acoustical comfort to residents. At night, more than 30% are exposed to equivalent sound pressure levels exceeding 55 dB(A), which are disturbing to sleep. Noise pollution is also severe in cities of developing countries. It is caused mainly by traffic and alongside densely-travelled roads equivalent sound pressure levels for 24 hours can reach 75–80 dB(A).

In contrast to many other environmental problems, noise pollution continues to grow and it is accompanied by an increasing number of complaints from people exposed to the noise. The growth in noise pollution is unsustainable because it involves direct, as well as cumulative, adverse health effects. It also adversely affects future generations, and has socio-cultural, esthetic and economic effects.

2. Noise sources and measurement

Physically, there is no distinction between sound and noise. Sound is a sensory perception and the complex pattern of sound waves is labeled noise, music, speech etc. Noise is thus defined as unwanted sound.

Most environmental noises can be approximately described by several simple measures. All measures consider the frequency content of the sounds, the overall sound pressure levels and the variation of these levels with time. Sound pressure is a basic measure of the vibrations of air that make up sound. Because the range of sound pressures that human listeners can detect is very wide, these levels are measured on a logarithmic scale with units of decibels. Consequently, sound pressure levels cannot be added or averaged arithmetically. Also, the sound levels of most noises vary with time, and when sound pressure levels are calculated, the instantaneous pressure fluctuations must be integrated over some time interval.

Most environmental sounds are made up of a complex mix of many different frequencies. Frequency refers to the number of vibrations per second of the air in which the sound is propagating and it is measured in Hertz (Hz). The audible frequency range is normally considered to be 20–20 000 Hz for younger listeners with unimpaired hearing. However, our hearing systems are not equally sensitive to all sound frequencies, and to compensate for this various types of filters or frequency weighting have been used to determine the relative strengths of frequency components making up a particular environmental noise. The A-weighting is most commonly used and weights lower frequencies as less important than mid- and higher-frequencies. It is intended to approximate the frequency response of our hearing system.

The effect of a combination of noise events is related to the combined sound energy of those events (the equal energy principle). The sum of the total energy over some time period gives a level equivalent to the average sound energy over that period. Thus, LAeq,T is the energy average equivalent level of the A-weighted sound over a period T. LAeq,T should be used to measure continuing sounds, such as road traffic noise or types of more-or-less continuous industrial noises. However, when there are distinct events to the noise, as with aircraft or railway noise, measures of individual events such as the maximum noise level (LAmax), or the weighted sound exposure level (SEL), should also be obtained in addition to LAeq,T. Time-varying environmental sound levels have also been described in terms of percentile levels.

Currently, the recommended practice is to assume that the equal energy principle is approximately valid for most types of noise and that a simple LAeq,T measure will indicate the expected effects of the noise reasonably well. When the noise consists of a small number of discrete events, the A-weighted maximum level (LAmax) is a better indicator of the disturbance to sleep and other activities. In most cases, however, the A-weighted sound exposure level (SEL) provides a more consistent measure of single-noise events because it is based on integration over the complete noise event. In combining day and night LAeq,T values, night-time weightings are often added. Night-time weightings are intended to reflect the expected increased sensitivity to annoyance at night, but they do not protect people from sleep disturbance.

Where there are no clear reasons for using other measures, it is recommended that LAeq,T be used to evaluate more-or-less continuous environmental noises. Where the noise is principally composed of a small number of discrete events, the additional use of LAmax or SEL is recommended. There are definite limitations to these simple measures, but there are also many practical advantages, including economy and the benefits of a standardized approach.

3. Adverse health effects of noise

The health significance of noise pollution is given in chapter 3 of the *Guidelines* under separate headings according to the specific effects: noise-induced hearing impairment; interference with speech communication; disturbance of rest and sleep; psychophysiological, mental-health and performance effects; effects on residential behaviour and annoyance; and interference with intended activities. This chapter also considers vulnerable groups and the combined effects of mixed noise sources.

Hearing impairment is typically defined as an increase in the threshold of hearing. Hearing deficits may be accompanied by tinnitus (ringing in the ears). Noise-induced hearing impairment occurs predominantly in the higher frequency range of 3 000–6 000 Hz, with the largest effect at 4 000 Hz. But with increasing LAeq,8h and increasing exposure time, noise-induced hearing impairment occurs even at frequencies as low as 2 000 Hz. However, hearing impairment is not expected to occur at LAeq,8h levels of 75 dB(A) or below, even for prolonged occupational noise exposure.

Worldwide, noise-induced hearing impairment is the most prevalent irreversible occupational hazard and it is estimated that 120 million people worldwide have disabling hearing difficulties.

In developing countries, not only occupational noise but also environmental noise is an increasing risk factor for hearing impairment. Hearing damage can also be caused by certain diseases, some industrial chemicals, ototoxic drugs, blows to the head, accidents and hereditary origins. Hearing deterioration is also associated with the ageing process itself (presbyacusis).

The extent of hearing impairment in populations exposed to occupational noise depends on the value of LAeq,8h, the number of noise-exposed years, and on individual susceptibility. Men and women are equally at risk for noise-induced hearing impairment. It is expected that environmental and leisure-time noise with a LAeq,24h of 70 dB(A) or below will not cause hearing impairment in the large majority of people, even after a lifetime exposure. For adults exposed to impulse noise at the workplace, the noise limit is set at peak sound pressure levels of 140 dB, and the same limit is assumed to be appropriate for environmental and leisure-time noise. In the case of children, however, taking into account their habits while playing with noisy toys, the peak sound pressure should never exceed 120 dB. For shooting noise with LAeq,24h levels greater than 80 dB(A), there may be an increased risk for noise-induced hearing impairment.

The main social consequence of hearing impairment is the inability to understand speech in daily living conditions, and this is considered to be a severe social handicap. Even small values of hearing impairment (10 dB averaged over 2 000 and 4 000 Hz and over both ears) may adversely affect speech comprehension.

Speech intelligibility is adversely affected by noise. Most of the acoustical energy of speech is in the frequency range of 100–6 000 Hz, with the most important cue-bearing energy being between 300–3 000 Hz. Speech interference is basically a masking process, in which simultaneous interfering noise renders speech incapable of being understood. Environmental noise may also mask other acoustical signals that are important for daily life, such as door bells, telephone signals, alarm clocks, fire alarms and other warning signals, and music.

Speech intelligibility in everyday living conditions is influenced by speech level; speech pronunciation; talker-to-listener distance; sound level and other characteristics of the interfering noise; hearing acuity; and by the level of attention. Indoors, speech communication is also affected by the reverberation characteristics of the room. Reverberation times over 1 s produce loss in speech discrimination and make speech perception more difficult and straining. For full sentence intelligibility in listeners with normal hearing, the signal-to-noise ratio (i.e. the difference between the speech level and the sound level of the interfering noise) should be at least 15 dB(A). Since the sound pressure level of normal speech is about 50 dB(A), noise with sound levels of 35 dB(A) or more interferes with the intelligibility of speech in smaller rooms. For vulnerable groups even lower background levels are needed, and a reverberation time below 0.6 s is desirable for adequate speech intelligibility, even in a quiet environment.

The inability to understand speech results in a large number of personal handicaps and behavioural changes. Particularly vulnerable are the hearing impaired, the elderly, children in the process of language and reading acquisition, and individuals who are not familiar with the spoken language.

Sleep disturbance is a major effect of environmental noise. It may cause primary effects during sleep, and secondary effects that can be assessed the day after night-time noise exposure. Uninterrupted sleep is a prerequisite for good physiological and mental functioning, and the primary effects of sleep disturbance are: difficulty in falling asleep; awakenings and alterations of sleep stages or depth; increased blood pressure, heart rate and finger pulse amplitude; vasoconstriction; changes in respiration; cardiac arrhythmia; and increased body movements. The difference between the sound levels of a noise event and background sound levels, rather than the absolute noise level, may determine the reaction probability. The probability of being awakened increases with the number of noise events per night. The secondary, or after-effects, the following morning or day(s) are: reduced perceived sleep quality; increased fatigue; depressed mood or well-being; and decreased performance.

For a good night's sleep, the equivalent sound level should not exceed 30 dB(A) for continuous background noise, and individual noise events exceeding 45 dB(A) should be avoided. In setting limits for single night-time noise exposures, the intermittent character of the noise has to be taken into account. This can be achieved, for example, by measuring the number of noise events, as well as the difference between the maximum sound level and the background sound level. Special attention should also be given to: noise sources in an environment with low background sound levels; combinations of noise and vibrations; and to noise sources with low-frequency components.

Physiological Functions. In workers exposed to noise, and in people living near airports, industries and noisy streets, noise exposure may have a large temporary, as well as permanent, impact on physiological functions. After prolonged exposure, susceptible individuals in the general population may develop permanent effects, such as hypertension and ischaemic heart disease associated with exposure to high sound levels. The magnitude and duration of the effects are determined in part by individual characteristics, lifestyle behaviours and environmental conditions. Sounds also evoke reflex responses, particularly when they are unfamiliar and have a sudden onset.

Workers exposed to high levels of industrial noise for 5–30 years may show increased blood pressure and an increased risk for hypertension. Cardiovascular effects have also been demonstrated after long-term exposure to air- and road-traffic with LAeq,24h values of 65–70 dB(A). Although the associations are weak, the effect is somewhat stronger for ischaemic heart disease than for hypertension. Still, these small risk increments are important because a large number of people are exposed.

Mental Illness. Environmental noise is not believed to cause mental illness directly, but it is assumed that it can accelerate and intensify the development of latent mental disorders. Exposure to high levels of occupational noise has been associated with development of neurosis, but the findings on environmental noise and mental-health effects are inconclusive. Nevertheless, studies on the use of drugs such as tranquillizers and sleeping pills, on psychiatric symptoms and on mental hospital admission rates, suggest that community noise may have adverse effects on mental health.

Performance. It has been shown, mainly in workers and children, that noise can adversely affect performance of cognitive tasks. Although noise-induced arousal may produce better performance in simple tasks in the short term, cognitive performance substantially deteriorates for more complex tasks. Reading, attention, problem solving and memorization are among the cognitive effects most strongly affected by noise. Noise can also act as a distracting stimulus and impulsive noise events may produce disruptive effects as a result of startle responses.

Noise exposure may also produce after-effects that negatively affect performance. In schools around airports, children chronically exposed to aircraft noise under-perform in proof reading, in persistence on challenging puzzles, in tests of reading acquisition and in motivational capabilities. It is crucial to recognize that some of the adaptation strategies to aircraft noise, and the effort necessary to maintain task performance, come at a price. Children from noisier areas have heightened sympathetic arousal, as indicated by increased stress hormone levels, and elevated resting blood pressure. Noise may also produce impairments and increase in errors at work, and some accidents may be an indicator of performance deficits.

Social and Behavioural Effects of Noise; Annoyance. Noise can produce a number of social and behavioural effects as well as annoyance. These effects are often complex, subtle and indirect and many effects are assumed to result from the interaction of a number of non-auditory variables. The effect of community noise on annoyance can be evaluated by questionnaires or by assessing the disturbance of specific activities. However, it should be recognized that equal levels of different traffic and industrial noises cause different magnitudes of annoyance. This is because annoyance in populations varies not only with the characteristics of the noise, including the noise source, but also depends to a large degree on many non-acoustical factors of a social, psychological, or economic nature. The correlation between noise exposure and general annoyance is much higher at group level than at individual level. Noise above 80 dB(A) may also reduce helping behaviour and increase aggressive behaviour. There is particular concern that high-level continuous noise exposures may increase the susceptibility of schoolchildren to feelings of helplessness.

Stronger reactions have been observed when noise is accompanied by vibrations and contains low-frequency components, or when the noise contains impulses, such as with shooting noise. Temporary, stronger reactions occur when the noise exposure increases over time, compared to a constant noise exposure. In most cases, LAeq,24h and L_{dn} are acceptable approximations of noise exposure related to annoyance. However, there is growing concern that all the component parameters should be individually assessed in noise exposure investigations, at least in the complex cases. There is no consensus on a model for total annoyance due to a combination of environmental noise sources.

Combined Effects on Health of Noise from Mixed Sources. Many acoustical environments consist of sounds from more than one source, i.e. there are mixed sources, and some combinations of effects are common. For example, noise may interfere with speech in the day and create sleep disturbance at night. These conditions certainly apply to residential areas heavily polluted with noise. Therefore, it is important that the total adverse health load of noise be considered over 24 hours, and that the precautionary principle for sustainable development be applied.

Vulnerable Subgroups. Vulnerable subgroups of the general population should be considered when recommending noise protection or noise regulations. The types of noise effects, specific environments and specific lifestyles are all factors that should be addressed for these subgroups. Examples of vulnerable subgroups are: people with particular diseases or medical problems (e.g. high blood pressure); people in hospitals or rehabilitating at home; people dealing with complex cognitive tasks; the blind; people with hearing impairment; fetuses, babies and young children; and the elderly in general. People with impaired hearing are the most adversely affected with respect to speech intelligibility. Even slight hearing impairments in the high-frequency sound range may cause problems with speech perception in a noisy environment. A majority of the population belongs to the subgroup that is vulnerable to speech interference.

4. Guideline values

In chapter 4, guideline values are given for specific health effects of noise and for specific environments.

Specific health effects.

Interference with Speech Perception. A majority of the population is susceptible to speech interference by noise and belongs to a vulnerable subgroup. Most sensitive are the elderly and persons with impaired hearing. Even slight hearing impairments in the high-frequency range may cause problems with speech perception in a noisy environment. From about 40 years of age, the ability of people to interpret difficult, spoken messages with low linguistic redundancy is impaired compared to people 20–30 years old. It has also been shown that high noise levels and long reverberation times have more adverse effects in children, who have not completed language acquisition, than in young adults.

When listening to complicated messages (at school, foreign languages, telephone conversation) the signal-to-noise ratio should be at least 15 dB with a voice level of 50 dB(A). This sound level corresponds on average to a casual voice level in both women and men at 1 m distance. Consequently, for clear speech perception the background noise level should not exceed 35 dB(A). In classrooms or conference rooms, where speech perception is of paramount importance, or for sensitive groups, background noise levels should be as low as possible. Reverberation times below 1 s are also necessary for good speech intelligibility in smaller rooms. For sensitive groups, such as the elderly, a reverberation time below 0.6 s is desirable for adequate speech intelligibility even in a quiet environment.

Hearing Impairment. Noise that gives rise to hearing impairment is by no means restricted to occupational situations. High noise levels can also occur in open air concerts, discotheques, motor sports, shooting ranges, in dwellings from loudspeakers, or from leisure activities. Other important sources of loud noise are headphones, as well as toys and fireworks which can emit impulse noise. The ISO standard 1999 gives a method for estimating noise-induced hearing impairment in populations exposed to all types of noise (continuous, intermittent, impulse) during working hours. However, the evidence strongly suggests that this method should also be used to calculate hearing impairment due to noise exposure from environmental and leisure time activities. The ISO standard 1999 implies that long-term exposure to LAeq,24h noise levels of up to 70 dB(A) will not result in hearing impairment. To avoid hearing loss from impulse noise exposure, peak sound pressures should never exceed 140 dB for adults, and 120 dB for children.

Sleep Disturbance. Measurable effects of noise on sleep begin at LAeq levels of about 30 dB. However, the more intense the background noise, the more disturbing is its effect on sleep. Sensitive groups mainly include the elderly, shift workers, people with physical or mental disorders and other individuals who have difficulty sleeping.

Sleep disturbance from intermittent noise events increases with the maximum noise level. Even if the total equivalent noise level is fairly low, a small number of noise events with a high maximum sound pressure level will affect sleep. Therefore, to avoid sleep disturbance, guidelines for community noise should be expressed in terms of the equivalent sound level of the noise, as well as in terms of maximum noise levels and the number of noise events. It should be noted that low-frequency noise, for example, from ventilation systems, can disturb rest and sleep even at low sound pressure levels.

When noise is continuous, the equivalent sound pressure level should not exceed 30 dB(A) indoors, if negative effects on sleep are to be avoided. For noise with a large proportion of low-frequency sound a still lower guideline value is recommended. When the background noise is low, noise exceeding 45 dB LAmax should be limited, if possible, and for sensitive persons an even lower limit is preferred. Noise mitigation targeted to the first part of the night is believed to be an effective means for helping people fall asleep. It should be noted that the adverse effect of noise partly depends on the nature of the source. A special situation is for newborns in incubators, for which the noise can cause sleep disturbance and other health effects.

Reading Acquisition. Chronic exposure to noise during early childhood appears to impair reading acquisition and reduces motivational capabilities. Evidence indicates that the longer the exposure, the greater the damage. Of recent concern are the concomitant psychophysiological changes (blood pressure and stress hormone levels). There is insufficient information on these effects to set specific guideline values. It is clear, however, that daycare centres and schools should not be located near major noise sources, such as highways, airports, and industrial sites.

Annoyance. The capacity of a noise to induce annoyance depends upon its physical characteristics, including the sound pressure level, spectral characteristics and variations of these properties with time. During daytime, few people are highly annoyed at LAeq levels below 55 dB(A), and few are moderately annoyed at LAeq levels below 50 dB(A). Sound levels during the evening and night should be 5–10 dB lower than during the day. Noise with low-frequency components require lower guideline values. For intermittent noise, it is emphasized that it is necessary to take into account both the maximum sound pressure level and the number of noise events. Guidelines or noise abatement measures should also take into account residential outdoor activities.

Social Behaviour. The effects of environmental noise may be evaluated by assessing its interference with social behavior and other activities. For many community noises, interference with rest/recreation/watching television seem to be the most important effects. There is fairly consistent evidence that noise above 80 dB(A) causes reduced helping behavior, and that loud noise also increases aggressive behavior in individuals predisposed to aggressiveness. In schoolchildren, there is also concern that high levels of chronic noise contribute to feelings of helplessness. Guidelines on this issue, together with cardiovascular and mental effects, must await further research.

Specific environments.

A noise measure based only on energy summation and expressed as the conventional equivalent measure, LAeq, is not enough to characterize most noise environments. It is equally important to measure the maximum values of noise fluctuations, preferably combined with a measure of the number of noise events. If the noise includes a large proportion of low-frequency components, still lower values than the guideline values below will be needed. When prominent low-frequency components are present, noise measures based on A-weighting are inappropriate. The difference between dB(C) and dB(A) will give crude information about the presence of low-frequency components in noise, but if the difference is more than 10 dB, it is recommended that a frequency analysis of the noise be performed. It should be noted that a large proportion of low-frequency components in noise may increase considerably the adverse effects on health.

In Dwellings. The effects of noise in dwellings, typically, are sleep disturbance, annoyance and speech interference. For bedrooms the critical effect is sleep disturbance. Indoor guideline values for bedrooms are 30 dB LAeq for continuous noise and 45 dB LAmax for single sound events. Lower noise levels may be disturbing depending on the nature of the noise source. At night-time, outside sound levels about 1 metre from facades of living spaces should not exceed 45 dB LAeq, so that people may sleep with bedroom windows open. This value was obtained by assuming that the noise reduction from outside to inside with the window open is 15 dB. To enable casual conversation indoors during daytime, the sound level of interfering noise should not exceed 35 dB LAeq. The maximum sound pressure level should be measured with the sound pressure meter set at "Fast".

To protect the majority of people from being seriously annoyed during the daytime, the outdoor sound level from steady, continuous noise should not exceed 55 dB LAeq on balconies, terraces and in outdoor living areas. To protect the majority of people from being moderately annoyed during the daytime, the outdoor sound level should not exceed 50 dB LAeq. Where it is practical and feasible, the lower outdoor sound level should be considered the maximum desirable sound level for new development.

In Schools and Preschools. For schools, the critical effects of noise are speech interference, disturbance of information extraction (e.g. comprehension and reading acquisition), message communication and annoyance. To be able to hear and understand spoken messages in class rooms, the background sound level should not exceed 35 dB LAeq during teaching sessions. For hearing impaired children, a still lower sound level may be needed. The reverberation time in the classroom should be about 0.6 s, and preferably lower for hearing impaired children. For assembly halls and cafeterias in school buildings, the reverberation time should be less than 1 s. For outdoor playgrounds the sound level of the noise from external sources should not exceed 55 dB LAeq, the same value given for outdoor residential areas in daytime.

For preschools, the same critical effects and guideline values apply as for schools. In bedrooms in preschools during sleeping hours, the guideline values for bedrooms in dwellings should be used.

In Hospitals. For most spaces in hospitals, the critical effects are sleep disturbance, annoyance, and communication interference, including warning signals. The LAmax of sound events during the night should not exceed 40 dB(A) indoors. For ward rooms in hospitals, the guideline values indoors are 30dB LAeq, together with 40 dB LAmax during night. During the day and evening the guideline value indoors is 30 dB LAeq. The maximum level should be measured with the sound pressure instrument set at "Fast".

Since patients have less ability to cope with stress, the LAeq level should not exceed 35 dB in most rooms in which patients are being treated or observed. Attention should be given to the sound levels in intensive care units and operating theaters. Sound inside incubators may result in health problems for neonates, including sleep disturbance, and may also lead to hearing impairment. Guideline values for sound levels in incubators must await future research.

Ceremonies, Festivals and Entertainment Events. In many countries, there are regular ceremonies, festivals and entertainment events to celebrate life periods. Such events typically produce loud sounds, including music and impulsive sounds. There is widespread concern about the effect of loud music and impulsive sounds on young people who frequently attend concerts, discotheques, video arcades, cinemas, amusement parks and spectator events. At these events, the sound level typically exceeds 100 dB LAeq. Such noise exposure could lead to significant hearing impairment after frequent attendances.

Noise exposure for employees of these venues should be controlled by established occupational standards; and at the very least, the same standards should apply to the patrons of these premises. Patrons should not be exposed to sound levels greater than 100 dB LAeq during a four-hour period more than four times per year. To avoid acute hearing impairment the LAmax should always be below 110 dB.

Headphones. To avoid hearing impairment from music played back in headphones, in both adults and children, the equivalent sound level over 24 hours should not exceed 70 dB(A). This implies that for a daily one hour exposure the LAeq level should not exceed 85 dB(A). To avoid acute hearing impairment LAmax should always be below 110 dB(A). The exposures are expressed in free-field equivalent sound level.

Toys, Fireworks and Firearms. To avoid acute mechanical damage to the inner ear from impulsive sounds from toys, fireworks and firearms, adults should never be exposed to more than 140 dB(lin) peak sound pressure level. To account for the vulnerability in children when playing, the peak sound pressure produced by toys should not exceed 120 dB(lin), measured close to the ears (100 mm). To avoid acute hearing impairment LAmax should always be below 110 dB(A).

Parkland and Conservation Areas. Existing large quiet outdoor areas should be preserved and the signal-to-noise ratio kept low.

Table 1 presents the WHO guideline values arranged according to specific environments and critical health effects. The guideline values consider all identified adverse health effects for the specific environment. An adverse effect of noise refers to any temporary or long-term impairment of physical, psychological or social functioning that is associated with noise exposure. Specific noise limits have been set for each health effect, using the lowest noise level that produces an adverse health effect (i.e. the critical health effect). Although the guideline values refer to sound levels impacting the most exposed receiver at the listed environments, they are applicable to the general population. The time base for LAeq for "daytime" and "night-time" is 12–16 hours and 8 hours, respectively. No time base is given for evenings, but typically the guideline value should be 5–10 dB lower than in the daytime. Other time bases are recommended for schools, preschools and playgrounds, depending on activity.

It is not enough to characterize the noise environment in terms of noise measures or indices based only on energy summation (e.g., LAeq), because different critical health effects require different descriptions. It is equally important to display the maximum values of the noise fluctuations, preferably combined with a measure of the number of noise events. A separate characterization of night-time noise exposures is also necessary. For indoor environments, reverberation time is also an important factor for things such as speech intelligibility. If the noise includes a large proportion of low-frequency components, still lower guideline values should be applied. Supplementary to the guideline values given in Table 1, precautions should be taken for vulnerable groups and for noise of certain character (e.g. low-frequency components, low background noise).

Table 1: Guideline values for community noise in specific environments.

Specific environment	Critical health effect(s)	L_{Aeq} [dB(A)]	Time base [hours]	L_{Amax} fast [dB]
Outdoor living area	Serious annoyance, daytime and evening Moderate annoyance, daytime and evening	55 50	16 16	- -
Dwelling, indoors Inside bedrooms	Speech intelligibility & moderate annoyance, daytime & evening Sleep disturbance, night-time	35 30	16 8	 45
Outside bedrooms	Sleep disturbance, window open (outdoor values)	45	8	60
School class rooms & pre-schools, indoors	Speech intelligibility, disturbance of information extraction, message communication	35	during class	-
Pre-school bedrooms, indoor	Sleep disturbance	30	sleeping-time	45
School, playground outdoor	Annoyance (external source)	55	during play	-
Hospital, ward rooms, indoors	Sleep disturbance, night-time Sleep disturbance, daytime and evenings	30 30	8 16	40 -
Hospitals, treatment rooms, indoors	Interference with rest and recovery	#1		
Industrial, commercial shopping and traffic areas, indoors and outdoors	Hearing impairment	70	24	110
Ceremonies, festivals and entertainment events	Hearing impairment (patrons:<5 times/year)	100	4	110
Public addresses, indoors and outdoors	Hearing impairment	85	1	110
Music and other sounds through headphones/ earphones	Hearing impairment (free-field value)	85 #4	1	110
Impulse sounds from toys, fireworks and firearms	Hearing impairment (adults) Hearing impairment (children)	- -	- -	140 #2 120 #2
Outdoors in parkland and conservations areas	Disruption of tranquillity	#3		

#1: As low as possible.
#2: Peak sound pressure (not LAF, max) measured 100 mm from the ear.

#3: Existing quiet outdoor areas should be preserved and the ratio of intruding noise to natural background sound should be kept low.
#4: Under headphones, adapted to free-field values.

5. Noise Management

Chapter 5 is devoted to noise management with discussions on: strategies and priorities in managing indoor noise levels; noise policies and legislation; the impact of environmental noise; and on the enforcement of regulatory standards.

The fundamental goals of noise management are to develop criteria for deriving safe noise exposure levels and to promote noise assessment and control as part of environmental health programmes. These basic goals should guide both international and national policies for noise management. The United Nation's Agenda 21 supports a number of environmental management principles on which government policies, including noise management policies, can be based: the principle of precaution; the "polluter pays" principle; and noise prevention. In all cases, noise should be reduced to the lowest level achievable in the particular situation. When there is a reasonable possibility that the public health will be endangered, even though scientific proof may be lacking, action should be taken to protect the public health, without awaiting the full scientific proof. The full costs associated with noise pollution (including monitoring, management, lowering levels and supervision) should be met by those responsible for the source of noise. Action should be taken where possible to reduce noise at the source.

A legal framework is needed to provide a context for noise management. National noise standards can usually be based on a consideration of international guidelines, such as these *Guidelines for Community Noise*, as well as national criteria documents, which consider dose-response relationships for the effects of noise on human health. National standards take into account the technological, social, economic and political factors within the country. A staged program of noise abatement should also be implemented to achieve the optimum health protection levels over the long term.

Other components of a noise management plan include: noise level monitoring; noise exposure mapping; exposure modeling; noise control approaches (such as mitigation and precautionary measures); and evaluation of control options. Many of the problems associated with high noise levels can be prevented at low cost, if governments develop and implement an integrated strategy for the indoor environment, in concert with all social and economic partners. Governments should establish a "National Plan for a Sustainable Noise Indoor Environment" that applies both to new construction as well as to existing buildings.

The actual priorities in rational noise management will differ for each country. Priority setting in noise management refers to prioritizing the health risks to be avoided and concentrating on the most important sources of noise. Different countries have adopted a range of approaches to noise control, using different policies and regulations. A number of these are outlined in chapter 5 and Appendix 2, as examples. It is evident that noise emission standards have proven insufficient and that the trends in noise pollution are unsustainable.

The concept of environmental an environmental noise impact analysis is central to the philosophy of managing environmental noise. Such an analysis should be required before implementing any project that would significantly increase the level of environmental noise in a community (typically, greater than a 5 dB increase). The analysis should include: a baseline description of the existing noise environment; the expected level of noise from the new source; an assessment of the adverse health effects; an estimation of the population at risk; the calculation of exposure-response relationships; an assessment of risks and their acceptability; and a cost-benefit analysis.

Noise management should:

1. Start monitoring human exposures to noise.
2. Have health control require mitigation of noise immissions, and not just of noise source emissions. The following should be taken into consideration:
    - specific environments such as schools, playgrounds, homes, hospitals.
    - environments with multiple noise sources, or which may amplify the effects of noise.
    - sensitive time periods such as evenings, nights and holidays.
    - groups at high risk, such as children and the hearing impaired.
3. Consider the noise consequences when planning transport systems and land use.
4. Introduce surveillance systems for noise-related adverse health effects.
5. Assess the effectiveness of noise policies in reducing adverse health effects and exposure, and in improving supportive "soundscapes".
6. Adopt these *Guidelines for Community Noise* as intermediary targets for improving human health.
7. Adopt precautionary actions for a sustainable development of the acoustical environments.

Conclusions and recommendations

In chapter 6 are discussed: the implementation of the guidelines; further WHO work on noise; and research needs are recommended.

Implementation. For implementation of the guidelines it is recommended that:

- Governments should protection the population from community noise and consider it an integral part of their policy of environmental protection.
- Governments should consider implementing action plans with short-term, medium-term and long-term objectives for reducing noise levels.
- Governments should adopt the *Health Guidelines for Community Noise* values as targets to be achieved in the long-term.
- Governments should include noise as an important public health issue in environmental impact assessments.
- Legislation should be put in place to allow for the reduction of sound levels.
- Existing legislation should be enforced.
- Municipalities should develop low noise implementation plans.

- Cost-effectiveness and cost-benefit analyses should be considered potential instruments for meaningful management decisions.
- Governments should support more policy-relevant research.

Future Work. The Expert Task Force worked out several suggestions for future work for the WHO in the field of community noise. WHO should:

- Provide leadership and technical direction in defining future noise research priorities.
- Organize workshops on how to apply the guidelines.
- Provide leadership and coordinate international efforts to develop techniques for designing supportive sound environments (e.g. "soundscapes").
- Provide leadership for programs to assess the effectiveness of health-related noise policies and regulations.
- Provide leadership and technical direction for the development of sound methodologies for environmental and health impact plans.
- Encourage further investigation into using noise exposure as an indicator of environmental deterioration (e.g. black spots in cities).
- Provide leadership and technical support, and advise developing countries to facilitate development of noise policies and noise management.

Research and Development. A major step forward in raising the awareness of both the public and of decision makers is the recommendation to concentrate more research and development on variables which have monetary consequences. This means that research should consider not only dose-response relationships between sound levels, but also politically relevant variables, such as noise-induced social handicap; reduced productivity; decreased performance in learning; workplace and school absenteeism; increased drug use; and accidents.

In Appendices 1–6 are given: bibliographic references; examples of regional noise situations (African Region, American Region, Eastern Mediterranean Region, South East Asian Region, Western Pacific Region); a glossary; a list of acronyms; and a list of participants.

1. Introduction

Community noise (also called environmental noise, residential noise or domestic noise) is defined as noise emitted from all sources, except noise at the industrial workplace. Main sources of community noise include road, rail and air traffic, industries, construction and public work, and the neighbourhood. Typical neighbourhood noise comes from premises and installations related to the catering trade (restaurant, cafeterias, discotheques, etc.); from live or recorded music; from sporting events including motor sports; from playgrounds and car parks; and from domestic animals such as barking dogs. The main indoor sources are ventilation systems, office machines, home appliances and neighbours. Although many countries have regulations on community noise from road, rail and air traffic, and from construction and industrial plants, few have regulations on neighbourhood noise. This is probably due to the lack of mcthods to define and measure it, and to the difficulty of controlling it. In developed countries, too, monitoring of compliance with, and enforcement of, noise regulations are weak for lower levels of urban noise that correspond to occupationally controlled levels (>85 dB LAeq,8h; Frank 1998). Recommended guideline values based on the health effects of noise, other than occupationally-induced effects, are often not taken into account.

The extent of the community noise problem is large. In the European Union about 40% of the population is exposed to road traffic noise with an equivalent sound pressure level exceeding 55 dBA daytime; and 20% is exposed to levels exceeding 65 dBA (Lambert & Vallet 19 1994). When all transportation noise is considered, about half of all European Union citizens live in zones that do not ensure acoustical comfort to residents. At night, it is estimated that more than 30% is exposed to equivalent sound pressure levels exceeding 55 dBA, which are disturbing to sleep. The noise pollution problem is also severe in the cities of developing countries and is caused mainly by traffic. Data collected alongside densely traveled roads were found to have equivalent sound pressure levels for 24 hours of 75–80 dBA (e.g. National Environment Board Thailand 19 1990; Mage & Walsh 19 1998).

(a) In contrast to many other environmental problems, noise pollution continues to grow, accompanied by an increasing number of complaints from affected individuals. Most people are typically exposed to several noise sources, with road traffic noise being a dominant source (OECD-ECMT 19 1995). Population growth, urbanization and to a large extent technological development are the main driving forces, and future enlargements of highway systems, international airports and railway systems will only increase the noise problem. Viewed globally, the growth in urban environmental noise pollution is unsustainable, because it involves not simply the direct and cumulative adverse effects on health. It also adversely affects future generations by degrading residential, social and learning environments, with corresponding economical losses (Berglund 1998). Thus, noise is not simply a local problem, but a global issue that affects everyone (Lang 1999; Sandberg 1999) and calls for precautionary action in any environmental planning situation.

The objective of the World Health Organization (WHO) is the attainment by all peoples of the highest possible level of health. As the first principle of the WHO Constitution the definition of 'health' is given as: "A state of complete physical, mental and social well-being and not merely the absence of disease or infirmity". This broad definition of health embraces the concept of well-being and, thereby, renders noise impacts such as population annoyance, interference with communication, and impaired task performance as 'health' issues. In 1992, a WHO Task Force also identified the following specific health effects for the general population that may result from community noise: interference with communication; annoyance responses; effects on sleep, and on the cardiovascular and psychophysiological systems; effects on performance, productivity, and social behavior; and noise-induced hearing impairment (WHO 1993; Berglund & Lindvall 1995; *cf.* WHO 1980). Hearing damage is expected to result from both occupational and environmental noise, especially in developing countries, where compliance with noise regulation is known to be weak (Smith 1998).

Noise is likely to continue as a major issue well into the next century, both in developed and in developing countries. Therefore, strategic action is urgently required, including continued noise control at the source and in local areas. Most importantly, joint efforts among countries are necessary at a system level, in regard to the access and use of land, airspace and seawaters, and in regard to the various modes of transportation. Certainly, mankind would benefit from societal reorganization towards healthy transport. To understand noise we must understand the different types of noise and how we measure it, where noise comes from and the effects of noise on human beings. Furthermore, noise mitigation, including noise management, has to be actively introduced and in each case the policy implications have to be evaluated for efficiency.

This document is organized as follows. In Chapter 2 noise sources and measurement are discussed, including the basic aspects of source characteristics, sound propagation and transmission. In Chapter 3 the adverse health effects of noise are characterized. These include noise-induced hearing impairment, interference with speech communication, sleep disturbance, cardiovascular and physiological effects, mental health effects, performance effects, and annoyance reactions. This chapter is rounded out by a consideration of combined noise sources and their effects, and a discussion of vulnerable groups. In Chapter 4 the Guideline values are presented. Chapter 5 is devoted to noise management. Included are discussions of: strategies and priorities in the management of indoor noise levels; noise policies and legislation; environmental noise impact; and enforcement of regulatory standards. In Chapter 6 implementation of the WHO Guidelines is discussed, as well as future WHO work on noise and its research needs. In Appendices 1–6 are given: bibliographic references; examples of regional noise situations (African Region, American Region, Eastern Mediterranean Region, South East Asian Region, Western Pacific Region); a glossary; a list of acronyms; and a list of participants.

2. Noise sources and their measurement

2.1. Basic Aspects of Acoustical Measurements

Most environmental noises can be approximately described by one of several simple measures. They are all derived from overall sound pressure levels, the variation of these levels with time and the frequency of the sounds. Ford (1987) gives a more extensive review of various environmental noise measures. Technical definitions are found in the glossary in Appendix 3.

2.1.1. Sound pressure level

The sound pressure level is a measure of the air vibrations that make up sound. All measured sound pressures are referenced to a standard pressure that corresponds roughly to the threshold of hearing at 1 000 Hz. Thus, the sound pressure level indicates how much greater the measured sound is than this threshold of hearing. Because the human ear can detect a wide range of sound pressure levels (10–102 Pascal (Pa)), they are measured on a logarithmic scale with units of decibels (dB). A more technical definition of sound pressure level is found in the glossary.

The sound pressure levels of most noises vary with time. Consequently, in calculating some measures of noise, the instantaneous pressure fluctuations must be integrated over some time interval. To approximate the integration time of our hearing system, sound pressure meters have a standard *Fast* response time, which corresponds to a time constant of 0.125 s. Thus, all measurements of sound pressure levels and their variation over time should be made using the *Fast* response time, to provide sound pressure measurements more representative of human hearing. Sound pressure meters may also include a *Slow* response time with a time constant of 1 s, but its sole purpose is that one can more easily estimate the average value of rapidly fluctuating levels. Many modern meters can integrate sound pressures over specified periods and provide average values. It is not recommended that the *Slow* response time be used when integrating sound pressure meters are available.

Because sound pressure levels are measured on a logarithmic scale they cannot be added or averaged arithmetically. For example, adding two sounds of equal pressure levels results in a total pressure level that is only 3 dB greater than each individual sound pressure level. Consequently, when two sounds are combined the resulting sound pressure level will be significantly greater than the individual sound levels only if the two sounds have similar pressure levels. Details for combining sound pressure levels are given in Appendix 2.

2.1.2. Frequency and frequency weighting

The unit of frequency is the Hertz (Hz), and it refers to the number of vibrations per second of the air in which the sound is propagating. For tonal sounds, frequency is associated with the perception of pitch. For example, orchestras often tune to the frequency of 440 Hz. Most environmental sounds, however, are made up of a complex mix of many different frequencies. They may or may not have discrete frequency components superimposed on noise with a broad frequency spectrum (i.e. sound with a broad range of frequencies). The audible frequency range is normally considered to range from 20–20 000 Hz. Below 20 Hz we hear individual sound pulses rather than recognizable tones. Hearing sensitivity to higher frequencies decreases with age and exposure to noise. Thus, 20 000 Hz represents an upper limit of audibility for younger listeners with unimpaired hearing.

Our hearing systems are not equally sensitive to all sound frequencies (ISO 1987a). Thus, not all frequencies are perceived as being equally loud at the same sound pressure level, and when calculating overall environmental noise ratings it is necessary to consider sounds at some frequencies as more important than those at other frequencies. Detailed frequency analyses are commonly performed with standard sets of octave or 1/3 octave bandwidth filters. Alternatively, Fast Fourier Transform techniques or other types of filters can be used to determine the relative strengths of the various frequency components making up a particular environmental noise.

Frequency weighting networks provide a simpler approach for weighting the importance of different frequency components in one single number rating. The A-weighting is most commonly used and is intended to approximate the frequency response of our hearing system. It weights lower frequencies as less important than mid- and higher-frequency sounds. C-weighting is also quite common and is a nearly flat frequency response with the extreme high and low frequencies attenuated. When no frequency analysis is possible, the difference between A-weighted and C-weighted levels gives an indication of the amount of low frequency content in the measured noise. When the sound has an obvious tonal content, a correction to account for the additional annoyance may be used (ISO 1987b).

2.1.3. Equivalent continuous sound pressure level

According to the equal energy principle, the effect of a combination of noise events is related to the combined sound energy of those events. Thus, measures such as the equivalent continuous sound pressure level (LAeq,T) sum up the total energy over some time period (T) and give a level equivalent to the average sound energy over that period. Such average levels are usually based on integration of A-weighted levels. Thus LAeq,T is the average energy equivalent level of the A-weighted sound over a period T.

2.1.4. Individual noise events

It is often desired to measure the maximum level (LAmax) of individual noise events. For cases such as the noise from a single passing vehicle, LAmax values should be measured using the *Fast* response time because it will give a good correlation with the integration of loudness by our hearing system. However, for very short-duration impulsive sounds it is often desirable to measure the instantaneous peak amplitude to assess potential hearing-damage risk. If actual instantaneous pressure cannot be determined, then a time-integrated 'peak' level with a time constant of no more than 0.05 ms should be used (ISO 1987b). Such peak readings are often made using the C- (or linear) frequency weightings.

Alternatively, discrete sound events can be evaluated in terms of their A-weighted sound exposure level (SEL, for defintion see appendix 5). The total amount of sound energy in a particular event is assessed by the SEL. One can add up the SEL values of individual events to calculate a LAeq,T over some time period, T, of interest. In some cases the SEL may provide more consistent evaluations of individual noise events because they are derived from the complete history of the event and not just one maximum value. However, A-weighted SEL measurements have been shown to be inadequate for assessing the (perceived) loudness of complex impulsive sounds, such as those from large and small weapons (Berglund et al. 1986). In contrast, C-weighted SEL values have been found useful for rating impulsive sounds such as gun shots (Vos 1996; Buchta 1996; ISO 1987b).

2.1.5. Choice of noise measure

LAeq,T should be used to measure continuing sounds such as road traffic noise, many types of industrial noises and noise from ventilation systems in buildings. When there are distinct events to the noise such as with aircraft or railway noise, measures of the individual events should be obtained (using, for example, LAmax or SEL), in addition to LAeq,T measurements.

In the past, time-varying environmental sound levels have also been described in terms of percentile levels. These are derived from a statistical distribution of measured sound levels over some period. For example, L10 is the A-weighted level exceeded 10% of the time. L10 values have been widely used to measure road-traffic noise, but they are usually found to be highly correlated measures of the individual events, as are LAmax and SEL. L90 or L95 can be used as a measure of the general background sound pressure level that excludes the potentially confounding influence of particular local noise events.

2.1.6. Sound and noise

Physically, there is no distinction between sound and noise: sound is a sensory perception evoked by physiological processes in the auditory brain. The complex pattern of sound waves is perceptually classified as "Gestalts" and are labeled as noise, music, speech, etc. Consequently, it is not possible to define noise exclusively on the basis of the physical parameters of sound. Instead, it is common practice to define noise simply as unwanted sound. However, in some situations noise may adversely affect health in the form of acoustical energy.

2.2. Sources of Noise

This section describes various sources of noise that can affect a community. Namely, noise from industry, transportation, and from residential and leisure areas. It should be noted that equal values of LAeq,T for different sources do not always imply the same expected effect.

2.2.1. Industrial noise

Mechanized industry creates serious noise problems. It is responsible for intense noise indoors as well as outdoors. This noise is due to machinery of all kinds and often increases with the power of the machines. Sound generation mechanisms of machinery are reasonably well understood. The noise may contain predominantly low or high frequencies, tonal components, be impulsive or have unpleasant and disruptive temporal sound patterns. Rotating and reciprocating machines generate sound that includes tonal components; and air-moving equipment tends also to generate noise with a wide frequency range. The high sound pressure levels are caused by components or gas flows that move at high speed (for example, fans, steam pressure relief valves), or by operations involving mechanical impacts (for example, stamping, riveting, road breaking). Machinery should preferably be silenced at the source.

Noise from fixed installations, such as factories or construction sites, heat pumps and ventilation systems on roofs, typically affect nearby communities. Reductions may be achieved by encouraging quieter equipment or by zoning of land into industrial and residential areas. Requirements for passive (sound insulating enclosures) and active noise control, or restriction of operation time, may also be effective.

2.2.2. Transportation noise

Transportation noise is the main source of environmental noise pollution, including road traffic, rail traffic and air traffic. As a general rule, larger and heavier vehicles emit more noise than smaller and lighter vehicles. Exceptions would include: helicopters and 2- and 3-wheeled road vehicles.

The noise of road vehicles is mainly generated from the engine and from frictional contact between the vehicle and the ground and air. In general, road-contact noise exceeds engine noise at speeds higher than 60 km/h. The physical principle responsible for generating noise from tire-road contact is less well understood. The sound pressure level from traffic can be predicted from the traffic flow rate, the speed of the vehicles, the proportion of heavy vehicles, and the nature of the road surface. Special problems can arise in areas where the traffic movements involve a change in engine speed and power, such as at traffic lights, hills, and intersecting roads; or where topography, meteorological conditions and low background levels are unfavourable (for example, mountain areas).

Railway noise depends primarily on the speed of the train, but variations are present depending upon the type of engine, wagons, and rails and their foundations, as well as the roughness of wheels and rails. Small radius curves in the track, such as may occur for urban trains, can lead to very high levels of high-frequency sound referred to as wheel squeal. Noise can be generated in stations because of running engines, whistles and loudspeakers, and in marshaling yards because of shunting operations. The introduction of high-speed trains has created special noise problems with sudden, but not impulsive, rises in noise. At speeds greater than 250 km/h, the proportion of high-frequency sound energy increases and the sound can be perceived as similar to that of overflying jet aircraft. Special problems can arise in areas close to tunnels, in valleys or in areas where the ground conditions help generate vibrations. The long-distance propagation of noise from high-speed trains will constitute a problem in the future if otherwise environment-friendly railway systems are expanded.

Aircraft operations generate substantial noise in the vicinity of both commercial and military airports. Aircraft takeoffs are known to produce intense noise, including vibration and rattle. The landings produce substantial noise in long low-altitude flight corridors. The noise is produced by the landing gear and automatic power regulation, and also when reverse thrust is applied, all for safety reasons. In general, larger and heavier aircraft produce more noise than lighter aircraft. The main mechanism of noise generation in the early turbojet-powered aircraft was the turbulence created by the jet exhaust mixing with the surrounding air. This noise source has been significantly reduced in modern high by-pass ratio turbo-fan engines that surround the high-velocity jet exhaust with lower velocity airflow generated by the fan. The fan itself can be a significant noise source, particularly during landing and taxiing operations. Multi-bladed turbo-prop engines can produce relatively high levels of tonal noise. The sound pressure level from aircraft is, typically, predicted from the number of aircraft, the types of airplanes, their flight paths, the proportions of takeoffs and landings and the atmospheric conditions. Severe noise problems may arise at airports hosting many helicopters or smaller aircraft used for private business, flying training and leisure purposes. Special noise problems may also arise inside airplanes because of vibration. The noise emission from future superjets is unknown.

A sonic boom consists of a shock wave in the air, generated by an aircraft when it flies at a speed slightly greater than the local speed of sound. An aircraft in supersonic flight trails a sonic boom that can be heard up to 50 km on either side of its ground track, depending upon the flight altitude and the size of the aircraft (Warren 1972). A sonic boom can be heard as a loud double-boom sound. At high intensity it can damage property.

Noise from military airfields may present particular problems compared to civil airports (von Gierke & Harris 1987). For example, when used for night-time flying, for training interrupted landings and takeoffs (so-called touch-and-go), or for low-altitude flying. In certain instances, including wars, specific military activities introduce other intense noise pollution from heavy vehicles (tanks), helicopters, and small and large fire-arms.

2.2.3. Construction noise and building services noise

Building construction and excavation work can cause considerable noise emissions. A variety of sounds come from cranes, cement mixers, welding, hammering, boring and other work processes. Construction equipment is often poorly silenced and maintained, and building operations are sometimes carried out without considering the environmental noise consequences. Street services such as garbage disposal and street cleaning can also cause considerable disturbance if carried out at sensitive times of day. Ventilation and air conditioning plants and ducts, heat pumps, plumbing systems, and lifts (elevators), for example, can compromise the internal acoustical environment and upset nearby residents.

2.2.4. Domestic noise and noise from leisure activities

In residential areas, noise may stem from mechanical devices (e.g. heat pumps, ventilation systems and traffic), as well as voices, music and other kinds of sounds generated by neighbours (e.g. lawn movers, vacuum cleaners and other household equipment, music reproduction and noisy parties). Aberrant social behavior is a well-recognized noise problem in multifamily dwellings, as well as at sites for entertainment (e.g. sports and music events). Due to predominantly low-frequency components, noise from ventilation systems in residential buildings may also cause considerable concern even at low and moderate sound pressure levels.

The use of powered machines in leisure activities is increasing. For example, motor racing, off-road vehicles, motorboats, water skiing, snowmobiles etc., and these contribute significantly to loud noises in previously quiet areas. Shooting activities not only have considerable potential for disturbing nearby residents, but can also damage the hearing of those taking part. Even tennis playing, church bell ringing and other religious activities can lead to noise complaints.

Some types of indoor concerts and discotheques can produce extremely high sound pressure levels. Associated noise problems outdoors result from customers arriving and leaving. Outdoor concerts, fireworks and various types of festivals can also produce intense noise. The general problem of access to festivals and leisure activity sites often adds to road traffic noise problems. Severe hearing impairment may also arise from intense sound produced as music in headphones or from children's toys.

2.3. The Complexity of Noise and Its Practical Implications

2.3.1. The problem

One must consider many different characteristics to describe environmental noises completely. We can consider the sound pressure level of the noise and how this level varies over a variety of periods, ranging from minutes or seconds to seasonal variations over several months. Where sound pressure levels vary quite substantially and rapidly, such as in the case of low-level jet aircraft, one might also want to consider the rate of change of sound pressure levels (Berry 1995; Kerry et al. 1997). At the same time, the frequency content of each noise will also determine its effect on people, as will the number of events when there are relatively small numbers of discrete noisy events. Combinations of these characteristics determine how each type of environmental noise affects people. These effects may be annoyance, sleep disturbance, speech interference, increased stress, hearing impairment or other health-related effects.

Thus, in total there is a very complex multidimensional relationship between the various characteristics of the environmental noise and the effects it has on people. Unfortunately, we do not completely understand all of the complex links between noise characteristics and the resulting effects on people. Thus, current practice is to reduce the assessment of environmental noise to a small number of quite simple quantities that are known to be reasonably well related to the effects of noise on people (LAeq,T for continuing sounds and LAmax or SEL where there are a small number of distinct noise events). These simple measures have the distinct advantage that they are relatively easy and inexpensive to obtain and hence are more likely to be widely adopted. On the other hand, they may ignore some details of the noise characteristics that relate to particular types of effects on people.

2.3.2. Time variation

There is evidence that the pattern of noise variation with time relates to annoyance (Berglund et al. 1976). It has been suggested that the equal-energy principle is a simple concept for obtaining a measure representative of the annoyance of a number of noise events. For example, the LAeq,T of the noise from a busy road may be a good indicator of the annoyance this noise may cause for nearby residents. However, such a measure may not be very useful for predicting the disturbance to sleep of a small number of very noisy aircraft fly-overs. The disturbance caused by small numbers of such discrete events is usually better related to maximum sound pressure levels and the number of events.

While using LAeq,T measures is the generally accepted approach, it is still important to appreciate the limitations and errors that may occur. For example, some years ago measures that assessed the variation of sound pressure levels with time were popular. Subsequently, these have been shown not to improve predictions of annoyance with road traffic noise (Bradley 1978). However, it is possible that time variations may contribute to explaining the very different amounts of annoyance caused by equal LAeq,T levels of road-traffic noise, train noise and aircraft noise (*cf.* Miedema & Vos 1998).

More regular variations of sound pressure levels with time have been found to increase the annoying aspects of the noise. For example, noises that vary periodically to create a throbbing or pulsing sensation can be more disturbing than continuous noise (Bradley 1994b). Research suggests that variations at about 4 per second are most disturbing (Zwicker 1989). Noises with very rapid onsets could also be more disturbing than indicated by their LAeq,T (Berry 1995; Kerry et al. 1997).

LAeq,T values can be calculated for various time periods and it is very important to specify this period. It is quite common to calculate LAeq,T values separately for day- and night-time periods. In combining day and night LAeq,T values it is usually assumed that people will be more sensitive to noise during the night-time period. A weighting is thus normally added to night-time LAeq,T values when calculating a combined measure for a 24 hour period. For example, day-night sound pressure measures commonly include a 10 dB night-time weighting. Other night-time weightings have been proposed, but it has been suggested that it is not possible to determine precisely an optimum value for night-time weightings from annoyance survey responses, because of the large variability in responses within groups of people (Fields 1986; see also Berglund & Lindvall 1995). Night-time weightings are intended to indicate the expected increased sensitivity to annoyance at night and do not protect people from sleep disturbance.

2.3.3. Frequency content and loudness

Noise can also be characterized by its frequency content. This can be assessed by various types of frequency analysis to determine the relative contributions of the frequency components to the total noise. The combined effects of the different frequencies on people, perceived as noise, can be approximated by simple frequency weightings. The A-weighting is now widely used to obtain an approximate, single-number rating of the combined effects of the various frequencies. The A-weighting response is a simplification of an equal-loudness contour. There is a family of these equal-loudness contours (ISO 1987a) that describe the frequency response of the hearing system for a wide range of frequencies and sound pressure levels. These equal-loudness contours can be used to determine the perceived loudness of a single frequency sound. More complicated procedures have been derived to estimate the perceived loudness of complex sounds (ISO 1975). These methods involve determining the level of the sound in critical bands and the mutual masking of these bands.

Many studies have compared the accuracy of predictions based on A-weighted levels with those based on other frequency weightings, as well as more complex measures such as loudness levels and perceived noise levels (see also Berglund & Lindvall 1995). The comparisons depend on the particular effect that is being predicted, but generally the correlation between the more complex measures and subjective scales are a little stronger. A-weighted measures have been particularly criticized as not being accurate indicators of the disturbing effects of noises with strong low-frequency components (Kjellberg et al. 1984; Persson & Björkman 1988; Broner & Leventhall 1993; Goldstein 1994). However, these differences in prediction accuracy are usually smaller than the variability of responses among groups of people (Fields 1986; see also Berglund & Lindvall 1995). Thus, in practical situations the limitations of A-weighted measures may not be so important.

In addition to equal-loudness contours, equal-noisiness contours have also been developed for calculating perceived noise levels (PNL) (Kryter 1959; Kryter 1994; see also section 2.7.2). Critics have pointed out that in addition to equal-loudness and equal-noisiness contours, we could have many other families of equal-sensation contours corresponding to other attributes of the noises (Molino 1974). There seems to be no limit to the possible complexity and number of such measures.

2.3.4. Influence of ambient noise level

A number of studies have suggested that the annoyance effect of a particular noise would depend on how much that noise exceeded the level of ambient noise. This has been shown to be true for noises that are relatively constant in level (Bradley 1993), but has not been consistently found for time-varying noises such as aircraft noise (Gjestland et al. 1990; Fields 1998). Because at some time during an aircraft fly-over the noise almost always exceeds the ambient level, responses to this type of noise are less likely to be influenced by the level of the ambient noise.

2.3.5. Types of noise

A number of studies have concluded that equal levels of different noise types lead to different annoyance (Hall et al. 1981; Griffiths 1983; Miedema 1993; Bradley 1994a; Miedema & Vos 1998). For example, equal LAeq,T levels of aircraft noise and road traffic noise will not lead to the same mean annoyance in groups of people exposed to these noises. This may indicate that the LAeq,T measure is not a completely satisfactory description of these noises and perhaps does not completely reflect the characteristics of these noises that lead to annoyance. Alternatively, the differences may be attributed to various other factors that are not part of the noise characteristics (e.g. Flindell & Stallen 1999). For example, it has been said that aircraft noise is more disturbing, because of the associated fear of aircraft crashing on people's homes (cf. Berglund & Lindvall 1995).

2.3.6. Individual differences

Finally, there is the problem of individual response differences. Different people will respond quite differently to the same noise stimulus (Job 1988). These individual differences can be quite large and it is often most useful to consider the average response of groups of people exposed to the same sound pressure levels. In annoyance studies the percentage of highly annoyed individuals is usually considered, because it correlates better with measured sound pressure levels. Individual differences also exist for susceptibility to hearing impairment (e.g. Katz 1994).

2.3.7. Recommendations

In many cases we do not have specific, accurate measures of how annoying sound will be and must rely on the simpler quantities. As a result, current practice is to assume that the equal energy principle is approximately valid for most types of noise, and that a simple LAeq,T type measure will indicate reasonably well the expected effects of the noise. Where the noise consists of a small number of discrete events, the A-weighted maximum level (LAmax) will be a better indicator of the disturbance to sleep and other activities. However, in most cases the A-weighted sound exposure level (SEL) will provide a more consistent measure of such single-noise events, because it is based on an integration over the complete noise event.

2.4. Measurement Issues

2.4.1. Measurement objectives

The details of noise measurements must be planned to meet some relevant objective or purpose. Some typical objectives would include:

a. Investigating complaints.
b. Assessing the number of persons exposed.
c. Compliance with regulations.
d. Land use planning and environmental impact assessments.
e. Evaluation of remedial measures.
f. Calibration and validation of predictions.
g. Research surveys.
h. Trend monitoring.

The sampling procedure, measurement location, type of measurements and the choice of equipment should be in accord with the objective of the measurements.

2.4.2. Instrumentation

The most critical component of a sound pressure meter is the microphone, because it is difficult to produce microphones with the same precision as the other, electronic components of a pressure meter. In contrast, it is usually not difficult to produce the electronic components of a microphone with the desired sensitivity and frequency-response characteristics. Lower quality microphones will usually be less sensitive and so cannot measure very low sound pressure levels. They may also not be able to accurately measure very high sound pressure levels found closer to loud noise sources. Lower quality microphones will also have less well-defined frequency-response characteristics. Such lower quality microphones may be acceptable for survey type measurements of overall A-weighted levels, but would not be preferred for more precise measurements, including detailed frequency analysis of the sounds.

Sound pressure meters will usually include both A- and C-weighting frequency-response curves. The uses of these frequency weightings were discussed above. They may also include a linear weighting. Linear weightings are not defined in standards and may in practice be limited by the response of the particular microphone being used. Instead of, or in addition to, frequency-response weightings, more complex sound pressure meters can also include sets of standard bandpass filters, to permit frequency analysis of sounds. For acoustical measurements, octave and one-third octave bandwidth filters are widely used with centre frequencies defined in standards (ISO 1975b).

The instantaneous sound pressures are integrated with some time constant to provide sound pressure levels. As mentioned above most meters will include both *Fast*- and *Slow*-response times. *Fast*-response corresponds to a time constant of 0.125 s and is intended to approximate the time constant of the human hearing system. *Slow*-response corresponds to a time constant of 1 s and is an old concept intended to make it easier to obtain an approximate average value of fluctuating levels from simple meter readings.

Standards (IEC 1979) classify sound pressure meters as type 1 or type 2. Type 2 meters are adequate for broad band A-weighted level measurements, where extreme precision is not required and where very low sound pressure levels are not to be measured. Type 1 meters are usually much more expensive and should be used where more precise results are needed, or in cases where frequency analysis is required.

Many modern sound pressure meters can integrate sound pressure levels over some specified time period, or may include very sophisticated digital processing capabilities. Integrating meters make it possible to directly obtain accurate measures of LAeq,T values over a user-specified time interval, T. By including small computers in some sound pressure meters, quite complex calculations can be performed on the measured levels and many such results can be stored for later read out. For example, some meters can determine the statistical distribution of sound pressure levels over some period, in addition to the simple LAeq,T value. Recently, hand-held meters that perform loudness calculations in real time have become available. Continuing rapid developments in instrumentation capabilities are to be expected.

2.4.3. Measurement locations

Where local regulations do not specify otherwise, measurements of environmental noise are usually best made close to the point of reception of the noise. For example, if there is concern about residents exposed to road traffic noise it is better to measure close to the location of the residents, rather than close to the road. If environmental noises are measured close to the source, one must then estimate the effect of sound propagation to the point of reception. Sound propagation can be quite complicated and estimates of sound pressure levels at some distance from the source will inevitably introduce further errors into the measured sound pressure levels. These errors can be avoided by measuring at locations close to the point of reception.

Measurement locations should normally be selected so that there is a clear view of the sound source and so that the propagation of the sound to the microphone is not shielded or blocked by structures that would reduce the incident sound pressure levels. For example, measurements of aircraft noise should be made on the side of the building directly exposed to the noise. The position of the measuring microphone relative to building façades or other sound-reflective surfaces is also important and will significantly influence measured sound pressure levels (ISO 1978). If the measuring microphone is located more than several meters from reflecting surfaces, it will provide an unbiased indication of the incident sound pressure level. At the other extreme, when a measuring microphone is mounted on a sound-reflecting surface, such as a building façade, sound pressure levels will be increased by 6 dB, because the direct and reflected sound will coincide. Some standards recommend a position 2 m from the façade and an associated 3 dB correction (ISO 1978; ASTM 1992). The effect of façade reflections must be accounted for to represent the true level of the incident sound. Thus, while locating the measuring microphone close to the point of reception is desirable, it leads to some other issues that must be considered to accurately interpret measurement results. Where exposures are measured indoors, it is necessary to measure at several positions to characterize the average sound pressure level in a room. In other situations, it may be necessary to measure at the position of the exposed person.

2.4.4. Sampling

Many environmental noises vary over time, such as for different times of day or from season to season. For example, road traffic noise may be considerably louder during some hours of the day but much quieter at night. Aircraft noise may vary with the season due to different numbers of aircraft operations. Although permanent noise monitoring systems are becoming common around large airports, it is usually not possible to measure sound pressure levels continuously over a long enough period of time to completely define the environmental noise exposure. In practice, measurements usually only sample some part of the total exposure. Such sampling will introduce uncertainties in the estimates of the total noise exposure.

Traffic noise studies have identified various sampling schemes that can introduce errors of 2-3 dB in estimates of daytime LAeq,T values and even larger errors in night-time sound pressure levels (Vaskor et al. 1979). These errors relate to the statistical distributions of sound pressure levels over time (Bradley et al. 1979). Thus, the sampling errors associated with road traffic noise may be quite different from those associated with other noise, because of the quite different variations of sound pressure levels over time. It is also difficult to give general estimates of sampling errors due to seasonal variations. When making environmental noise measurements it is important that the measurement sample is representative of all of the variations in the noise in question, including variations of the source and variations in sound propagation, such as due to varying atmospheric conditions.

2.4.5. Calibration and quality assurance

Sound pressure meters can be calibrated using small calibrated sound sources. These devices are placed on the measurement microphone and produce a known sound pressure level with a specified accuracy. Such calibrations should be made at least daily, and more often if there is some possibility that handling of the sound pressure meter may have modified its sensitivity. It is also important to have a complete quality assurance plan. This should require annual calibration of all noise measuring equipment to traceable standards and should clearly specify correct measurement and operating procedures (ISO 1994).

2.5. Source Characteristics and Sound Propagation

To make a correct assessment of noise it is important to have some appreciation of the characteristics of environmental noise sources and of how sound propagates from them. One should consider the directionality of noise sources, the variability with time and the frequency content. If these are in some way unusual, the noise may be more disturbing than expected. The most common types of environmental noise sources are directional and include: road-traffic noise, aircraft noise, train noise, industrial noise and outdoor entertainment facilities (*cf.* section 2.2). All of these types of environmental noise are produced by multiple sources, which in many cases are moving. Thus, the characteristics of individual sources, as well as the characteristics of the combined sources, must be considered.

For example, we can consider the radiation of sound from individual vehicles, as well as from a line of vehicles on a particular road. Sound from an ideal point source (i.e. non-directional source) will spread out spherically and sound pressure levels would decrease 6 dB for each doubling of distance from the source. However, for a line of such sources, or for an integration over the complete pass-by of an individual moving source, the combined effect leads to sound that spreads cylindrically and to sound pressure levels that decrease at 3 dB per doubling of distance. Thus, there are distinct differences between the propagation of sound from an ideal point source and from moving sources. In practice one cannot adequately assess the noise from a fixed source with measurements at a single location; it is essential to measure in a number of directions from the source. If the single source is moving, it is necessary to measure over a complete pass-by, to account for sound variation with direction and time.

In most real situations this simple behaviour is considerably modified by reflections from the ground and from other nearby surfaces. One expects that when sound propagates over loose ground, such as grass, that some sound energy will be absorbed and sound pressure levels will actually decrease more rapidly with distance from the source. Although this is approximately true, the propagation of sound between sources and receivers close to the ground is much more complicated than this. The combination of direct and ground-reflected sound can combine in a complex manner which can lead to strong cancellations at some frequencies and not at others (Embleton & Piercy 1976). Even at quite short source-to-receiver distances, these complex interference effects can significantly modify the propagating sound. At larger distances (approximately 100 m or more), the propagation of sound will also be significantly affected by various atmospheric conditions. Temperature and wind gradients as well as atmospheric turbulence can have large effects on more distant sound pressure levels (Daigle et al. 1986). Temperature and wind gradients can cause propagating sound to curve either upwards or downwards, creating either areas of increased or decreased sound pressure levels at points quite distant from the source. Atmospheric turbulence can randomize sound so that the interference effects resulting from combinations of sound paths are reduced. Higher frequency sound is absorbed by air depending on the exact temperature and relative humidity of the air (Crocker &

Price 1975; Ford 1987). Because there are many complex effects, it is not usually possible to accurately predict sound pressure levels at large distances from a source.

Using barriers or screens to block the direct path from the source to the receiver can reduce the propagation of sound. The attenuating effects of the screen are limited by sound energy that diffracts or bends around the screen. Screens are more effective at higher frequencies and when placed either close to the sound source or the receiver; they are less effective when placed far from the receiver. Although higher screens are better, in practice it is difficult to achieve more than about a 10 dB reduction. There should be no gaps in the screen and it must have an adequate mass per unit area. A long building can be an effective screen, but gaps between buildings will reduce the sound attenuation.

In some cases, it may be desirable to estimate environmental sound pressure levels using mathematical models implemented as computer programmes (House 1987). Such computer programmes must first model the characteristics of the source and then estimate the propagation of the sound from the source to some receiver point. Although such prediction schemes have several advantages, there will be some uncertainty as to the accuracy of the predicted sound pressure levels. Such models are particularly useful for road traffic noise and aircraft noise, because it is possible to create data bases of information describing particular sources. For more varied types of noise, such as industrial noise, it would be necessary to first characterize the noise sources. The models then sum up the effects of multiple sources and calculate how the sound will propagate to receiver points. Techniques for estimating sound propagation are improving and the accuracy of these models is also expected to improve. These models can be particularly useful for estimating the combined effect of a large number of sources over an extended period of time. For example, aircraft noise prediction models are typically used to predict average yearly noise exposures, based on the combination of aircraft events over a complete year. Such models can be applied to predict sound pressure level contours around airports for these average yearly conditions. This is of course much less expensive than measuring at many locations over a complete one year-period. However, such models can be quite complex, and require skilled users and accurate data bases. Because environmental noise prediction models are still developing, it is advisable to confirm predictions with measurements.

2.6. Sound transmission Into and Within Buildings

Sources of environmental noise are usually located outdoors; for example, road traffic, aircraft or trains. However, people exposed to these noises are often indoors, inside their home or some other building. It is, therefore, important to understand how environmental noises are transmitted into buildings. Most of the same fundamentals discussed earlier apply to airborne sound propagation between homes in multifamily dwellings, via common walls and floors. However, within buildings we can also consider impact sound sources, such as footsteps, as well as airborne sounds.

The amount of incident sound that is transmitted through a building façade is measured in terms of the sound reduction index. The sound reduction index, or transmission loss, is defined as 10 times the logarithm of the ratio of incident-to-transmitted sound power, and it describes in decibels how much the incident sound is reduced on passing through a particular panel. This index of constructions usually increases with the frequency of the incident sound and with the mass of the construction (Kremer 1950). Thus, heavier or more massive constructions tend to have higher sound reductions. When it is not possible to achieve the desired transmission loss by increasing the mass of a panel, increased sound reduction can be achieved by a double panel construction. The two layers should be isolated with respect to vibrations and there should be sound absorbing material in the cavity. Such double panel constructions can provide much greater sound reduction than a single panel. Because sound reduction is also greater at higher frequencies most problems occur at lower frequencies, where most environmental noise sources produce relatively high sound pressure levels.

The sound reduction of buildings can be measured in standard laboratory tests, where the test panel is constructed in an opening between two reverberant test chambers (ISO 1995; ASTM 1997). In these tests sound fields are quite diffuse in both test chambers and the sound reduction index is calculated as the difference between the average sound pressure levels in the two rooms, plus a correction involving the area of the test panel and the total sound absorption in the receiving room. The sound reduction of a complete building façade can also be measured in the field using either natural environmental noises or test signals from loudspeakers (ISO 1978; ASTM 1992). In either case the noise, as transmitted through the façade, must be greater in level than other sounds in the receiving room. For this outdoor-to-indoor sound propagation case, the measured sound reduction index will also depend on the angle of incidence of the outdoor sound, as well as the position of the outdoor measuring microphone relative to the building façade. Corrections of up to 6 dB must be made to the sound pressure level measured outdoors, to account for the effect of reflections from the façade (see also section 2.4.3).

The sound reduction of most real building façades is determined by a combination of several different elements. For example, a wall might include windows, doors or some other type of element. If the sound reduction index values of each element are known, the values for the combined construction can be calculated from the area-weighted sums of the sound energy transmitted through each separate element. Although parts of the building façade, such as massive wall constructions, can be very effective barriers to sound, the sound reduction index of the complete façade is often greatly reduced by less effective elements such as windows, doors or ventilation openings. Completely open windows as such would have a sound reduction index of 0 dB. If window openings makes up 10% of the area of a wall, the sound reduction index of the combined wall and open window could not exceed 10 dB. Thus it is not enough to specify effective sound reducing façade constructions, without also solving the problem of adequate ventilation that does not compromise the sound transmission reduction by the building façade.

Sound reduction index values are measured at different frequencies and from these, single number ratings are determined. Most common are the ISO weighted sound reduction index (ISO 1996) and the equivalent ASTM sound transmission class (ASTM 1994a). However, in their original form these single number ratings are only appropriate for typical indoor noises that usually do not have strong low frequency components. Thus, they are usually not appropriate single number ratings of the ability of a building façade to block typical environmental noises. More recent additions to the ISO procedure have included source spectrum corrections intended to correct approximately for other types of sources (ISO 1996). Alternatively, the ASTM-Outdoor-Indoor Transmission Class rating calculates the A-weighted level reduction to a standard environmental noise source spectrum (ASTM 1994b). Within buildings the impact sound insulation index can be measured with a standard impact source and determined according to ISO and ASTM standards (ISO 1998; ASTM 1994c 1996)

2.7. More Specialized Noise Measures

2.7.1. Loudness and perceived noise levels

There are procedures to accurately rate the loudness of complex sounds (Zwicker 1960; Stevens 1972; ISO 1975a). These usually start from a 1/3 octave spectrum of the noise. The combination of the loudness contributions of each 1/3 octave band with estimates of mutual masking effects, leads to a single overall loudness rating in sones. A similar system for rating the noisiness of sounds has also been developed (Kryter 1994). Again a 1/3 octave spectrum of the noise is required and the 1/3 octave noise levels are compared with a set of equal-noisiness contours. The individual 1/3 octave band noisiness estimates are combined to give an overall perceived noise level (PNL) that is intended to accurately estimate subjective evaluations of the same sound. The PNL metric was initially developed to rate jet aircraft noise.

PNL values will vary with time, for example when an aircraft flies by a measuring point. The effective perceived noise level measure (EPNL) is derived from PNL values and is intended to provide a complete rating of an aircraft fly-over. EPNL values add both a duration correction and a tone correction to PNL values. The duration correction ensures that longer duration events are rated as more disturbing. Similarly, noise spectra that seem to have prominent tonal components are rated as more disturbing by the tone-correction procedure. There is some evidence that these tone corrections are not always successful in improving predictions of adverse responses to noise events (Scharf & Hellman 1980). EPNL values are used in the certification testing of new aircraft. These more precise measures ensure that the noise from new aircraft is rated as accurately as possible.

2.7.2. Aviation noise measures

There are many measures for evaluating the long-term average sound pressure levels from aircraft near airports (Ford 1987; House 1987). They include different frequency weightings, different summations of levels and numbers of events, as well as different time-of-day weightings. Most measures are based on either A-weighted or PNL-weighted sound pressure levels. Because of the many other large uncertainties in predicting community response to aircraft noise, there seems little justification for using the more complex PNL-weighted sound pressure levels and there is a trend to change to A-weighted measures.

Most aviation noise measures are based on an equal energy approach and hence they sum up the total energy of a number of aircraft fly-overs. However, some older measures were based on different combinations of the level of each event and the number of events. These types of measures are gradually being replaced by measures based on the equal energy hypothesis such as LAeq,T values. There is also a range of time-of-day weightings incorporated into current aircraft noise measures. Night-time weightings of 6–12 dB are currently in use. Some countries also include an intermediate evening weighting.

The day-night sound pressure level L_{dn} (von Gierke 1975; Ford 1987) is an LAeq,T based measure with a 10 dB night-time weighting. It is based on A-weighted sound pressure levels and the equal energy principle. The noise exposure forecast (NEF) (Bishop & Horonjeff 1967) is based on the EPNL values of individual aircraft events and includes a 12 dB night-time weighting. It sums multiple events on an equal energy basis. However, the Australian variation of the NEF measure has a 6 dB evening weighting and a 6 dB night-time weighting (Bullen & Hede 1983). The German airport noise equivalent level (LEQ(FLG)) is based on A-weighted levels, but does not follow the equal energy principle.

The weighted equivalent continuous perceived noise level (WECPNL) measure (Ford 1987) proposed by ICAO is based on the equal energy principle and maximum PNL values of aircraft fly-overs. However, in Japan an approximation to this measure is used and is based on maximum A-weighted levels. The noise and number index (NNI), formerly used in the United Kingdom, was derived from maximum PNL values but was not based on the equal energy principle. An approximation to the original version of the NNI has been used in Switzerland and is based on maximum A-weighted levels of aircraft fly-overs, but its use will soon be discontinued. Changes in these measures are slow because their use is often specified in national legislation. However, several countries have changed to measures that are based on the equal energy principle and A-weighted sound pressure levels.

2.7.3. Impulsive noise measures

Impulsive sounds, such as gun shots, hammer blows, explosions of fireworks or other blasts, are sounds that significantly exceed the background sound pressure level for a very short duration. Typically each impulse lasts less than one second. Measurements with the meter set to 'Fast' response (section 2.1.1) do not accurately represent impulsive sounds. Therefore the meter response time must be shorter to measure such impulse type sounds. C-weighted levels have been found useful for ratings of gun shots (ISO 1987). Currently no mathematical description exists which unequivocally defines impulsive sounds, nor is there a universally accepted procedure for rating the additional annoyance of impulsive sounds (HCN 1997). Future versions of ISO Standard 1996 (present standard in ISO 1987b) are planned to improve this situation.

2.7.4. Measures of speech intelligibility

The intelligibility of speech depends primarily on the speech-to-noise ratio. If the level of the speech sounds are 15 dB or more above the level of the ambient noise, the speech intelligibility at 1 m distance will be close to 100% (Houtgast 1981; Bradley 1986b). This can be most simply rated in terms of the speech-to-noise ratio of the A-weighted speech and noise levels. Alternatively, the speech intelligibility index (formerly the articulation index) can be used if octave or 1/3 octave band spectra of the speech and noise are available (ANSI 1997).

When indoors, speech intelligibility also depends on the acoustical properties of the space. The acoustical properties of spaces have for many years been rated in terms of reverberation times. The reverberation time is approximately the time it takes for a sound in a room to decrease to inaudibility after the source has been stopped. Optimum reverberation times for speech have been specified as a function of the size of the room. In large rooms, such as lecture halls and theaters, a reverberation time for speech of about 1 s is recommended. In smaller rooms such as classrooms, the recommended value for speech is about 0.6 s (Bradley 1986b,c). More modern measures of room acoustics have been found to be better correlates of speech intelligibility, and some combine an assessment of both the speech/noise ratio and room acoustics (Bradley 1986a,c). The most widely known is the speech transmission index (STI) (Houtgast & Steeneken 1983), or the abbreviated version of this measure referred to as RASTI (Houtgast & Steeneken 1985; IEC 1988). In smaller rooms, such as school classrooms, the conventional approach of requiring adequately low ambient noise levels, as well as some optimum reverberation time, is probably adequate to ensure good speech intelligibility (Bradley 1986b). In larger rooms and other more specialized situations, use of the more modern measures may be helpful.

2.7.5. Indoor noise ratings

The simplest procedure for rating levels of indoor noise is to measure them in terms of integrated A-weighted sound pressure levels, as measured by LAeq,T. As discussed earlier, this approach has been criticized as not being the most accurate rating of the negative effects of various types of noises, and is thought to be particularly inadequate when there are strong low-frequency components. Several more complex rating schemes are available based on octave band measurements of indoor noises. In Europe the noise rating system (Burns 1968), and in North America the noise criterion (Beranek 1971), both include sets of equal-disturbance type contours. Measured octave band sound pressure levels are compared with these contours and an overall noise rating is determined. More recently, two new schemes have been proposed: the balanced noise criterion procedure (Beranek 1989) and the room criterion system (Blazier 1998). These schemes are based on a wider range of octave bands extending from 16–8 000 Hz. They provide both a numerical and a letter rating of the noise. The numerical part indicates the level of the central frequencies important for speech communication and the letter indicates whether the quality of the sound is predominantly low-, medium- or high-frequency in nature. Extensive comparisons of these room noise rating procedures have yet to be performed. Because the newer measures include a wider range of frequencies, they can better assess a wider range of noise problems.

2.8. Summary

Where there are no clear reasons for using other measures, it is recommended that LAeq,T be used to evaluate more-or-less continuous environmental noises. LAeq,T should also be used to assess ongoing noises that may be composed of individual events with randomly varying sound pressure levels. Where the noise is principally composed of a small number of discrete events the additional use of LAmax or SEL is recommended. As pointed out in this chapter, there are definite limitations to these simple measures, but there are also many practical advantages, including economy and the benefits of a standardized approach.

The sound pressure level measurements should include all variations over time to provide results that best represent the noise in question. This would include variations in both the source and in propagation of the noise from the source to the receiver. Measurements should normally be made close to typical points of reception. The accuracy of the measurements and the details of the measurement procedure must be adapted to the type of noise and to other details of the noise exposure. Assessment of speech intelligibility, aviation noise or impulse noise may require the use of more specialized methods. Where the exposed people are indoors and noise measurements are made outdoors, the sound attenuating properties of the building façade must also be measured or estimated.

3. Adverse Health Effects Of Noise

3.1. Introduction

The perception of sounds in day-to-day life is of major importance for human well-being. Communication through speech, sounds from playing children, music, natural sounds in parklands, parks and gardens are all examples of sounds essential for satisfaction in every day life. Conversely, this document is related to the adverse effects of sound (noise). According to the International Programme on Chemical Safety (WHO 1994), an adverse effect of noise is defined as a change in the morphology and physiology of an organism that results in impairment of functional capacity, or an impairment of capacity to compensate for additional stress, or increases the susceptibility of an organism to the harmful effects of other environmental influences. This definition includes any temporary or long-term lowering of the physical, psychological or social functioning of humans or human organs. The health significance of noise pollution is given in this chapter under separate headings, according to the specific effects: noise-induced hearing impairment; interference with speech communication; disturbance of rest and sleep; psychophysiological, mental-health and performance effects; effects on residential behaviour and annoyance; as well as interference with intended activities. This chapter also considers vulnerable groups and the combined effects of sounds from different sources. Conclusions based on the details given in this chapter are given in Chapter 4 as they relate to guideline values.

3.2. Noise-Induced Hearing Impairment

Hearing impairment is typically defined as an increase in the threshold of hearing. It is assessed by threshold audiometry. Hearing handicap is the disadvantage imposed by hearing impairment sufficient to affect one's personal efficiency in the activities of daily living. It is usually expressed in terms of understanding conventional speech in common levels of background noise (ISO 1990). Worldwide, noise-induced hearing impairment is the most prevalent irreversible occupational hazard. In the developing countries, not only occupational noise, but also environmental noise is an increasing risk factor for hearing impairment. In 1995, at the World Health Assembly, it was estimated that there are 120 million persons with disabling hearing difficulties worldwide (Smith 1998). It has been shown that men and women are equally at risk of noise-induced hearing impairment (ISO 1990; Berglund & Lindvall 1995).

Apart from noise-induced hearing impairment, hearing damage in populations is also caused by certain diseases; some industrial chemicals; ototoxic drugs; blows to the head; accidents; and hereditary origins. Deterioration of hearing capability is also associated with the aging process *per se* (presbyacusis). Present knowledge of the physiological effects of noise on the auditory system is based primarily on laboratory studies on animals. After noise exposure, the first morphological changes are usually found in the inner and outer hair cells of the cochlea, where the stereocilia become fused and bent. After more prolonged exposure, the outer and inner hair cells related to transmission of high-frequency sounds are missing. See Berglund & Lindvall (1995) for further discussion.

The ISO Standard 1999 (ISO 1990) gives a method for calculating noise-induced hearing impairment in populations exposed to all types of noise (continuous, intermittent, impulse) during working hours. Noise exposure is characterized by LAeq over 8 hours (LAeq,8h). In the Standard, the relationships between LAeq,8h and noise-induced hearing impairment are given for frequencies of 500–6 000 Hz, and for exposure times of up to 40 years. These relations show that noise-induced hearing impairment occurs predominantly in the high-frequency range of 3 000–6 000 Hz, the effect being largest at 4 000 Hz. With increasing LAeq,8h and increasing exposure time, noise-induced hearing impairment also occurs at 2 000 Hz. But at LAeq,8h levels of 75 dBA and lower, even prolonged occupational noise exposure will not result in noise-induced hearing impairment (ISO 1990). This value is equal to that specified in 1980 by the World Health Organization (WHO 1980a).

The ISO Standard 1999 (ISO 1990) specifies hearing impairment in statistical terms (median values, and percentile fractions between 0.05 and 0.95). The extent of noise-induced hearing impairment in populations exposed to occupational noise depends on the value of LAeq,8h and the number of years of noise exposure. However, for high LAeq,8h values, individual susceptibility seems to have a considerable effect on the rate of progression of hearing impairment. For daily exposures of 8–16 h, noise-induced hearing impairment can be reasonably well estimated from LAeq,8h extrapolated to the longer exposure times (Axelsson et al. 1986). In this adaptation of LAeq,8h for daily exposures other than 8 hours, the equal energy principle is assumed to be applicable. For example, the hearing impairment due to a 16 h daily exposure is equivalent to that at LAeq,8h plus 3 dB (LAeq,16h = LAeq,8h + 10*$\log_{10}$ (16/8) = LAeq,8h + 3 dB. For a 24 h exposure, LAeq,24h = LAeq,8h + 10*$\log_{10}$ (24/8) = LAeq,8h + 5 dB).

Since the calculation method specified in the ISO Standard 1999 (ISO 1990) is the only universally adopted method for estimating occupational noise-induced hearing impairment, attempts have been made to assess whether the method is also applicable to hearing impairment due to environmental noise, including leisure-time noise. There is ample evidence that shooting noise, with LAeq,24h values of up to 80 dB, induces the same hearing impairment as an equivalent occupational noise exposure (Smoorenburg 1998). Moreover, noise-induced hearing impairment studies from motorbikes are also in agreement with results from ISO Standard 1999 (ISO 1990). Hearing impairment in young adults and children 12 years and older has been assessed by LAeq on a 24 h time basis, for a variety of environmental and leisure-time exposure patterns (e.g. Passchier-Vermeer 1993; HCN 1994). These include pop music in discotheques and concerts (Babisch & Ising 1989; ISO 1990); pop music through headphones (Ising et al. 1994; Struwe et al. 1996; Passchier-Vermeer et al. 1998); music played by brass bands and symphony orchestras (van Hees 1992). The results are in agreement with values predicted by the ISO Standard 1999 method on the basis of adjusted time.

In the publications cited above, exposure to noise with known characteristics, such as duration and level, was related to hearing impairment. In addition to these publications, there is also an extensive literature showing hearing impairment in populations exposed to specific types of non-occupational noise, although these exposures are not well characterized. These noises originate from shooting, motorcycling, snowmobile driving, playing in arcades, listening to music at concerts and through headphones, using noisy toys, and fireworks (e.g. Brookhouser et al. 1992; see also Berglund & Lindvall 1995). Although the characteristics of these exposures are to a certain extent unknown, the details in the publications suggest that LAeq,24h values of these exposures exceed 70 dB.

In contrast, epidemiological studies failed to show hearing damage in populations exposed to an LAeq,24h of less than 70 dB (Lindemann et al. 1987). The data imply that even a lifetime exposure to environmental and leisure-time noise with an LAeq,24h <70 dBA would not cause hearing impairment in the large majority of people (over 95%). Overall, the results of many studies strongly suggest that the method from ISO Standard 1999 can also be used to estimate hearing impairment due to environmental and leisure-time noise, in addition to estimating the effects of occupational noise exposure.

Although the evidence suggests that the calculation method from ISO Standard 1999 (ISO 1990) should also be accepted for environmental and leisure time noise exposures, large-scale epidemiological studies of the general population do not exist to support this proposition. Taking into account the limitations of the studies, care should be taken with respect to the following aspects:

a. Data from animal experiments indicate that children may be more vulnerable in acquiring noise-induced hearing impairment than adults.

b. At very high instantaneous sound pressure levels, mechanical damage to the ear may occur (Hanner & Axelsson 1988). Occupational limits are set at peak sound pressure levels of 140 dB (EU 1986a). For adults exposed to environmental and leisure-time noise, this same limit is assumed to be valid. In the case of children, however, taking into account their habits while playing with noisy toys, peak sound pressure levels should never exceed 120 dB.

c. For shooting noise with LAeq,24h over 80 dB, studies on temporary threshold shift suggest the possibility of an increased risk for noise-induced hearing impairment (Smoorenburg 1998).

d. Risk for noise-induced hearing impairment may increase when the noise exposure is combined with exposure to vibrations, the use of ototoxic drugs, or some chemicals (Fechter 1999). In these circumstances, long-term exposure to LAeq,24h of 70 dBA may induce small hearing impairments.

e. It is uncertain whether the relationships between hearing impairment and noise exposure given in ISO Standard 1999 (ISO 1990) are applicable for environmental sounds of short rise time. For example, in the case of military low-altitude flying areas (75–300 m above ground) LAmax values of 110–130 dB occur within seconds after the onset of the sound.

Usually noise-induced hearing impairment is accompanied by an abnormal loudness perception which is known as loudness recruitment (*cf.* Berglund & Lindvall 1995). With a considerable loss of auditory sensitivity, some sounds may be perceived as distorted (paracusis). Another sensory effect that results from noise exposure is tinnitus (ringing in the ears). Commonly, tinnitus is referred to as sounds that are emitted by the inner ear itself (physiological tinnitus). Tinnitus is a common and often disturbing accompaniment of occupational hearing impairment (Vernon and Moller 1995) and has become a risk for teenagers attending pop concerts and discotheques (Hetu & Fortin 1995; Passchier-Vermeer et al. 1998; Axelsson & Prasher 1999). Noise-induced tinnitus may be temporary, lasting up to 24 hours after exposure, or may have a more permanent character, such as after prolonged occupational noise exposure. Sometimes tinnitus is due to the sound produced by the blood flow through structures in the ear.

The main social consequence of hearing impairment is an inability to understand speech in daily living conditions, which is considered a severe social handicap. Even small values of hearing impairment (10 dB averaged over 2 000 and 4 000 Hz, and over both ears) may have an effect on the understanding of speech. When the hearing impairment exceeds 30 dB (again averaged over 2 000 and 4 000 Hz and both ears) a social hearing handicap is noticeable (*cf.* Katz 1994; Berglund & Lindvall 1995).

In the past, hearing protection has mainly emphasized occupational noise exposures at high values of LAeq,8h, or situations with high impulsive sounds. The near-universal adoption of an LAeq,8h value of 85 dB (or lower) as the limit for unprotected occupational noise exposure, together with requirements for personal hearing protection, has made cases of severe unprotected exposures more rare. This is particularly true for developed countries. However, monitoring of compliance and enforcement action for sound pressure levels just over the limits may be weak, especially in non-industrial environments in developed countries (Franks 1998), as well as in occupational and urban environments in developing countries (Smith 1998). Nevertheless, regulations for occupational noise exposure exist almost worldwide and exposures to occupational noise are to a certain extent under control.

On the other hand, environmental noise exposures due to a number of noisy activities, especially those during leisure-time activities of children and young adults, have scarcely been regulated. Given both the increasing number of noisy activities and the increasing exposure duration, such as loud music in cars and the use of Walkmen and Discmen, regulatory activities in this field are to be encouraged. Dose-response data are lacking for the general population. However, judging from the limited data for study groups (teenagers, young adults and women), and the assumption that time of exposure can be equated with sound energy, the risk for hearing impairment would be negligible for LAeq,24h values of 70 dBA over a lifetime. To avoid hearing impairment, impulse noise exposures should never exceed 140 dB peak sound pressure in adults, and 120 dB peak sound pressure in children.

3.3. Interference with Speech Communication

Noise interference with speech comprehension results in a large number of personal disabilities, handicaps and behavioural changes. Problems with concentration, fatigue, uncertainty and lack of self-confidence, irritation, misunderstandings, decreased working capacity, problems in human relations, and a number of stress reactions have all been identified (Lazarus 1998). Particularly vulnerable to these types of effects are the hearing impaired, the elderly, children in the process of language and reading acquisition, and individuals who are not familiar with the spoken language (e.g., Lazarus 1998). Thus, vulnerable persons constitute a substantial proportion of a country's population.

Most of the acoustical energy of speech is in the frequency range 100–6 000 Hz, with the most important cue-bearing energy being between 300–3 000 Hz. Speech interference is basically a masking process in which simultaneous, interfering noise renders speech incapable of being understood. The higher the level of the masking noise, and the more energy it contains at the most important speech frequencies, the greater will be the percentage of speech sounds that become indiscernible to the listener. Environmental noise may also mask many other acoustical signals important for daily life, such as door bells, telephone signals, alarm clocks, fire alarms and other warning signals, and music (e.g., Edworthy & Adams 1996). The masking effect of interfering noise in speech discrimination is more pronounced for hearing-impaired persons than for persons with normal hearing, particularly if the interfering noise is composed of speech or babble.

As the sound pressure level of an interfering noise increases, people automatically raise their voice to overcome the masking effect upon speech (increase of vocal effort). This imposes an additional strain on the speaker. For example, in quiet surroundings, the speech level at 1 m distance averages 45–50 dBA, but is 30 dBA higher when shouting. However, even if the interfering noise is moderately loud, most of the sentences during ordinary conversation can still be understood fairly well. Nevertheless, the interpretation required for compensating the masking effect of the interfering sounds, and for comprehending what was said, imposes an additional strain on the listener. One contributing factor could be that speech spoken loudly is more difficult to understand than speech spoken softly, when compared at a constant speech-to-noise ratio (*cf.* Berglund & Lindvall 1995).

Speech levels vary between individuals because of factors such as gender and vocal effort. Moreover, outdoor speech levels decrease by about 6 dB for a doubling in the distance between talker and listener. Speech intelligibility in everyday living conditions is influenced by speech level, speech pronunciation, talker-to-listener distance, sound pressure levels, and to some extent other characteristics of interfering noise, as well as room characteristics (e.g. reverberation). Individual capabilities of the listener, such as hearing acuity and the level of attention of the listener, are also important for the intelligibility of speech. Speech communication is affected also by the reverberation characteristics of the room. For example, reverberation times greater than 1 s produce loss in speech discrimination. Longer reverberation times, especially when combined with high background interfering noise, make speech perception more difficult. Even in a quiet environment, a reverberation time below 0.6 s is desirable for adequate speech intelligibility by vulnerable groups. For example, for older hearing-handicapped persons, the optimal reverberation time for speech intelligibility is 0.3–0.5 s (Plomp 1986).

For complete sentence intelligibility in listeners with normal hearing, the signal-to-noise ratio (i.e. the difference between the speech level and the sound pressure level of the interfering noise) should be 15–18 dBA (Lazarus 1990). This implies that in smaller rooms, noise levels above 35 dBA interferes with the intelligibility of speech (Bradley 1985). Earlier recommendations suggested that sound pressure levels as high as 45 dBA would be acceptable (US EPA 1974). With raised voice (increased vocal effort) sentences may be 100% intelligible for noise levels of up to 55 dBA; and sentences spoken with straining vocal effort can be 100% intelligible with noise levels of about 65 dBA. For speech to be intelligible when listening to complicated messages (at school, listening to foreign languages, telephone conversation), it is recommended that the signal-to-noise ratio should be at least 15 dBA. Thus, with a speech level of 50 dBA, (at 1 m distance this level corresponds to a casual speech level of both women and men), the sound pressure level of interfering noise should not exceed 35 dBA. For vulnerable groups even lower background levels are needed. If it is not possible to meet the strictest criteria for vulnerable persons in sensitive situations (e.g. in classrooms), one should strive for as low background levels as possible.

3.4. Sleep Disturbance

Uninterrupted sleep is known to be a prerequisite for good physiological and mental functioning of healthy persons (Hobson 1989); sleep disturbance, on the other hand, is considered to be a major environmental noise effect. It is estimated that 80-90% of the reported cases of sleep disturbance in noisy environments are for reasons other than noise originating outdoors. For example, sanitary needs; indoor noises from other occupants; worries; illness; and climate (e.g. Reyner & Horne 1995). Our understanding of the impact of noise exposure on sleep stems mainly from experimental research in controlled environments. Field studies conducted with people in their normal living situations are scarce. Most of the more recent field research on sleep disturbance has been conducted for aircraft noise (Fidell et al. 1994 1995a,b 1998; Horne et al. 1994 1995; Maschke et al. 1995 1996; Ollerhead et al. 1992; Passchier-Vermeer 1999). Other field studies have examined the effects of road traffic and railway noise (Griefahn et al. 1996 1998).

The primary sleep disturbance effects are: difficulty in falling asleep (increased sleep latency time); awakenings; and alterations of sleep stages or depth, especially a reduction in the proportion of REM-sleep (REM = rapid eye movement) (Hobson 1989). Other primary physiological effects can also be induced by noise during sleep, including increased blood pressure; increased heart rate; increased finger pulse amplitude; vasoconstriction; changes in respiration; cardiac arrhythmia; and an increase in body movements (cf. Berglund & Lindvall 1995). For each of these physiological effects, both the noise threshold and the noise-response relationships may be different. Different noises may also have different information content and this also could affect physiological threshold and noise-response relationships (Edworthy 1998).

Exposure to night-time noise also induces secondary effects, or so-called after effects. These are effects that can be measured the day following the night-time exposure, while the individual is awake. The secondary effects include reduced perceived sleep quality; increased fatigue; depressed mood or well-being; and decreased performance (Öhrström 1993a; Passchier-Vermeer 1993; Carter 1996; Pearsons et al. 1995; Pearsons 1998).

Long-term effects on psychosocial well-being have also been related to noise exposure during the night (Öhrström 1991). Noise annoyance during the night-time increased the total noise annoyance expressed by people in the following 24 h. Various studies have also shown that people living in areas exposed to night-time noise have an increased use of sedatives or sleeping pills. Other frequently reported behavioural effects of night-time noise include closed bedroom windows and use of personal hearing protection. Sensitive groups include the elderly, shift workers, persons especially vulnerable to physical or mental disorders and other individuals with sleeping difficulties.

Questionnaire data indicate the importance of night-time noise on the perception of sleep quality. A recent Japanese investigation was conducted for 3 600 women (20–80 years old) living in eight roadside zones with different road traffic noise. The results showed that four measures of perceived sleep quality (difficulty in falling asleep; waking up during sleep; waking up too early; feelings of sleeplessness one or more days a week) correlated significantly with the average traffic volumes during night-time. An in-depth investigation of 19 insomnia cases and their matched controls (age,work) measured outdoor and indoor sound pressure levels during sleep (Kageyama et al. 1997). The study showed that road traffic noise in excess of 30 dB LAeq for nighttime induced sleep disturbance, consistent with the results of Öhrström (1993b).

Meta-analyses of field and laboratory studies have suggested that there is a relationship between the SEL for a single night-time noise event and the percentage of people awakened, or who showed sleep stage changes (e.g. Ollerhead et al. 1992; Passchier-Vermeer 1993; Finegold et al. 1994; Pearsons et al. 1995). All of these studies assumed that the number of awakenings per night for each SEL value is proportional to the number of night-time noise events. However, the results have been criticized for methodological reasons. For example, there were small groups of sleepers; too few original studies; and indoor exposure was estimated from outdoor sound pressure levels (NRC-CNRC 1994; Beersma & Altena 1995; Vallet 1998). The most important result of the meta-analyses is that there is a clear difference in the dose-response curves for laboratory and field studies, and that noise has a lower effect under real-life conditions (Pearsons et al. 1995; Pearsons 1998).

However, this result has been questioned, because the studies were not controlled for such things as the sound insulation of the buildings, and the number of bedrooms with closed windows. Also, only two indicators of sleep disturbance were considered (awakening and sleep stage changes). The meta-analyses thus neglected other important sleep disturbance effects (Öhrström 1993b; Carter et al. 1994a; Carter et al. 1994b; Carter 1996; Kuwano et al. 1998). For example, for road traffic noise, perceived sleep quality is related both to the time needed to fall asleep and the total sleep time (Öhrström & Björkman 1988). Individuals who are more sensitive to noise (as assessed by different questionnaires) report worse sleep quality both in field studies and in laboratory studies.

A further criticism of the meta-analyses is that laboratory experiments have shown that habituation to night-time noise events occurs, and that noise-induced awakening decreases with increasing number of sound exposures per night. This is in contrast to the assumption used in the meta-analyses, that the percentage of awakenings is linearly proportional to the number of night-time noise events. Studies have also shown that the frequency of noise-induced awakenings decreases for at least the first eight consecutive nights. So far, habituation has been shown for awakenings, but not for heart rate and after effects such as perceived sleep quality, mood and performance (Öhrström and Björkman 1988).

Other studies suggest that it is the difference in sound pressure levels between a noise event and background, rather than the absolute sound pressure level of the noise event, that determines the reaction probability. The time interval between two noise events also has an important influence of the probability of obtaining a response (Griefahn 1977; *cf.* Berglund & Lindvall 1995). Another possible factor is the person's age, with older persons having an increased probability of awakening. However, one field study showed that noise-induced awakenings are independent of age (Reyner & Horne 1995).

For a good sleep, it is believed that indoor sound pressure levels should not exceed approximately 45 dB LAmax more than 10–15 times per night (Vallet & Vernet 1991), and most studies show an increase in the percentage of awakenings at SEL values of 55–60 dBA (Passchier-Vermeer 1993; Finegold et al. 1994; Pearsons et al. 1995). For intermittent events that approximate aircraft noise, with an effective duration of 10–30 s, SEL values of 55–60 dBA correspond to a LAmax value of 45 dB. Ten to 15 of these events during an eight-hour night-time implies an LAeq,8h of 20–25 dB. This is 5–10 dB below the LAeq,8h of 30 dB for continuous night-time noise exposure, and shows that the intermittent character of noise has to be taken into account when setting night-time limits for noise exposure. For example, this can be achieved by considering the number of noise events and the difference between the maximum sound pressure level and the background level of these events.

Special attention should also be given to the following considerations:

a. Noise sources in an environment with a low background noise level. For example, night-traffic in suburban residential areas.

b. Environments where a combination of noise and vibrations are produced. For example, railway noise, heavy duty vehicles.

c. Sources with low-frequency components. Disturbances may occur even though the sound pressure level during exposure is below 30 dBA.

If negative effects on sleep are to be avoided the equivalent sound pressure level should not exceed 30 dBA indoors for continuous noise. If the noise is not continuous, sleep disturbance correlates best with LAmax and effects have been observed at 45 dB or less. This is particularly true if the background level is low. Noise events exceeding 45 dBA should therefore be limited if possible. For sensitive people an even lower limit would be preferred. It should be noted that it should be possible to sleep with a bedroom window slightly open (a reduction from outside to inside of 15 dB). To prevent sleep disturbances, one should thus consider the equivalent sound pressure level and the number and level of sound events. Mitigation targeted to the first part of the night is believed to be effective for the ability to fall asleep.

3.5. Cardiovascular and Physiological Effects

Epidemiological and laboratory studies involving workers exposed to occupational noise, and general populations (including children) living in noisy areas around airports, industries and noisy streets, indicate that noise may have both temporary and permanent impacts on physiological functions in humans. It has been postulated that noise acts as an environmental stressor (for a review see Passchier-Vermeer 1993; Berglund & Lindvall 1995). Acute noise exposures activate the autonomic and hormonal systems, leading to temporary changes such as increased blood pressure, increased heart rate and vasoconstriction. After prolonged exposure, susceptible individuals in the general population may develop permanent effects, such as hypertension and ischaemic heart disease associated with exposures to high sound pressure levels (for a review see Passchier-Vermeer 1993; Berglund & Lindvall 1995). The magnitude and duration of the effects are determined in part by individual characteristics, lifestyle behaviours and environmental conditions. Sounds also evoke reflex responses, particularly when they are unfamiliar and have a sudden onset.

Laboratory experiments and field quasi-experiments show that if noise exposure is temporary, the physiological system usually returns - after the exposure terminates - to a normal (pre-exposure) state within a time in the range of the exposure duration. If the exposure is of sufficient intensity and unpredictability, cardiovascular and hormonal responses may appear, including increases in heart rate and peripheral vascular resistance; changes in blood pressure, blood viscosity and blood lipids; and shifts in electrolyte balance (Mg/Ca) and hormonal levels (epinephrine, norepinephrine, cortisol). The first four effects are of interest because of noise-related coronary heart disease (Ising & Günther 1997). Laboratory and clinical data suggest that noise may significantly elevate gastrointestinal motility in humans.

By far the greatest number of occupational and community noise studies have focused on the possibility that noise may be a risk factor for cardiovascular disease. Many studies in occupational settings have indicated that workers exposed to high levels of industrial noise for 5–30 years have increased blood pressure and statistically significant increases in risk for hypertension, compared to workers in control areas (Passchier-Vermeer 1993). In contrast, only a few studies on environmental noise have shown that populations living in noisy areas around airports and on noisy streets have an increased risk for hypertension. The overall evidence suggests a weak association between long-term environmental noise exposure and hypertension (HCN 1994; Berglund & Lindvall 1995; IEH 1997), and no dose-response relationships could be established.

Recently, an updated summary of available studies for ischaemic heart disease has been presented (Babisch 1998a; Babisch 1998b; Babisch et al. 1999; see also Thompson 1996). The studies reviewed include case-control and cross-sectional designs, as well as three longitudinal studies. However, it has not yet been possible to conduct the most advanced quantitative integrated analysis of the available studies. Relative risks and their confidence intervals could be estimated only for the classes of high noise levels (mostly >65 dBA during daytime) and low levels (mostly <55 dBA during daytime), rather than a range of exposure levels. For methodological reasons identified in the meta-analysis, a cautious interpretation of the results is warranted (Lercher et al. 1998).

Prospective studies that controlled for confounding factors suggest an increase in ischaemic heart disease when the noise levels exceed 65–70 dB for LAeq (6–22). (For road traffic noise, the difference between LAeq (6-22h) and LAeq,24h usually is of the order of 1.5 dB). When orientation of the bedroom, window opening habits and years of exposure are taken into account, the risk of heart disease is slightly higher (Babisch et al. 1998; Babisch et al. 1999). However, disposition, behavioural and environmental factors were not sufficiently accounted for in the analyses carried out to date. In epidemiological studies the lowest level at which traffic noise had an effect on ischaemic heart disease was 70 dB for LAeq,24h (HCN 1994).

The overall conclusion is that cardiovascular effects are associated with long-term exposure to LAeq,24h values in the range of 65–70 dB or more, for both air- and road-traffic noise. However, the associations are weak and the effect is somewhat stronger for ischaemic heart disease than for hypertension. Nevertheless, such small risks are potentially important because a large number of persons are currently exposed to these noise levels, or are likely to be exposed in the future. Furthermore, only the average risk is considered and sensitive subgroups of the populations have not been sufficiently characterized. For example, a 10% increase in risk factors (a relative risk of 1.1) may imply an increase of up to 200 cases per 100 000 people at risk per year. Other observed psychophysiological effects, such as changes in stress hormones, magnesium levels, immunological indicators, and gastrointestinal disturbances are too inconsistent for conclusions to be drawn about the influence of noise pollution.

3.6. Mental Health Effects

Mental health is defined as the absence of identifiable psychiatric disorders according to current norms (Freeman 1984). Environmental noise is not believed to be a direct cause of mental illness, but it is assumed that it accelerates and intensifies the development of latent mental disorder. Studies on the adverse effects of environmental noise on mental health cover a variety of symptoms, including anxiety; emotional stress; nervous complaints; nausea; headaches; instability; argumentativeness; sexual impotency; changes in mood; increase in social conflicts, as well as general psychiatric disorders such as neurosis, psychosis and hysteria. Large-scale population studies have suggested associations between noise exposure and a variety of mental health indicators, such as single rating of well-being; standard psychological symptom profiles; the intake of psychotropic drugs; and consumption of tranquilizers and sleeping pills. Early studies showed a weak association between exposure to aircraft noise and psychiatric hospital admissions in the general population surrounding an airport (see also Berglund & Lindvall 1995). However, the studies have been criticized because of problems in selecting variables and in response bias (Halpern 1995).

Exposure to high levels of occupational noise has been associated with development of neurosis and irritability; and exposure to high levels of environmental noise with deteriorated mental health (Stansfeld 1992). However, the findings on environmental noise and mental health effects are inconclusive (HCN 1994; Berglund & Lindvall 1995; IEH 1997). The only longitudinal study in this field (Stansfeld et al. 1996) showed an association between the initial level of road traffic noise and minor psychiatric disorders, although the association for increased anxiety was weak and non-linear. It turned out that psychiatric disorders are associated with noise sensitivity, rather than with noise exposure, and the association was found to disappear after adjustment for baseline trait anxiety. These and other results show the importance of taking vulnerable groups into account, because they may not be able to cope sufficiently with unwanted environmental noise (e.g. Stansfeld 1992). This is particularly true of children, the elderly and people with preexisting illnesses, especially depression (IEH 1997). Despite the weaknesses of the various studies, the possibility that community noise has adverse effects on mental health is suggested by studies on the use of medical drugs, such as tranquilizers and sleeping pills, on psychiatric symptoms and on mental hospital admission rates.

3.7. The Effects of Noise on Performance

It has been documented in both laboratory subjects and in workers exposed to occupational noise, that noise adversely affects cognitive task performance. In children, too, environmental noise impairs a number of cognitive and motivational parameters (Cohen et al. 1980; Evans & Lepore 1993; Evans 1998; Hygge et al. 1998; Haines et al. 1998). However, there are no published studies on whether environmental noise at home also impairs cognitive performance in adults. Accidents may also be an indicator of performance deficits. The few field studies on the effects of noise on performance and safety showed that noise may produce some task impairment and increase the number of errors in work, but the effects depend on the type of noise and the task being performed (Smith 1990).

Laboratory and workplace studies showed that noise can act as a distracting stimulus. Also, impulsive noise events (e.g. sonic booms) may produce disruptive effects as a result of startle responses. In the short term, noise-induced arousal may produce better performance of simple tasks, but cognitive performance deteriorates substantially for more complex tasks (i.e. tasks that require sustained attention to details or to multiple cues; or tasks that demand a large capacity of working memory, such as complex analytical processes). Some of the effects are related to loss in auditory comprehension and language acquisition, but others are not (Evans & Maxwell 1997). Among the cognitive effects, reading, attention, problem solving and memory are most strongly affected by noise. The observed effects on motivation, as measured by persistence with a difficult cognitive task, may either be independent or secondary to the aforementioned cognitive impairments.

Two types of memory deficits have been identified under experimental noise exposure: incidental memory and memory for materials that the observer was not explicitly instructed to focus on during a learning phase. For example, when presenting semantic information to subjects in the presence of noise, recall of the information content was unaffected, but the subjects were significantly less able to recall, for example, in which corner of the slide a word had been located. There is also some evidence that the lack of "helping behavior" that was noted under experimental noise exposure may be related to inattention to incidental cues (Berglund & Lindvall 1995). Subjects appear to process information faster in working memory during noisy performance conditions, but at a cost of available memory capacity. For example, in a running memory task, in which subjects were required to recall in sequence letters that they had just heard, subjects recalled recent items better under noisy conditions, but made more errors farther back into the list.

Experimental noise exposure consistently produces negative after-effects on performance (Glass & Singer 1972). Following exposure to aircraft noise, schoolchildren in the vicinity of Los Angeles airport were found to be deficient in proofreading, and in persistence with challenging puzzles (Cohen et al. 1980). The uncontrollability of noise, rather than the intensity of the noise, appears to be the most critical variable. The only prospective study on noise-exposed schoolchildren, designed around the move of the Munich airport (Hygge et al. 1996; Evans et al. 1998), confirmed the results of laboratory and workplace studies in adults, as well the results of the Los Angeles airport study with children (Cohen et al. 1980). An important finding was that some of the adaptation strategies for dealing with aircraft noise, such as tuning out or ignoring the noise, and the effort necessary to maintain task performance, come at a price. There is heightened sympathetic arousal, as indicated by increased levels of stress hormone, and elevation of resting blood pressure (Evans et al. 1995; Evans et al. 1998). Notably, in the airport studies reported above, the adverse effects were larger in children with lower school achievement.

For aircraft noise, it has been shown that chronic exposure during early childhood appears to impair reading acquisition and reduces motivational capabilities. Of recent concern are concomitant psychophysiological changes (blood pressure and stress hormone levels). Evidence indicates that the longer the exposure, the greater the damage. It seems clear that daycare centers and schools should not be located near major sources of noise, such as highways, airports and industrial sites.

3.8. Effects of Noise on Residential Behaviour and Annoyance

Noise annoyance is a global phenomenon. A definition of annoyance is "a feeling of displeasure associated with any agent or condition, known or believed by an individual or group to adversely affect them" (Lindvall & Radford 1973; Koelega 1987). However, apart from "annoyance", people may feel a variety of negative emotions when exposed to community noise, and may report anger, disappointment, dissatisfaction, withdrawal, helplessness, depression, anxiety, distraction, agitation, or exhaustion (Job 1993; Fields et al. 1997 1998). Thus, although the term annoyance does not cover all the negative reactions, it is used for convenience in this document.

Noise can produce a number of social and behavioural effects in residents, besides annoyance (for review see Berglund & Lindvall 1995). The social and behavioural effects are often complex, subtle and indirect. Many of the effects are assumed to be the result of interactions with a number of non-auditory variables. Social and behavioural effects include changes in overt everyday behaviour patterns (e.g. closing windows, not using balconies, turning TV and radio to louder levels, writing petitions, complaining to authorities); adverse changes in social behaviour (e.g. aggression, unfriendliness, disengagement, non-participation); adverse changes in social indicators (e.g. residential mobility, hospital admissions, drug consumption, accident rates); and changes in mood (e.g. less happy, more depressed).

Although changes in social behaviour, such as a reduction in helpfulness and increased aggressiveness, are associated with noise exposure, noise exposure alone is not believed to be sufficient to produce aggression. However, in combination with provocation or pre-existing anger or hostility, it may trigger aggression. It has also been suspected that people are less willing to help, both during exposure and for a period after exposure. Fairly consistent evidence shows that noise above 80 dBA is associated with reduced helping behaviour and increased aggressive behaviour. Particularly, there is concern that high-level continuous noise exposures may contribute to the susceptibility of schoolchildren to feelings of helplessness (Evans & Lepore 1993)

The effects of community noise can be evaluated by assessing the extent of annoyance (low, moderate, high) among exposed individuals; or by assessing the disturbance of specific activities, such as reading, watching television and communication. The relationship between annoyance and activity disturbances is not necessarily direct and there are examples of situations where the extent of annoyance is low, despite a high level of activity disturbance. For aircraft noise, the most important effects are interference with rest, recreation and watching television. This is in contrast to road traffic noise, where sleep disturbance is the predominant effect (Berglund & Lindvall 1995).

A number of studies have shown that equal levels of traffic and industrial noises result in different magnitudes of annoyance (Hall et al. 1981; Griffiths 1983; Miedema 1993; Bradley 1994a; Miedema & Vos 1998). This has led to criticism (e.g. Kryter 1994; Bradley 1994a) of averaged dose-response curves determined by meta-analysis, which assumed that all traffic noises are the same (Fidell et al. 1991; Fields 1994a; Finegold et al. 1994). Schultz (1978) and Miedema & Vos (1998) have synthesized curves of annoyance associated with three types of traffic noise (road, air, railway). In these curves, the percentage of people highly or moderately annoyed was related to the day and night continuous equivalent sound level, L_{dn}. For each of the three types of traffic noise, the percentage of highly annoyed persons in a population started to increase at an L_{dn} value of 42 dBA, and the percentage of moderately annoyed persons at an L_{dn} value of 37 dBA (Miedema & Vos 1998). Aircraft noise produced a stronger annoyance response than road traffic, for the same L_{dn} exposure, consistent with earlier analyses (Kryter 1994; Bradley 1994a). However, caution should be exercised when interpreting synthesized data from different studies, since five major parameters should be randomly distributed for the analyses to be valid: personal, demographic, and lifestyle factors, as well as the duration of noise exposure and the population experience with noise (Kryter 1994).

Annoyance in populations exposed to environmental noise varies not only with the acoustical characteristics of the noise (source, exposure), but also with many non-acoustical factors of social, psychological, or economic nature (Fields 1993). These factors include fear associated with the noise source, conviction that the noise could be reduced by third parties, individual noise sensitivity, the degree to which an individual feels able to control the noise (coping strategies), and whether the noise originates from an important economic activity. Demographic variables such as age, sex and socioeconomic status, are less strongly associated with annoyance. The correlation between noise exposure and general annoyance is much higher at the group level than at the individual level, as might be expected. Data from 42 surveys showed that at the group level about 70% of the variance in annoyance is explained by noise exposure characteristics, whereas at the individual level it is typically about 20% (Job 1988).

When the type and amount of noise exposure is kept constant in the meta-analyses, differences between communities, regions and countries still exist (Fields 1990; Bradley 1996). This is well demonstrated by a comparison of the dose-response curve determined for road-traffic noise

(Miedema & Vos 1998) and that obtained in a survey along the North-South transportation route through the Austrian Alps (Lercher 1998b). The differences may be explained in terms of the influence of topography and meteorological factors on acoustical measures, as well as the low background noise level on the mountain slopes.

Stronger reactions have been observed when noise is accompanied by vibrations and contains low frequency components (Paulsen & Kastka 1995; Öhrström 1997; for review see Berglund et al. 1996), or when the noise contains impulses, such as shooting noise (Buchta 1996; Vos 1996; Smoorenburg 1998). Stronger, but temporary, reactions also occur when noise exposure is increased over time, in comparison to situations with constant noise exposure (e.g. HCN 1997; Klæboe et al. 1998). Conversely, for road traffic noise, the introduction of noise protection barriers in residential areas resulted in smaller reductions in annoyance than expected for a stationary situation (Kastka et al. 1995).

To obtain an indicator for annoyance, other methods of combining parameters of noise exposure have been extensively tested, in addition to metrics such as LAeq,24h and L_{dn}. When used for a set of community noises, these indicators correlate well both among themselves and with LAeq,24h or L_{dn} values (e.g. HCN 1997). Although LAeq,24h and L_{dn} are in most cases acceptable approximations, there is a growing concern that all the component parameters of the noise should be individually assessed in noise exposure investigations, at least in the complex cases (Berglund & Lindvall 1995).

3.9. The Effects of Combined Noise Sources

Many acoustical environments consist of sounds from more than one source. For these environments, health effects are associated with the total noise exposure, rather than with the noise from a single source (WHO 1980b). When considering hearing impairment, for example, the total noise exposure can be expressed in terms of LAeq,24h for the combined sources. For other adverse health effects, however, such a simple model most likely will not apply. It is possible that some disturbances (e.g. speech interference, sleep disturbance) may more easily be attributed to specific noises. In cases where one noise source clearly dominates, the magnitude of an effect may be assessed by taking into account the dominant source only (HCN 1997). Furthermore, at a policy level, there may be little need to identify the adverse effect of each specific noise, unless the responsibility for these effects is to be shared among several polluters (*cf.* The Polluter Pays Principle in Chapter 5, UNCED 1992).

There is no consensus on a model for assessing the total annoyance due to a combination of environmental noise sources. This is partly due to a lack of research into the temporal patterns of combined noises. The current approach for assessing the effects of "mixed noise sources" is limited to data on "total annoyance" transformed to mathematical principles or rules of thumb (Ronnebaum et al. 1996; Vos 1992; Miedema 1996; Berglund & Nilsson 1997). Models to assess the total annoyance of combinations of environmental noises may not be applicable to those health effects for which the mechanisms of noise interaction are unknown, and for which different cumulative or synergistic effects cannot be ruled out. When noise is combined with different types of environmental agents, such as vibrations, ototoxic chemicals, or chemical odours, again there is insufficient knowledge to accurately assess the combined effects on health

(Berglund & Lindvall 1995; HCN 1994; Miedema 1996; Zeichart 1998; Passchier-Vermeer & Zeichart 1998). Therefore, caution should be exercised when trying to predict the adverse health effects of combined factors in residential populations.

The evidence on low-frequency noise is sufficiently strong to warrant immediate concern. Various industrial sources emit continuous low-frequency noise (compressors, pumps, diesel engines, fans, public works); and large aircraft, heavy-duty vehicles and railway traffic produce intermittent low-frequency noise. Low-frequency noise may also produce vibrations and rattles as secondary effects. Health effects due to low-frequency components in noise are estimated to be more severe than for community noises in general (Berglund et al. 1996). Since A-weighting underestimates the sound pressure level of noise with low-frequency components, a better assessment of health effects would be to use C-weighting.

In residential populations heavy noise pollution will most certainly be associated with a combination of health effects. For example, cardiovascular disease, annoyance, speech interference at work and at home, and sleep disturbance. Therefore, it is important that the total adverse health load over 24 hours be considered and that the precautionary principle for sustainable development is applied in the management of health effects (see Chapter 5).

3.10. Vulnerable Groups

Protective standards are essentially derived from observations on the health effects of noise on "normal" or "average" populations. The participants of these investigations are selected from the general population and are usually adults. Sometimes, samples of participants are selected because of their easy availability. However, vulnerable groups of people are typically underrepresented. This group includes people with decreased personal abilities (old, ill, or depressed people); people with particular diseases or medical problems; people dealing with complex cognitive tasks, such as reading acquisition; people who are blind or who have hearing impairment; fetuses, babies and young children; and the elderly in general (Jansen 1987; AAP 1997). These people may be less able to cope with the impacts of noise exposure and be at greater risk for harmful effects.

Persons with impaired hearing are the most adversely affected with respect to speech intelligibility. Even slight hearing impairments in the high-frequency range may cause problems with speech perception in a noisy environment. From about 40 years of age, people typically demonstrate an impaired ability to understand difficult, spoken messages with low linguistic redundancy. Therefore, based on interference with speech perception, a majority of the population belongs to the vulnerable group.

Children have also been identified as vulnerable to noise exposure (see Agenda 21: UNCED 1992). The evidence on noise pollution and children's health is strong enough to warrant monitoring programmes at schools and preschools to protect children from the effects of noise. Follow up programmes to study the main health effects of noise on children, including effects on speech perception and reading acquisition, are also warranted in heavily noise polluted areas (Cohen et al. 1986; Evans et al. 1998).

The issue of vulnerable subgroups in the general population should thus be considered when developing regulations or recommendations for the management of community noise. This consideration should take into account the types of effects (communication, recreation, annoyance, etc.), specific environments (*in utero*, incubator, home, school, workplace, public institutions, etc.) and specific lifestyles (listening to loud music through headphones, or at discotheques and festivals; motor cycling, etc.).

4. Guideline Values

4.1. Introduction

The human ear and lower auditory system continuously receive stimuli from the world around us. However, this does not mean that all the acoustical inputs are necessarily disturbing or have harmful effects. This is because the auditory nerve provides activating impulses to the brain that enable us to regulate the vigilance and wakefulness necessary for optimal performance. On the other hand, there are scientific reports that a completely silent world can have harmful effects, because of sensory deprivation. Thus, both too little sound and too much sound can be harmful. For this reason, people should have the right to decide for themselves the quality of the acoustical environment they live in.

Exposure to noise from various sources is most commonly expressed as the average sound pressure level over a specific time period, such as 24 hours. This means that identical average sound levels for a given time period could be derived from either a large number of sound events with relatively low, almost inaudible levels, or from a few events with high sound levels. This technical concept does not fully agree with common experience on how environmental noise is experienced, or with the neurophysiological characteristics of the human receptor system.

Human perception of the environment through vision, hearing, touch, smell and taste is characterized by a good discrimination of stimulus intensity differences, and by a decaying response to a continuous stimulus (adaptation or habituation). Single sound events cannot be discriminated if the interval between events drops below a threshold value; if this occurs, the sound is interpreted as continuous. These characteristics are linked to survival, since new and different stimuli with low probability and high information value indicate warnings. Thus, when assessing the effects of environmental noise on people it is relevant to consider the importance of the background noise level, the number of events, and the noise exposure level independently.

Community noise studies have traditionally considered noise annoyance from single specific sources such as aircraft, road traffic or railways. In recent years, efforts have been made to compare the results from road traffic, aircraft and railway surveys. Data from a number of sources show that aircraft noise is more annoying than road traffic noise, which, in turn, is more annoying than railway noise. However, there is not a clear understanding of the mechanisms that create these differences. Some populations may also be at greater risk for the harmful effects of noise. Young children (especially during language acquisition), the blind, and perhaps fetuses are examples of such populations. There are no definite conclusions on this topic, but the reader should be alerted that guidelines in this report are developed for the population at large; guidelines for potentially more vulnerable groups are addressed only to a limited extent.

In the following, guideline values are summarized with regard to specific environments and effects. For each environment and situation, the guideline values take into consideration the identified health effects and are set, based on the lowest levels of noise that affect health (critical health effect). Guideline values typically correspond to the lowest effect level for general populations, such as those for indoor speech intelligibility. By contrast, guideline values for annoyance have been set at 50 or 55 dBA, representing daytime levels below which a majority of the adult population will be protected from becoming moderately or seriously annoyed, respectively.

In these *Guidelines for Community Noise* only guideline values are presented. These are essentially values for the onset of health effects from noise exposure. It would have been preferred to establish guidelines for exposure-response relationships. Such relationships would indicate the effects to be expected if standards were set above the WHO guideline values and would facilitate the setting of standards for sound pressure levels (noise immission standards). However, exposure-response relationships could not be established as the scientific literature is very limited. The best-studied exposure-response relationship is that between L_{dn} and annoyance (WHO 1995a; Berglund & Lindvall 1995; Miedema & Vos 1998). Even the most recent relationships between integrated noise levels and the percentage of highly or moderately annoyed people are still being scrutinized. The results of a forthcoming meta-analysis are expected to be published in the near future (Miedema, personal communication).

4.2. Specific Effects

4.2.1. Interference with communication

Noise tends to interfere with auditory communication, in which speech is a most important signal. However, it is also vital to be able to hear alarming and informative signals such as door bells, telephone signals, alarm clocks, fire alarms etc., as well as sounds and signals involved in occupational tasks. The effects of noise on speech discrimination have been studied extensively and deal with this problem in lexical terms (mostly words but also sentences). For communication distances beyond a few metres, speech interference starts at sound pressure levels below 50 dB for octave bands centered on the main speech frequencies at 500, 1 000 and 2 000 Hz. It is usually possible to express the relationship between noise levels and speech intelligibility in a single diagram, based on the following assumptions and empirical observations, and for speaker-to-listener distance of about 1 m:

a. Speech in relaxed conversation is 100% intelligible in background noise levels of about 35 dBA, and can be understood fairly well in background levels of 45 dBA.

b. Speech with more vocal effort can be understood when the background sound pressure level is about 65 dBA.

A majority of the population belongs to groups sensitive to interference with speech perception. Most sensitive are the elderly and persons with impaired hearing. Even slight hearing impairments in the high-frequency range may cause problems with speech perception in a noisy environment. From about 40 years of age, people demonstrate impaired ability to interpret difficult, spoken messages with low linguistic redundancy, when compared to people aged 20–30 years. It has also been shown that children, before language acquisition has been completed, have more adverse effects than young adults to high noise levels and long reverberation times.

For speech outdoors and for moderate distances, the sound level drops by approximately 6 dB for a doubling of the distance between speaker and listener. This relationship is also applicable to indoor conditions, but only up to a distance of about 2 m. Speech communication is affected also by the reverberation characteristics of the room, and reverberation times beyond 1 s can produce a loss in speech discrimination. A longer reverberation time combined with background noise makes speech perception still more difficult.

Speech signal perception is of paramount importance, for example, in classrooms or conference rooms. To ensure any speech communication, the signal-to-noise relationship should exceed zero dB. But when listening to complicated messages (at school, listening to foreign languages, telephone conversation) the signal-to-noise ratio should be at least 15 dB. With a voice level of 50 dBA (at 1 m distance this corresponds on average to a casual voice level in both women and men), the background level should not exceed 35 dBA. This means that in classrooms, for example, one should strive for as low background levels as possible. This is particularly true when listeners with impaired hearing are involved, for example, in homes for the elderly. Reverberation times below 1 s are necessary for good speech intelligibility in smaller rooms; and even in a quiet environment a reverberation time below 0.6 s is desirable for adequate speech intelligibility for sensitive groups.

4.2.2. Noise-induced hearing impairment

The ISO Standard 1999 (ISO 1990) gives a method of calculating noise-induced hearing impairment in populations exposed to all types of occupational noise (continuous, intermittent, impulse). However, noise-induced hearing impairment is by no means restricted to occupational situations alone. High noise levels can also occur in open-air concerts, discotheques, motor sports, shooting ranges, and from loudspeakers or other leisure activities in dwellings. Other loud noise sources, such as music played back in headphones and impulse noise from toys and fireworks, are also important. Evidence strongly suggests that the calculation method from ISO Standard 1999 for occupational noise (ISO 1990) should also be used for environmental and leisure time noise exposures. This implies that long term exposure to LAeq,24h of up to 70 dBA will not result in hearing impairment. However, given the limitations of the various underlying studies, care should be taken with respect to the following:

a. Data from animal experiments indicate that children may be more vulnerable in acquiring noise-induced hearing impairment than adults.

b. At very high instantaneous sound pressure levels mechanical damage to the ear may occur (Hanner & Axelsson 1988). Occupational limits are set at peak sound pressure levels of 140 dBA (EU 1986a). For adults, this same limit is assumed to be in order for exposure to environmental and leisure time noise. In the case of children, however, considering their habits while playing with noisy toys, peak sound pressure levels should never exceed 120 dBA.

c. For shooting noise with LAeq,24h over 80 dB, studies on temporary threshold shift suggest there is the possibility of an increased risk for noise-induced hearing impairment (Smoorenburg 1998).

d. The risk for noise-induced hearing impairment increases when noise exposure is combined with vibrations, ototoxic drugs or chemicals (Fechter 1999). In these circumstances, long-term exposure to LAeq,24h of 70 dB may induce small hearing impairments.

e. It is uncertain whether the relationships in ISO Standard 1999 (ISO 1990) are applicable to environmental sounds having a short rise time. For example, in the case of military low-altitude flying areas (75–300 m above ground) LAmax values of 110–130 dB occur within seconds after onset of the sound.

In conclusion, dose-response data are lacking for the general population. However, judging from the limited data for study groups (teenagers, young adults and women), and on the assumption that time of exposure can be equated with sound energy, the risk for hearing impairment would be negligible for LAeq,24h values of 70 dB over a lifetime. To avoid hearing impairment, impulse noise exposures should never exceed a peak sound pressure of 140 dB peak in adults, and 120 dB in children.

4.2.3. Sleep disturbance effects

Electrophysiological and behavioral methods have demonstrated that both continuous and intermittent noise indoors lead to sleep disturbance. The more intense the background noise, the more disturbing is its effect on sleep. Measurable effects on sleep start at background noise levels of about 30 dB LAeq. Physiological effects include changes in the pattern of sleep stages, especially a reduction in the proportion of REM sleep. Subjective effects have also been identified, such as difficulty in falling asleep, perceived sleep quality, and adverse after-effects such as headache and tiredness. Sensitive groups mainly include elderly persons, shift workers and persons with physical or mental disorders.
Where noise is continuous, the equivalent sound pressure level should not exceed 30 dBA indoors, if negative effects on sleep are to be avoided. When the noise is composed of a large proportion of low-frequency sounds a still lower guideline value is recommended, because low-frequency noise (e.g. from ventilation systems) can disturb rest and sleep even at low sound pressure levels. It should be noted that the adverse effect of noise partly depends on the nature of the source. A special situation is for newborns in incubators, for which the noise can cause sleep disturbance and other health effects.

If the noise is not continuous, LAmax or SEL are used to indicate the probability of noise-induced awakenings. Effects have been observed at individual LAmax exposures of 45 dB or less. Consequently, it is important to limit the number of noise events with a LAmax exceeding 45 dB. Therefore, the guidelines should be based on a combination of values of 30 dB LAeq,8h and 45 dB LAmax. To protect sensitive persons, a still lower guideline value would be preferred when the background level is low. Sleep disturbance from intermittent noise events increases with the maximum noise level. Even if the total equivalent noise level is fairly low, a small number of noise events with a high maximum sound pressure level will affect sleep.

Therefore, to avoid sleep disturbance, guidelines for community noise should be expressed in terms of equivalent sound pressure levels, as well as LAmax/SEL and the number of noise events. Measures reducing disturbance during the first part of the night are believed to be the most effective for reducing problems in falling asleep.

4.2.4. Cardiovascular and psychophysiological effects

Epidemiologial studies show that cardiovascular effects occur after long-term exposure to noise (aircraft and road traffic) with LAeq,24h values of 65–70 dB. However, the associations are weak. The association is somewhat stronger for ischaemic heart disease than for hypertension. Such small risks are important, however, because a large number of persons are currently exposed to these noise levels, or are likely to be exposed in the future. Other possible effects, such as changes in stress hormone levels and blood magnesium levels, and changes in the immune system and gastro-intestinal tract, are too inconsistent to draw conclusions. Thus, more research is required to estimate the long-term cardiovascular and psychophysiological risks due to noise. In view of the equivocal findings, no guideline values can be given.

4.2.5. Mental health effects

Studies that have examined the effects of noise on mental health are inconclusive and no guideline values can be given. However, in noisy areas, it has been observed that there is an increased use of prescription drugs such as tranquilizers and sleeping pills, and an increased frequency of psychiatric symptoms and mental hospital admissions. This strongly suggests that adverse mental health effects are associated with community noise.

4.2.6. Effects on performance

The effects of noise on task performance have mainly been studied in the laboratory and to some extent in work situations. But there have been few, if any, detailed studies on the effects of noise on human productivity in community situations. It is evident that when a task involves auditory signals of any kind, noise at an intensity sufficient to mask or interfere with the perception of these signals will also interfere with the performance of the task. A novel event, such as the start of an unfamiliar noise, will also cause distraction and interfere with many kinds of tasks. For example, impulsive noises such as sonic booms can produce disruptive effects as the result of startle responses; and these types of responses are more resistant to habituation.

Mental activities involving high load in working memory, such as sustained attention to multiple cues or complex analysis, are all directly sensitive to noise and performance suffers as a result. Some accidents may also be indicators of noise-related effects on performance. In addition to the direct effects on performance, noise also has consistent after-effects on cognitive performance with tasks such as proof-reading, and on persistence with challenging puzzles. In contrast, the performance of tasks involving either motor or monotonous activities is not always degraded by noise.

Chronic exposure to aircraft noise during early childhood appears to damage reading acquisition. Evidence indicates that the longer the exposure, the greater the damage. Although there is insufficient information on these effects to set specific guideline values, it is clear that day-care centres and schools should not be located near major noise sources, such as highways, airports and industrial sites.

4.2.7. Annoyance responses

The capacity of a noise to induce annoyance depends upon many of its physical characteristics, including its sound pressure level and spectral characteristics, as well as the variations of these properties over time. However, annoyance reactions are sensitive to many non-acoustical factors of social, psychological or economic nature, and there are also considerable differences in individual reactions to the same noise. Dose-response relations for different types of traffic noise (air, road and railway) clearly demonstrate that these noises can cause different annoyance effects at equal LAeq,24h values. And the same type of noise, such as that found in residential areas around airports, can also produce different annoyance responses in different countries.

The annoyance response to noise is affected by several factors, including the equivalent sound pressure level and the highest sound pressure level of the noise, the number of such events, and the time of day. Methods for combining these effects have been extensively studied. The results are not inconsistent with the simple, physically based equivalent energy theory, which is represented by the LAeq noise index.

Annoyance to community noise varies with the type of activity producing the noise. Speech communication, relaxation, listening to radio and TV are all examples of noise-producing activities. During the daytime, few people are seriously annoyed by activities with LAeq levels below 55 dB; or moderately annoyed with LAeq levels below 50 dB. Sound pressure levels during the evening and night should be 5–10 dB lower than during the day. Noise with low-frequency components require even lower levels. It is emphasized that for intermittent noise it is necessary to take into account the maximum sound pressure level as well as the number of noise events. Guidelines or noise abatement measures should also take into account residential outdoor activities.

4.2.8. Effects on social behaviour

The effects of environmental noise may be evaluated by assessing the extent to which it interferes with different activities. For many community noises, interference with rest, recreation and watching television seem to be the most important issues. However, there is evidence that noise has other effects on social behaviour: helping behaviour is reduced by noise in excess of 80 dBA; and loud noise increases aggressive behavior in individuals predisposed to aggressiveness. There is concern that schoolchildren exposed to high levels of chronic noise could be more susceptible to helplessness. Guidelines on these issues must await further research.

4.3. Specific Environments

Noise measures based solely on LAeq values do not adequately characterize most noise environments and do not adequately assess the health impacts of noise on human well-being. It is also important to measure the maximum noise level and the number of noise events when deriving guideline values. If the noise includes a large proportion of low-frequency components, values even lower than the guideline values will be needed, because low-frequency components in noise may increase the adverse effects considerably. When prominent low-frequency components are present, measures based on A-weighting are inappropriate. However, the difference between dBC (or dBlin) and dBA will give crude information about the presence of low-frequency components in noise. If the difference is more than 10 dB, it is recommended that a frequency analysis of the noise be performed.

4.3.1. Dwellings

In dwellings, the critical effects of noise are on sleep, annoyance and speech interference. To avoid sleep disturbance, indoor guideline values for bedrooms are 30 dB LAeq for continuous noise and 45 dB LAmax for single sound events. Lower levels may be annoying, depending on the nature of the noise source. The maximum sound pressure level should be measured with the instrument set at "*Fast*".

To protect the majority of people from being seriously annoyed during the daytime, the sound pressure level on balconies, terraces and outdoor living areas should not exceed 55 dB LAeq for a steady, continuous noise. To protect the majority of people from being moderately annoyed during the daytime, the outdoor sound pressure level should not exceed 50 dB LAeq. These values are based on annoyance studies, but most countries in Europe have adopted 40 dB LAeq as the maximum allowable level for new developments (Gottlob 1995). Indeed, the lower value should be considered the maximum allowable sound pressure level for all new developments whenever feasible.

At night, sound pressure levels at the outside façades of the living spaces should not exceed 45 dB LAeq and 60 dB LAmax, so that people may sleep with bedroom windows open. These values have been obtained by assuming that the noise reduction from outside to inside with the window partly open is 15 dB.

4.3.2. Schools and preschools

For schools, the critical effects of noise are on speech interference, disturbance of information extraction (e.g. comprehension and reading acquisition), message communication and annoyance. To be able to hear and understand spoken messages in classrooms, the background sound pressure level should not exceed 35 dB LAeq during teaching sessions. For hearing impaired children, an even lower sound pressure level may be needed. The reverberation time in the classroom should be about 0.6 s, and preferably lower for hearing-impaired children. For assembly halls and cafeterias in school buildings, the reverberation time should be less than 1 s. For outdoor playgrounds, the sound pressure level of the noise from external sources should not exceed 55 dB LAeq, the same value given for outdoor residential areas in daytime.

For preschools, the same critical effects and guideline values apply as for schools. In bedrooms in preschools during sleeping hours, the guideline values for bedrooms in dwellings should be used.

4.3.3. Hospitals

For most spaces in hospitals, the critical effects of noise are on sleep disturbance, annoyance and communication interference, including interference with warning signals. The LAmax of sound events during the night should not exceed 40 dB indoors. For wardrooms in hospitals, the guideline values indoors are 30 dB LAeq, together with 40 dB LAmax during the night. During the day and evening the guideline value indoors is 30 dB LAeq. The maximum level should be measured with the instrument set at "*Fast*".

Since patients have less ability to cope with stress, the equivalent sound pressure level should not exceed 35 dB LAeq in most rooms in which patients are being treated or observed. Particular attention should be given to the sound pressure levels in intensive care units and operating theatres. Sound inside incubators may result in health problems, including sleep disturbance, and may lead to hearing impairment in neonates. Guideline values for sound pressure levels in incubators must await future research.

4.3.4. Ceremonies, festivals and entertainment events

In many countries, there are regular ceremonies, festivals and other entertainment to celebrate life events. Such events typically produce loud sounds including music and impulsive sounds. There is widespread concern about the effect of loud music and impulse sounds on young people who frequently attend concerts, discotheques, video arcades, cinemas, amusement parks and spectator events, etc. The sound pressure level is typically in excess of 100 dB LAeq. Such a noise exposure could lead to significant hearing impairment after frequent attendance.

Noise exposure for employees of these venues should be controlled by established occupational standards. As a minimum, the same standards should apply to the patrons of these premises. Patrons should not be exposed to sound pressure levels greater than 100 dB LAeq during a 4-h period, for at most four times per year. To avoid acute hearing impairment the LAmax should always be below 110 dB.

4.3.5. Sounds through headphones

To avoid hearing impairment in both adults and children from music and other sounds played back in headphones, the LAeq,24h should not exceed 70 dB. This implies that for a daily one-hour exposure the LAeq should not exceed 85 dB. The exposures are expressed in free-field equivalent sound pressure levels. To avoid acute hearing impairment, the LAmax should always be below 110 dB.

4.3.6. Impulsive sounds from toys, fireworks and firearms

To avoid acute mechanical damage to the inner ear, adults should never be exposed to more than 140 dB peak sound pressure. To account for the vulnerability in children, the peak sound pressure level produced by toys should not surpass 120 dB, measured close to the ears (100 mm). To avoid acute hearing impairment, LAmax should always be below 110 dB.

4.3.7. Parkland and conservation areas

Existing large quiet outdoor areas should be preserved and the signal-to-noise ratio kept low.

4.4. WHO Guideline Values

The WHO guideline values in Table 4.1 are organized according to specific environments. When multiple adverse health effects are identified for a given environment, the guideline values are set at the level of the lowest adverse health effect (the critical health effect). An adverse health effect of noise refers to any temporary or long-term deterioration in physical, psychological or social functioning that is associated with noise exposure. The guideline values represent the sound pressure levels that affect the most exposed receiver in the listed environment.

The time base for LAeq for "daytime" and "night-time" is 16 h and 8 h, respectively. No separate time base is given for evenings alone, but typically, guideline value should be 5 –10 dB lower than for a 12 h daytime period. Other time bases are recommended for schools, preschools and playgrounds, depending on activity.

The available knowledge of the adverse effects of noise on health is sufficient to propose guideline values for community noise for the following:

a. Annoyance.
b. Speech intelligibility and communication interference.
c. Disturbance of information extraction.
d. Sleep disturbance.
e. Hearing impairment.

The different critical health effects are relevant to specific environments, and guideline values for community noise are proposed for each environment. These are:

a. Dwellings, including bedrooms and outdoor living areas.
b. Schools and preschools, including rooms for sleeping and outdoor playgrounds.
c. Hospitals, including ward and treatment rooms.
d. Industrial, commercial shopping and traffic areas, including public addresses, indoors and outdoors.
e. Ceremonies, festivals and entertainment events, indoors and outdoors.
f. Music and other sounds through headphones.
g. Impulse sounds from toys, fireworks and firearms.

h. Outdoors in parkland and conservation areas.

It is not enough to characterize the noise environment in terms of noise measures or indices based only on energy summation (e.g. LAeq), because different critical health effects require different descriptions. Therefore, it is important to display the maximum values of the noise fluctuations, preferably combined with a measure of the number of noise events. A separate characterization of noise exposures during night-time would be required. For indoor environments, reverberation time is also an important factor. If the noise includes a large proportion of low frequency components, still lower guideline values should be applied.

Supplementary to the guideline values given in Table 4.1, precautionary recommendations are given in Section 4.2 and 4.3 for vulnerable groups, and for noise of a certain character (e.g. low-frequency components, low background noise), respectively. In Section 3.10, information is given regarding which critical effects and specific environments are considered relevant for vulnerable groups, and what precautionary noise protection would be needed in comparison to the general population.

Table 4.1: Guideline values for community noise in specific environments.

Specific environment	Critical health effect(s)	LAeq [dB]	Time base [hours]	LAmax, fast [dB]
Outdoor living area	Serious annoyance, daytime and evening Moderate annoyance, daytime and evening	55 50	16 16	- -
Dwelling, indoors Inside bedrooms	Speech intelligibility and moderate annoyance, daytime and evening Sleep disturbance, night-time	35 30	16 8	 45
Outside bedrooms	Sleep disturbance, window open (outdoor values)	45	8	60
School class rooms and pre-schools, indoors	Speech intelligibility, disturbance of information extraction, message communication	35	during class	-
Pre-school bedrooms, indoors	Sleep disturbance	30	sleeping -time	45
School, playground outdoor	Annoyance (external source)	55	during play	-
Hospital, ward rooms, indoors	Sleep disturbance, night-time Sleep disturbance, daytime and evenings	30 30	8 16	40 -
Hospitals, treatment rooms, indoors	Interference with rest and recovery	#1		
Industrial, commercial shopping and traffic areas, indoors and outdoors	Hearing impairment	70	24	110
Ceremonies, festivals and entertainment events	Hearing impairment (patrons:<5 times/year)	100	4	110
Public addresses, indoors and outdoors	Hearing impairment	85	1	110
Music through headphones/ earphones	Hearing impairment (free-field value)	85 #4	1	110
Impulse sounds from toys, fireworks and firearms	Hearing impairment (adults) Hearing impairment (children)	- -	- -	140 #2 120 #2
Outdoors in parkland and conservation areas	Disruption of tranquillity	#3		

#1: as low as possible;
#2: peak sound pressure (not LAmax, fast), measured 100 mm from the ear;
#3: existing quiet outdoor areas should be preserved and the ratio of intruding noise to natural background sound should be kept low;
#4: under headphones, adapted to free-field values

5. Noise Management

The goal of noise management is to maintain low noise exposures, such that human health and well-being are protected. The specific objectives of noise management are to develop criteria for the maximum safe noise exposure levels, and to promote noise assessment and control as part of environmental health programmes. This is not always achieved (Jansen 1998). The United Nations′ Agenda 21 (UNCED 1992), as well as the European Charter on Transport, Environment and Health (London Charter 1999), both support a number of environmental management principles on which government policies, including noise management policies, can be based. These include:

a. **The precautionary principle**. In all cases, noise should be reduced to the lowest level achievable in a particular situation. Where there is a reasonable possibility that public health will be damaged, action should be taken to protect public health without awaiting full scientific proof.

b. **The polluter pays principle**. The full costs associated with noise pollution (including monitoring, management, lowering levels and supervision) should be met by those responsible for the source of noise.

c. **The prevention principle**. Action should be taken where possible to reduce noise at the source. Land-use planning should be guided by an environmental health impact assessment that considers noise as well as other pollutants.

The government policy framework is the basis of noise management. Without an adequate policy framework and adequate legislation it is difficult to maintain an active or successful noise management programme. A policy framework refers to transport, energy, planning, development and environmental policies. The goals are more readily achieved if the interconnected government policies are compatible, and if issues which cross different areas of government policy are co-ordinated.

5.1. Stages in Noise Management

A legal framework is needed to provide a context for noise management (Finegold 1998; Hede 1998a). While there are many possible models, an example of one is given in Figure 5.1. This model depicts the six stages in the process for developing and implementing policies for community noise management. For each policy stage, there are groups of 'policy players' who ideally would participate in the process.

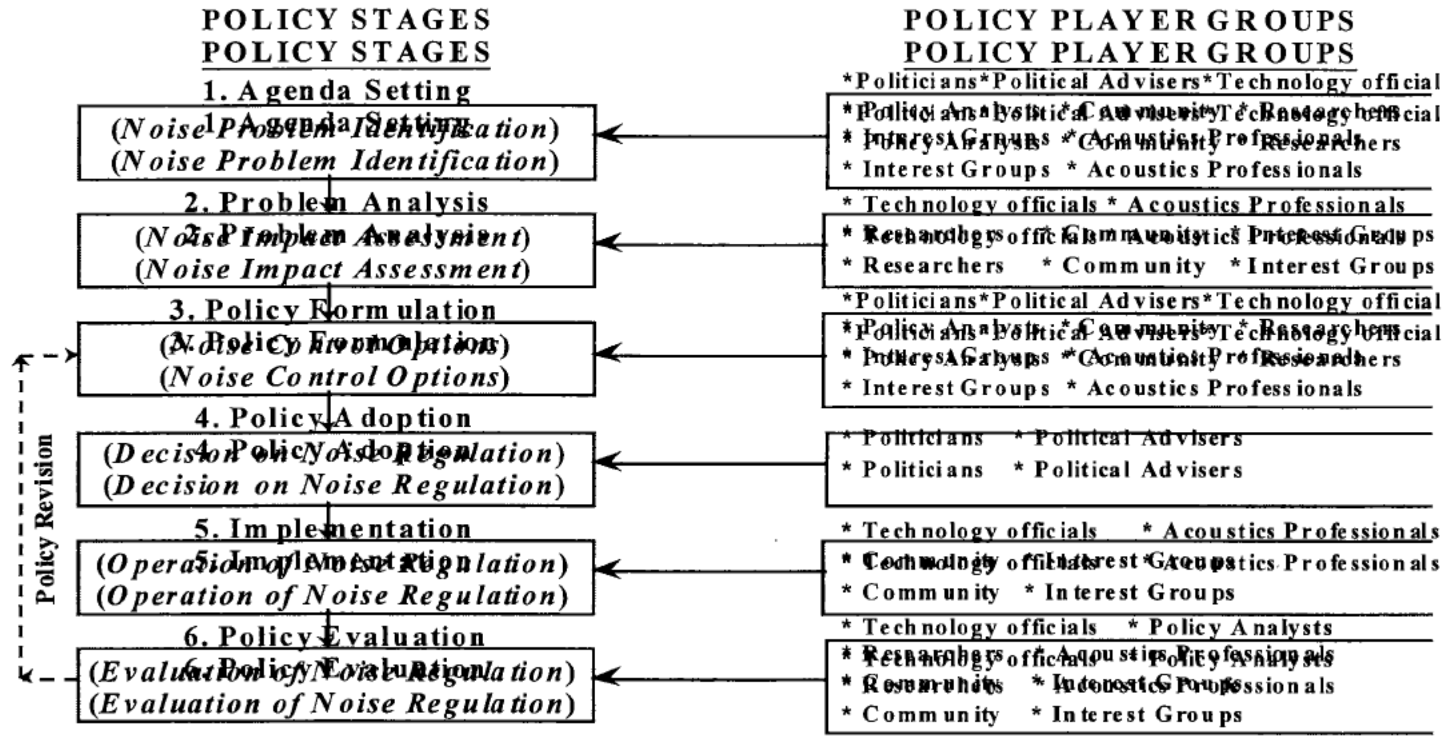

Figure 5.1. A model of the policy process for community noise management (Hede 1998a)

When goals and policies have been developed, the next stage is the development of the strategy or plan. Figure 5.2 summarizes the stages involved in the development of a noise management strategy. Specific abatement measures 19 are listed in Table 5.1.

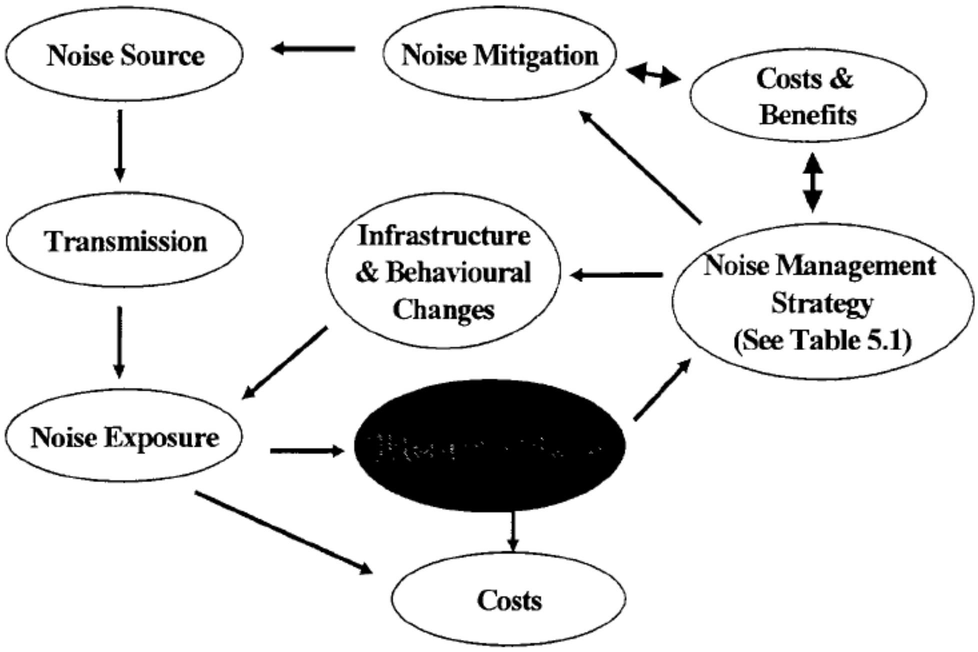

Figure 5.2. Stages involved in the development of a noise abatement strategy.

Table 5.1. Recommended Noise Management Measures (following EEA 1995)

Legal measures	Examples
Control of noise emissions	Emission standards for road and off-road vehicles; emission standards for construction equipment; emission standards for plants; national regulations, EU Directives
Control of noise transmission	Regulations on sound-obstructive measures
Noise mapping and zoning around roads, airports, industries	Initiation of monitoring and modeling programmes
Control of noise immissions	Limits for exposure levels such as national immission standards; noise monitoring and modeling; regulations for complex noise situations; regulations for recreational noise
Speed limits	Residential areas; hospitals
Enforcement of regulations	Low Noise Implementation Plan
Minimum requirements for acoustical properties of buildings	Construction codes for sound insulation of building parts
Engineering Measures	
Emission reduction by source modification	Tyre profiles; low-noise road surfaces; changes in engine properties
New engine technology	Road vehicles; aircraft; construction machines
Transmission reduction	Enclosures around machinery; noise screens
Orientation of buildings	Design and structuring of tranquille uses; using buildings for screening purposes
Traffic management	Speed limits; guidance of traffic flow by electronic means
Passive protection	Ear plugs; ear muffs; insulation of dwellings; façade design
Implementation of land-use planning	Minimum distance between industrial, busy roads and residential areas; location of tranquillity areas; by-pass roads for heavy traffic; separating out incompatible functons
Education and information	
Raising public awareness	Informing the public on the health impacts of noise, enforcement action taken, noise levels, complaints
Monitoring and modeling of soundscapes	Publication of results
Sufficient number of noise experts	University or highschool curricula
Initiation of research and development	Funding of information generation according to scientific research needs
Initiation of behaviour changes	Speed reduction when driving; use of horns; use of loudspeakers for advertisements

The process outlined in Figure 5.2 can start with the development of noise standards or guidelines. Ideally, it should also involve the identification and mapping of noise sources and exposed communities. Meteorological conditions and noise levels would also normally be monitored. These data can be used to validate the output of models that estimate noise levels. Noise standards and model outputs may be considered in devising noise control tactics aimed at achieving the noise standards. Before being enforced, current control tactics need to be revised, and if the standards are achieved they need continued enforcement. If the standards are not achieved after a reasonable period of time, the noise control tactics may need to be revised.

National noise standards can usually be based on a consideration of international guidelines, such as these Guidelines for Community Noise, as well as national criteria documents, which consider dose-response relations for the effects of noise on human health. National standards take into account the technological, social, economic, political and other factors specific for the country.

In many cases monitoring may show that noise levels are considerably higher than established guidelines. This may be particularly true in developing countries, and the question has to be raised as to whether national standards should reflect the optimum levels needed to protect human health, when this objective is unlikely to be achieved in the short- or medium-term with available resources. In some countries noise standards are set at levels that are realistically attainable under prevailing technological, social, economic and political conditions, even though they may not be fully consistent with the levels needed to protect human health. In such cases, a staged programme of noise abatement should be implemented to achieve the optimum health protection levels over the long term. Noise standards periodically change after reviews, as conditions in a country change over time, and with improved scientific understanding of the relationship between noise pollution and the health of the population. Noise level monitoring (Chapter 2) is used to assess whether noise levels at particular locations are in compliance with the standards selected.

5.2. Noise Exposure Mapping

A crucial component of a low-noise implementation plan is a reasonably quantitative knowledge of exposure (see Figure 5.2). Exposure should be mapped for all noise sources impacting a community; for example, road traffic, aircraft, railway, industry, construction, festivals and human activity in general. For some components of a noise exposure map or noise exposure inventory, accurate data may be available. In other cases, exposure can be calculated from the characteristics of the mechanical processes. While estimates of noise emissions are needed to develop exposure maps, measurements should be undertaken to confirm the veracity of the assumptions used in the estimates. Sample surveys may be used to provide an overall picture of the noise exposure. Such surveys would take account of all the relevant characteristics of the noise source. For example motor vehicle emissions may be estimated by calculations involving the types of vehicles, their number, their age and the characteristic properties of the road surface.

In developing countries, there is usually a lack of appropriate statistical information to produce noise exposure estimates. However, where action is needed to lower noise levels, the absence of comprehensive information should not prevent the development of provisional noise exposure estimates. Basic information about the exposed population, transport systems, industry and other relevant factors can be used to calculate provisional noise exposures. These can then be used to develop and implement interim noise management plans. The preliminary exposure estimates can be revised as more accurate information becomes available.

5.3. Noise Exposure Modeling

As indicated in Chapter 2 modeling is a powerful tool for the interpolation, prediction and optimization of control strategies. However, models need to be validated by monitoring data. A strength of models is that they enable examination and comparison of the consequences for noise exposure of the implementation of the various options for improving noise. However, the accuracy of the various models available depends on many factors, including the accuracy of the source emissions data and details of the topography (for which a geographical information system may be used). For transportation noise parameters such as the number, type and speed of vehicles, aircraft or trains, and the noise characteristics of each individual event must be known. An example of a model is the annoyance prediction model of the Government of the Netherlands (van den Berg 1996).

5.4. Noise Control Approaches

An integrated noise policy should include several control procedures: measures to limit the noise at the source, noise control within the sound transmission path, protection at the receiver's site, land-use planning, education and raising of public awareness. Ideally, countries should give priority to precautionary measures that prevent noise, but they must also implement measures to mitigate existing noise problems.

5.4.1. Mitigation measures

The most effective mitigation measure is to reduce noise emissions at the source. Therefore, regulations with noise level limits for the main noise sources should be introduced.

Road traffic noise. Limits on the noise emission of vehicles have been introduced in many countries (Sandberg 1995). Such limits, together with the relevant measuring methods, should also be introduced in other regions of the world. Besides these limits a special class of "low-noise trucks" has been introduced in Europe. These trucks follow state-of-the-art noise control and are widely used in Austria and Germany (Lang 1995). Their use is encouraged by economic incentives; for example, low-noise trucks are excepted from a night-time ban on certain routes, and their associated taxes are lower than for other trucks. In Europe, the maximum permissible noise levels range from 69 dBA for motor vehicles to 77 dBA for cars, and 83 dBA for heavy two-wheeled vehicles to 84 dBA for trucks. A number of European Directives give permissible sound levels for motor vehicles and motorcycles (EU 1970; EU 1978; EU 1996a; EU 1997). In addition to noise level limits for new vehicles (type test), noise emissions of vehicles already in use should be controlled regularly. Limits on the sound pressure levels for vehicles reduce the noise emission from the engines.

However, the main noise from traffic on highways is rolling noise. This may be reduced by quiet road surfaces (porous asphalt, "drain asphalt") or by selection of quiet tires. Road traffic noise may also be reduced by speed limits, provided the limits are enforced. For example, reducing the speed of trucks from 90 to 60 km/h on concrete roads would reduce the maximum sound pressure level by 5 dB, and the equivalent sound pressure level by 4 dB. Decreasing the speed of cars from 140 to 100 km/h would result in the same noise reduction (WHO 1995a). In the central parts of cities a speed limit of 30 km/h may be introduced. At 30 km/h cars produce maximum sound pressure levels that are 7 dB lower, and equivalent sound pressure levels that are 5 dB lower, than cars driving at 50 km/h.

Noise emission from road traffic may be further reduced by a night-time ban for all vehicles, or especially for heavy vehicles. Traffic management designed to ensure uniform traffic flow in towns also serves to reduce noise. "Low-noise behaviour" of drivers should be encouraged as well, by advocating defensive driving manners. In some countries, car drivers use their horns frequently, which results in noise with high peak levels. The unnecessary use of horns within cities should be forbidden, especially during night-time, and this rule should be enforced.

Railway noise and noise from trams. The main noise sources are the engine and the wheel-rail contact. Noise at the source can be reduced by well-maintained rails and wheels, and by the use of disc brakes. Sound pressure levels may vary by more than 10 dB, depending on the type of railway material. Replacement of steel wheels by rubber wheels could also reduce noise from railways and trams substantially. Other measures include innovations in engine and track technology (Moehler 1988; Öhrström & Skånberg 1996).

Aircraft noise. The noise emission of aircraft is limited by ICAO Annex 16, Chapter 2 and Chapter 3, which estimates maximum potential sound emissions under certification procedures (ICAO 1993). Aircraft following the norms of Chapter 3 represent the state-of-the-art of noise control of the 1970s. In many countries, non-certified aircraft (i.e. aircraft not fulfilling the ICAO requirements) are not permitted and Chapter 2 aircraft may not be registered again. After the year 2002 only Chapter 3 aircraft will be allowed to operate in many countries.

Similar legislation should be adopted in other countries. The use of low-noise aircraft may also be encouraged by setting noise-related charges (that is, landing charges that are related not only to aircraft weight and capacity, but also to noise emission). Examples of systems for noise-related financial charges are given in OECD 1991 (see also OECD-ECMT 1995). Night-time aircraft movements should be discouraged where they impact residential communities. Particular categories of aircraft (such as helicopters, rotorcraft and supersonic aircraft) pose additional problems that require appropriate controls. For subsonic airplanes two EU Directive give the permissible sound levels (EU 1980; EU 1989).

Machines and Equipment. Noise emission has to be considered a main property of all types of machines and equipment. Control measures include design, insulation, enclosure and maintenance.

Consumers should be encouraged to take noise emission into account when buying a product. Declaring the A-weighted sound power level of a product would assist the consumer in making this decision. The introduction of sound labeling is a major tool for reducing the noise emission of products on the market. For example, within the European Community, "permissible sound levels" and "sound power levels" have to be stated for several groups of machines; for example, lawn mowers, construction machines and household equipment (EU 1984a-f; EU 1986b,c). For other groups of machines sound level data have been compiled and are state-of-the-art with respect to noise control.

A second step would be the introduction of limits on the sound power levels for certain groups of machines, heating and ventilation systems (e.g. construction machines, household appliances). These limits may be set by law, in recommendations and by consumers, using state-of-the-art measurements. There have also been promising developments in the use of active noise control (involving noise cancellation techniques). These are to be encouraged.

Noise control within the sound transmission path. The installation of noise barriers can protect dwellings close to the traffic source. In several European countries noise barrier regulations have been established (WHO 1995b), but in practice they are often not adequately implemented. These regulations must define:

a. Measuring and calculation methods for deriving the equivalent sound pressure level of road or railway traffic, and schemes for determining the effectiveness of the barrier.

b. The sound pressure limits that are to be achieved by installing barriers.

c. The budgetary provisions.

d. The responsible authority.

Noise protection at the receiver's site. This approach is mainly used for existing situations. However, this approach must also be considered for new and, eventually, for old buildings in noisy areas. Residential buildings near main roads with heavy traffic, or near railway lines, may be provided with sound-proofed windows.

5.4.2. Precautionary measures

With careful planning, noise exposure can be avoided or reduced. A sufficient distance between residential areas and an airport will make noise exposure minimal, although the realization of such a situation is not always possible. Additional insulation of houses can help to reduce noise exposure from railroad and road traffic. For new buildings, standards or building codes should describe the positions of houses, as well as the ground plans of houses with respect to noise sources. The required sound insulation of the façades should also be described. Various countries have set standards for the maximum sound pressure levels in front of buildings and for the minimum sound insulation values required for façades.

Land use planning. Land use planning is one of the main tools for noise control and includes:

a. Calculation methods for predicting the noise impact caused by road traffic, railways, airports, industries and others.

b. Noise level limits for various zones and building types. The limits should be based on annoyance responses to noise.

c. Noise maps or noise inventories that show the existing noise situation. The construction of noise-sensitive buildings in noisy areas, or the construction of noisy buildings in quiet areas may thus be avoided.

Suggestions on how to use land use planning tools are given in several dedicated books (e.g. Miller & de Roo 1997). Different zones, such as quiet areas, hospitals, residential areas, commercial and industrial districts, can be characterized by the maximum equivalent sound pressure levels permissible in the zones. Examples of this approach can be found in OECD 1991 (also see OECD-ECMT 1995). More emphasis needs to be given to the design or retrofit of urban centres, with noise management as a priority (e.g. "soundscapes").

It is recommended that countries adopt the precautionary principle in their national noise policies. This principle should be applied to all noise situations where adverse noise effects are either expected or possible, even when the noise is below standard values.

Education and public awareness. Noise abatement policies can only be established if basic knowledge and background material is available, and the people and authorities are aware that noise is an environmental hazard that needs to be controlled. It is, therefore, necessary to include noise in school curricula and to establish scientific institutes to study acoustics and noise control. People working in such institutes should have the option of studying in other countries and exchanging information at international conferences. Dissemination of noise control information to the public is an issue for education and public awareness. Ideally, national and local advisory groups should be formed to promote the dissemination of information, to establish uniform methods of noise measurement and impact assessment, and to participate in the development and implementation of educational and public awareness programmes.

5.5. Evaluation of Control Options

Unless legal constraints in a country prescribe a particular option, the evaluation of control options must take into account technical, financial, social, health and environmental factors. The speed with which control options can be implemented, and their enforceability, must also be considered. Although considerable improvements in noise levels have been achieved in some developed countries, the financial costs have been high, and the resource demands of some of these approaches make them unsuitable for the poorer developing countries.

Technical factors. There needs to be confidence that the selected options are technically practical given the resources of the region. It must be possible to bring a selected option into operation, and maintain the expected level of performance in the long term, given the resources available. This may require regular staff training and other programmes, especially in developing countries.

Financial factors. The selected options must be financially viable in the long term. This may require a comparative cost-benefit assessment of different options. These assessments must include not only the capital costs of bringing an option into operation, but also the costs of maintaining the expected level of performance in the long term.

Social factors. The costs and benefits of each option should be assessed for social equity, and the potential impact of an option on people's way of life, community structures and cultural traditions must be considered. Impacts may include disruption or displacement of residents, changes of land-use, and impacts on community, culture and recreation. Some impacts can be managed; in other cases, the impacts of an option can be mitigated by substitution of resources or uses.

Health and environmental factors. The costs and benefits of each option should be assessed for health and environmental factors. This may involve use of dose-response relations, or risk assessment techniques.

Effect-oriented and source-oriented principles. Noise control requirements in European countries are typically determined from the effects of noise on health and the environment (effect oriented) (e.g. Gottlob 1995; ten Wolde 1998). Increased noise emissions may be permitted if there would be no adverse health impacts, or if noise standards would not be exceeded. Action may be taken to reduce noise levels when it is shown that adverse health impacts will occur, or when noise levels exceed limits. Other countries base their noise management policies on the requirement for best available technology, or for best available techniques that do not entail excessive cost (source-oriented) (e.g. for aircraft noise, ICAO 1993; for road traffic noise, Sandberg 1995). Most developed countries apply a combination of both source-oriented and effect-oriented principles (EU 1996b; Jansen 1998; ten Wolde 1998).

5.6. Management of Indoor Noise

In modern societies, human beings spend most of their time in indoor environments. Pollution and degradation of the indoor environment cause illness, increased mortality, loss of productivity, and have major economic and social implications. Indoor noise problems are related to inadequate urban planning, design, operation and maintenance of buildings, and to the materials and equipment in buildings. Problems with indoor noise affect all types of buildings, including homes, schools, offices, health care facilities and other public and commercial buildings. The health effects of indoor noise include an increase in the rates of diseases and disturbances described in chapter 2. World-wide, the medical and social cost associated with these illnesses, and the related reduction in human productivity, can result in substantial economic losses.

Protection against noise generated within a building, or originating from outside the building, is a very complex problem. Soundproofing of ceilings, walls, doors and windows against airborne noise is important. Soundproofing of ceilings has to be sufficient to absorb sounds due to treading. Finally, noise emissions from the technological devices in the house must be sufficiently low. Governments should provide measurement protocols and data for use in reducing noise exposures in buildings. Governments should also be encouraged to support research on the relationship between noise levels inside buildings and health effects.

5.6.1. Government policy on indoor noise

Many of the problems associated with high noise levels can be prevented at low cost if governments develop and implement an integrated strategy for the indoor environment, in concert with all social and economic partners. Governments should establish a "National Plan for a Sustainable Indoor Noise Environment", that would apply to new construction as well as to existing buildings. Governments should set up a specific structure at an appropriate governmental level to achieve acceptable sound exposure levels within buildings. An example of existing documents that provide guidance and regulations, including strategies and management for the design of buildings, is given by Jansen & Gottlob (1996).

Guidance/education. Because our understanding of indoor noise is still developing, government activity should be focused on raising the awareness of various audiences. This education can take the form of providing general information, as well as providing technical guidance and training on how to minimize indoor noise levels. General information presented in the form of documents, videos, and other media can bring indoor noise issues to the attention of the general public and building professionals, including architects

Research support. Research is needed to develop technology for indoor noise diagnosis, mitigation and control. Efforts are also required to provide economical and practical alternatives for mitigation and control. Better means of measuring the effectiveness of absorption devices are needed; and diagnostic tools that are inexpensive and easy to use also need to be developed to help facility personnel. There is a particular need, too, for improving soundproofing methods, their implementation and for predicting the health effects of soundproofing techniques.

To provide accurate information for use in setting priorities for public health problems, governments should support problem assessment and surveys of indoor noise conditions. Building surveys are also necessary to provide baseline information about building characteristics and noise levels. When combined with occupant health surveys, these studies will help to establish the correlations between noise levels and adverse health effects. Surveys should be conducted to identify building types or vintages in which problems occur more frequently. The results of these studies will support effective risk reduction programmes. Epidemiological studies are also needed to aid in differentiating between noise-related symptoms and those due to other causes. Moreover, epidemiological studies are needed to assist in quantifying the extent of risk for indoor noise levels.

Economic research is needed to measure the costs of indoor noise control strategies to individuals, businesses and society. This includes developing methods for quantifying productivity loss and increased health costs due to noise, and for measuring the costs of various control strategies, including increased soundproofing and source control.

Development of standards and protocols. Efforts should be made to protect public health by setting reasonable noise exposure limits (immission standards) from known dose-response relationships. In cases where dose-response relationships have yet to be determined, but where health effects are generally recognized, exposure limits should be set conservatively and take into account risk, economic impact and feasibility. Efforts should also be made to incorporate noise-related specifications into building codes. Areas to target with building codes include ventilation design, building envelope design, site preparation, materials selection and commissioning. Standards and other regulations governing the use of sound proofing materials should also be developed.

Individuals involved in the diagnosis and mitigation of indoor noise problems should be trained in the multidisciplinary nature of the noise field. By instituting a series of credentials that recognize and highlight areas of expertise, consumers would be provided with the information to make informed choices when procuring indoor noise services. Companies which provide such services should be officially accredited. Guidelines or standards for sound emissions of air-conditioners, power generators and other building devices, would also provide useful information for manufacturers, architects, design engineers, building managers and others who play a role in selecting products used indoors.

5.6.2. Design considerations

Site investigation. Potential sites should be evaluated to determine whether they are prone to indoor noise problems. This evaluation should be consistent with national and local land use planning guidelines. Sites should be investigated to determine past uses and whether any sources of sound remain as a result. The potential for outdoor noise being carried to the site from adjacent areas, such as busy streets, should also be evaluated.

Building design. Buildings should be designed to be soundproof, to improve control over indoor noise. Soundproofing requires that outside noise be prevented from entering the building, and this should be estimated as part of the architectural and engineering design process. When soundproofing for outdoor noise, the total indoor noise load and the desired quality of the indoor space should be considered. Adequate soundproofing against outdoor noise is important in residential as well as commercial properties, and should be re-evaluated when interior spaces are rebuilt or renovated.

Indoor Spaces. The architectural layout should aim to reduce noise and provide a good sound quality to the space. This would include designing indoor spaces to have sufficiently short reverberation times. Designers and contractors should be encouraged to use sound-absorbing materials that lead to lower indoor noise levels, and materials with the best sound-absorbing properties should be specified. However, use of these materials should not be the only solution (Harris 1991). Possible conflicts with other environmental demands should also be identified; for example, the special demands by allergic people.

5.6.3. Indoor noise level control

Building maintenance personnel should be trained to understand the indoor noise aspects of their work, and be aware of how their work can directly impact the health and comfort of occupants. Many maintenance activities directly affect indoor noise levels, and some may indicate potential problems. Preventive maintenance is essential for the building systems to operate correctly and to provide suitable comfort conditions and low indoor noise levels. Detailed maintenance logs should be kept for all equipment. A schedule should be developed for routine equipment checks and calibration of control system components. Selection of low-noise domestic products should encouraged as far as is possible.

5.6.4. Resolving indoor noise problems

Addressing occupant complaints and symptoms. When complaints are received from occupants of a building, the cognizant authority should be responsive. The initial investigation into the cause of the complaint may be conducted by the in-house management staff, and they should continue an investigation as far as possible. If necessary, they should be responsible for hiring an outside consultant

Building diagnostic procedures. After receiving complaints related to indoor noise levels, facility personnel or consultants should attempt to identify the cause of the problem through an iterative process of information collection and hypothesis testing. To begin, a walkthrough inspection of the building, including the affected areas and the mechanical systems serving these spaces is required. A walkthrough can provide information on the soundproofing system of the building, the sound pathways and sound sources. Visual indicators of sound sources and soundproofing malfunctions should be evaluated first. Symptom logs and schedules of building activities may provide enough additional information to resolve the problem.

If a walkthrough alone does not provide a solution, measurements of sound pressure levels at various locations should be taken, and indoor and ambient levels of noise pollution should be compared. As part of the investigation, the absorption characteristics of walls and ceilings should be evaluated. Sophisticated sampling methods may be necessary to provide proof of a problem to the building owner or other responsible party. The results may be used to confirm a hypothesis or ascertain the source of the indoor noise problem. Whenever a problem is discovered during the investigation, a remedy to the situation should be attempted and a determination made of whether the complaint has been resolved.

In some cases, it should be recognized that difficulties in interpreting the sampling results may exist. The costs of certain types of testing should also be taken into account. Simple, cost-effective screening methods should be developed to make sampling a more attractive option for both investigators and clients. Finally, it must be remembered that several factors cause symptoms similar to those induced by noise pollution. Examples include air pollutants, ergonomics, lighting, vibration and psychosocial factors. Consequently, any investigation of noise complaints should also evaluate non-noise factors.

5.7. Priority Setting in Noise Management

Priorities in noise management will differ between countries, according to policy objectives, needs and capabilities. Priority setting in noise management refers to prioritizing health risks and concentrating on the most important sources of noise. For effective noise management, the goals, policies and noise control schemes have to be defined. Goals for noise management include eliminating noise, or reducing noise to acceptable levels, and avoiding the adverse health effects of noise on human health. Policies for noise management encompass laws and regulations for setting noise standards and for ensuring compliance. The amount of information to be included in low-noise implementation plans and the use of cost-benefit comparisons also fall within the purview of noise management policies. Techniques for noise control include source control, barriers in noise pathways and receiver protection. Adequate calculation models for noise propagation, as well as programmes for noise monitoring, are part of an overall noise control scheme.

As emphasized above, a framework for a political, regulatory and administrative approach is required to guarantee the consistent and transparent promulgation of noise standards. This ensures a sound and practical framework for risk-reducing measures and for the selection of abatement strategies.

5.7.1. Noise policy and legislation

Noise is both a local and a global problem. Governments in every country have a responsibility to set up policies and legislation for controlling community noise. There is a direct relationship between the level of development in a country and the degree of noise pollution impacting its people. As a society develops, it increases its level of urbanization and industrialization, and the extent of its transportation system. Each of these developments brings an increase in noise load. Without appropriate intervention the noise impact on communities will escalate (see Figure 5.3). If governments implement only weak noise policies and regulations, they will not be able to prevent a continuous increase in noise pollution and associated adverse health effects. Failure to enforce strong regulations is ineffective in combating noise as well.

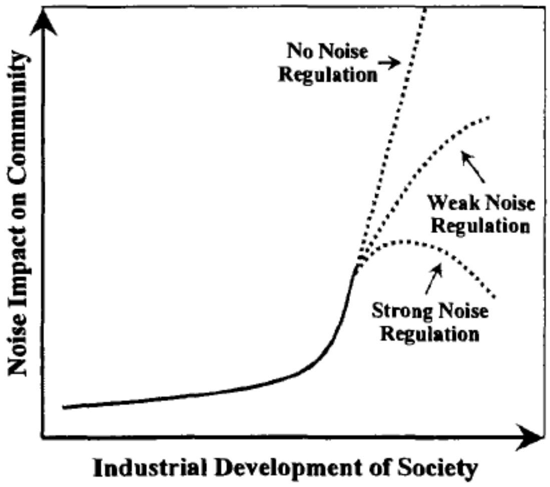

Figure 5.3. Relationship between noise regulation and impact with development (from Hede 1998b)

Policies for noise regulatory standards at the municipal, regional, national and supranational levels are usually determined by the legislatures. The regulatory standards adopted strongly depend on the risk management strategies of the legislatures, and can be influenced by sociopolitical considerations and/or international agreements. Although regulatory standards may be country specific, in general the following issues are taken into consideration:

a. Identification of the adverse public health effects that are to be avoided.

b. Identification of the population to be protected.

c. The type of parameters describing noise and the limit applicable to the parameters.

d. Applicable monitoring methodology and its quality assurance.

e. Enforcement procedures to achieve compliance with noise regulatory standards within a defined time frame.

f. Emission control measures and emission regulatory standards.

g. Immission standards (limits for sound pressure levels).

h. Identification of authorities responsible for enforcement.

i. Resource commitment.

Regulatory standards may be based solely on scientific and technical data showing the adverse effects of noise on public health. But other aspects are usually considered, either when setting standards or when designing appropriate noise abatement measures. These other aspects include the technological feasibility, costs of compliance, prevailing exposure levels, and the social, economic and cultural conditions. Several standards may be set. For example, effect-oriented regulatory standards may be set as a long-term goal, while less-stringent standards are adopted for the short term. As a consequence, noise regulatory standards differ widely from country to country (WHO 1995a; Gottlob 1995).

Noise regulatory standards can set the reference point for emission control and abatement policies at the national, regional or municipal levels, and can thus strongly influence the implementation of noise control policies. In many countries, exceeding regulatory standards is linked to an obligation to develop abatement action plans at the municipal, regional or national levels (low-noise implementation plans). Such plans have to address all relevant sources of noise pollution.

5.7.2. Examples of noise policies

Different countries have adopted a range of policies and regulations for noise control. A number of these are outlined in this section as examples.

Argentina. In Argentina, a national law recently limited the daily 8-h exposure to industrial noise to 80 dB, and it has had beneficial effects on hearing impairment and other hearing disorders among workers. In general, industry has responded by introducing constant controls on noise sources, combined with hearing tests and medical follow-ups for workers. Factory owners have recruited permanent health and safety engineers who control noise, supply advice on how to make further improvements, and routinely assess excessive noise levels. The engineers also provide education in personal protection and in the correct use of ear plugs, mufflers etc.

At the municipal level two types of noise have been considered. Unnecessary noise, which is forbidden; and excessive noise, which is defined for neighbourhood activities (zones), and for which both day and night-time maximum limits have been introduced. The results have been relatively successful in mitigating unwanted noise effects. At the provincial level, similar results have been accomplished for many cities in Argentina and Latin America.

Australia. In Australia, the responsibility for noise control is shared primarily by state and local governments. There are nationally-agreed regulatory standards for airport planning and new vehicle noise emissions. The Australian Noise Exposure Forecast (ANEF) index is used to describe how much aircraft noise is received at locations around an airport (DoTRS 1999). Around all airports, planning controls restrict the construction of dwellings within the 25 ANEF exposure contour and require sound insulation for those within 20 ANEF. Road traffic noise limits are set by state governments, but vary considerably in both the exposure metric and in maximum allowable levels. New vehicles are required to comply with stringent design rules for noise and air emissions. For example, new regulation in New South Wales adopts LAeq as the metric and sets noise limits of 60 dBA for daytime, and 55 dBA for night-time, along new roads. Local governments set regulations restricting noise emissions for household equipment, such as air conditioners, and the hours of use for noisy machines such as lawn mowers.

Europe. In Europe, noise legislation is not generally enforced. As a result, environmental noise levels are often higher than the legislated noise limits. Moreover, there is a gap between long-term political goals and what represents a "good acoustical environment". One reason for this gap is that noise pollution is most commonly regulated only for new land use or for the development of transportation systems, whereas enlargements at existing localities may be approved even though noise limits or guideline values are already surpassed (Gottlob 1995). A comprehensive overview of the noise situation in Europe is given in the Green Paper (EU 1996b), which was established to give noise abatement a higher priority in policy making. The Green Paper outlines a new framework for noise policy in Europe with the following options for future action:

a. Harmonizing the methods for assessing noise exposure, and encouraging the exchange of information among member states.

b. Establishing plans to reduce road traffic noise by applying newer technologies and fiscal instruments.

c. Paying more attention to railway noise in view of the future extension of rail networks.

d. Introducing more stringent regulation on air transport and using economic instruments to encourage compliance.

e. Simplifying the existing seven regulations on outdoor equipment by proposing a Framework Directive that covers a wider range of equipment, including construction machines and others.

Pakistan. In Pakistan, the Environmental Protection Agency is responsible for the control of air pollution nationwide. However, only recently have controls been enforced in Sindh in an attempt to raise public awareness and carry out administrative control on road vehicles producing noise (Zaidi, personal communication).

South Africa. In South Africa, noise control is three decades old. It began with codes of practice issued by the South African Bureau of Standards to address noise pollution in various sectors of the country (e.g. see SABS 1994 1996; and the contribution of Grond in Appendix 2). In 1989, the Environment Conservation Act made provision for the Minister of Environmental Affairs and Tourism to make regulations for noise, vibration and shock (DEAT 1989). These regulations were published in 1990 and local authorities could apply to the Minister to make them applicable in their areas. Later, the act was changed to make it obligatory for all authorities to apply the regulations. However, according to the new Constitution of South Africa of 1996, legislative responsibility for noise control rests exclusively with provincial and local authorities. The noise control regulations will apply to local authorities in South Africa as soon as they are published in the provinces. This will not only give local authorities the power to enforce the regulations, but also place an obligation on them to see that the regulations are enforced.

Thailand. In 1996, noise pollution regulations in Thailand stipulated that not more than 70 dBA LAeq,24h should be allowed in residential areas, and the maximum level of noise in industry should be no more than 85 dBA Leq 8h (Prasansuk 1997).

United States of America. Environmental noise was not addressed as a national policy issue in the USA until the implementation of the Noise Control Act of 1972. This congressional act directed the US Environmental Protection Agency to publish scientific information about noise exposure and its effects, and to identify acceptable levels of noise exposure under various conditions. The Noise Control Act was supposed to protect the public health and well-being with an adequate margin of safety. This was accomplished in 1974 with the publication of the US EPA "Levels Document" (US EPA 1974). It addressed issues such as the use of sound descriptions to describe sound exposure, the identification of the most important human effects resulting from noise exposure, and the specification of noise exposure criteria for various effects. Subsequent to the publication of the US EPA "Levels Document", guidelines for conducting environmental impact analysis were developed (Finegold et al. 1998). The day-night average sound level was thus established as the predominant sound descriptor for most environmental noise exposure.

It is evident from these examples that noise policies and regulations vary considerably across countries and regions. Moves towards global noise policies need to be encouraged to ensure that the world population gains the maximum health benefits from new developments in noise control.

5.7.3. Noise emission standards have proven to be inadequate

Much of the progress towards solving the noise pollution problem has come from advanced technology, which in turn has come about mainly as a result of governmental regulations (e.g. OECD-ECMT 1995). So far, however, the introduction of noise emission standards for vehicles has had limited impact on exposure to transportation noise, especially from aircraft and road traffic noise (Sandberg 1995). In part, this is because changes in human behaviour (of polluters, planners and citizens) have tended to offset some of the gains made. For example, mitigation efforts such as developing quieter vehicles, moving people to less noise-exposed areas, improving traffic systems and direct noise abatement and control (sound insulation, barriers etc.), have been counteracted by increases in the number of roads and highways built, by the number of traffic movements, and by higher driving speeds and the number of kilometers driven (OECD 1991; OECD-ECMT 1995).

Traffic planning and correction policies may diminish the number of people exposed to the very high community noise levels (>70 dB LAeq), but the number exposed to moderately high levels (55-65 dB LAeq) continues to increase in industrialized countries (Stanners & Bordeau 1995). In developing countries, exposure to excessive sound pressure levels (>85 dB LAeq), not only from occupational noise but also from urban, environmental noise, is the major avoidable cause of permanent hearing impairment (Smith 1998). Such sound pressure levels can also be reached by leisure activities at concerts, discotheques, motor sports and shooting ranges; by music played back in headphones; and by impulse noises from toys and fireworks.

A substantial growth in air transport is also expected in the future. Over the next 10 years large international airports may have to accommodate a doubling in passenger movements. General aviation noise at regional airports is also expected to increase (Large & House 1989). Although jet aircraft are expected to become less noisy due to regulation of noise emissions (ICAO 1993), the number of passengers is expected to increase. Increased air traffic movement between 1980 and 1990 is considered to be the main reason for the average 22% increase in the number of people exposed to noise above 67 dB LAeq at German airports (OECD 1993).

5.7.4. Unsustainable trends in noise pollution future policy planning

A number of trends are expected to increase environmental noise pollution, and are considered to be unsustainable in the long term. The OECD (1991) identified the following factors to be of increasing importance in the future:

a. The expanding use of increasingly powerful sources of noise.

b. The wider geographical dispersion of noise sources, together with greater individual mobility and spread of leisure activities.

c. The increasing invasion of noise, particularly into the early morning, evenings and weekends.

d. The increasing public expectations that are closely linked to increases in incomes and in education levels.

Apart from these, increased noise pollution is also linked to systemic changes in business practices (OECD-ECMT 1995). By accepting a just-in-time concept in transportation, products and components are stored in heavy-duty vehicles on roads, instead of in warehouses; and workers are recruited as temporary consultants just in time for the work, instead of as long-term employees.

In addition, the OECD (1991) report forecasts:

a. A strengthening of present noise abatement policies and their applications.

b. A further sharpening of emission standards.

c. A co-ordination of noise abatement measures and transport planning, to specifically reduce mobility.

d. A co-ordination of noise abatement measures with urban planning.

Planners need to know the likely effects of introducing a new noise source, or of increasing the level of an existing source, on the noise pollution in a community. Policy makers, when considering applications for new developmental projects, must take into account maximum levels, continuous equivalent sound pressure levels of both the background and the new noise source, the frequency of noise occurrence and the operating times of major noise sources.

5.7.5. Analysis of the impact of environmental noise

The concept of an environmental noise impact analysis (ENIA) is central to the philosophy of managing environmental noise. An ENIA should be required before implementing any project that would significantly increase the level of environmental noise in a community (typically, greater than a 5dB increase). The first step in performing an ENIA is to develop a baseline description of the existing noise environment. Next, the expected level of noise from a new source is added to the baseline exposure level to produce the new overall noise level. If the new total noise level is expected to cause an unacceptable impact on human health, trade-off analyses should then be performed to assess the cost, technical feasibility and community acceptance of noise mitigation measures. It is strongly recommended that countries develop standardized procedures for performing ENIAs (Finegold et al. 1998; SABS 1998).

Assessment of adverse health effects. In setting noise standards (for example on the basis of these guidelines), the adverse health effects from which the population is to be protected need to be defined. Health effects range from hearing impairment to sleep disturbance, speech interference to annoyance. The distinction between adverse and non-adverse effects sometimes poses considerable difficulties. Even the elaborate definition of an adverse health effect given in Chapter 3 incorporates significant subjectivity and uncertainty. More serious noise effects, such as hearing impairment or permanent threshold shift, are generally accepted as adverse. Consideration of health effects that are both temporary and reversible, or that involve functional changes with uncertain clinical significance, requires a judgement on whether these less-serious effects should be considered when deriving guideline values. Judgements as to the adversity of health effects may differ between countries, because of factors such as cultural backgrounds and different levels of health status.

Estimation of the population at risk. The population at risk is that part of the population in a given country or community that is exposed to enhanced levels of noise. Each population has sensitive groups or subpopulations that are at higher risk of developing health effects due to noise exposure. Sensitive groups include individuals impaired by concurrent diseases or other physiological limitations and those with specific characteristics that makes them more vulnerable to noise (e.g. premature babies; see the contribution of Zaidi in Appendix 2). The sensitive groups in a population may vary across countries due to differences in medical care, nutritional status, lifestyle and demographic factors, prevailing genetic factors, and whether endemic or debilitating diseases are prevalent.

Calculation of exposure-response relationships. In developing standards, regulators should consider the degree of uncertainty in the exposure-response relationships provided in the noise guidelines. Differences in the population structure (age, health status), climate (temperature, humidity) and geography (altitude, environment) can influence the prevalence and severity of noise-related health effects. In consequence, modified exposure-response relationships may need to be applied when setting noise standards.

Assessment of risks and their acceptability. In the absence of distinct thresholds for the onset of health effects, regulators must determine what constitutes an acceptable health risk for the population and select an appropriate noise standard to protect public health. This is also true in cases where thresholds are present, but where it would not be feasible to adopt noise guidelines as standards because of economical and/or technical constraints. The acceptability of the risks involved, and hence the standards selected, will depend on several factors. These include the expected incidence and severity of the potential effects, the size of the population at risk, the perception of related risks, and the degree of scientific uncertainty that the effects will occur at any given noise level. For example, if it is suspected that a health effect is severe and the size of the population at risk is large, a more cautious approach would be appropriate than if the effect were less troubling, or if the population were smaller.

Again, the acceptability of risk may vary among countries because of differences in social norms, and the degree of adversity and risk perception by the general population and stakeholders. Risk acceptability is also influenced by how the risks associated with noise compare with risks from other pollution sources or human activities.

5.7.6. Cost-benefit analysis

In the derivation of noise standards from noise guidelines two different approaches for decision making can be applied. Decisions can be based purely on health, cultural and environmental consequences, with little weight to economic efficiency. This approach has the objective of reducing the risk of adverse noise effects to a socially acceptable level. The second approach is based on a formal cost-effectiveness, or cost-benefit analysis (CBA). The objective is to identify control actions that achieve the greatest net economic benefit, or are the most economically efficient. The development of noise standards should account for both extremes, and involve stakeholders and assure social equity to all the parties involved. It should also provide sufficient information to guarantee that stakeholders understand the scientific and economic consequences.

To determine the costs of control action, the abatement measures used to reduce emissions must be known. This is usually the case for direct measures at the source and these measures can be monetarized. Costs of action should include all costs of investment, operation and maintenance. It may not be possible to monetarize indirect measures, such as alternative traffic plans or change in behaviour of individuals.

The steps in a cost-benefit analysis include:

a. The identification and cost analysis of control action (such as emission abatement strategies and tactics).

b. An assessment of noise and population exposure, with and without the control action.

c. The identification of benefit categories, such as improved health and reduced property loss.

d. A comparison of the health effects, with and without control action.

e. A comparison of the estimated costs of control action with the benefits that accrue from such action.

f. A sensitivity and uncertainty analysis.

Action taken to reduce one pollutant may increase or decrease the concentration of other pollutants. These additional effects should be considered, as well as pollutant interactions that may lead to double counting of costs or benefits, or to disregarding some costly but necessary action. Due to different levels of knowledge about the costs of control action and health effects, there is a tendency to overestimate the cost of control action and underestimate the benefits.

CBA is a highly interdisciplinary task. Appropriately applied, it is a legitimate and useful way of providing information for managers who must make decisions that impact health. CBA is also an appropriate tool for drawing the attention of politicians to the benefits of noise control. In any case, however, a CBA should be peer-reviewed and never be used as the sole and overriding determinant of decisions.

5.7.7. Review of standard setting

The setting of standards should involve stakeholders at all levels (industry, local authorities, non-governmental organizations and the general public), and should strive for social equity or fairness to all parties involved. It should also provide sufficient information to guarantee that the scientific and economic consequences of the proposed standards are clearly understood by the stakeholders. The earlier that stakeholders are involved, the more likely is their co-operation. Transparency in moving from noise guidelines to noise standards helps to increase public acceptance of necessary measures. Raising public awareness of noise-induced health effects (changing of risk perception) also leads to a better understanding of the issues involved (risk communication) and serves to obtain public support for necessary control action, such as reducing vehicle emissions. Noise standards should be regularly reviewed, and revised as new scientific evidence emerges.

5.7.8. Enforcement of noise standards: Low-noise implementation plans

The main objective of enforcing noise standards is to achieve compliance with the standards. The instrument used to achieve this goal is a Low-Noise Implementation Plan (LNIP). The outline of such a plan should be defined in the regulatory policies and should use the tactical instruments discussed above. A typical low-noise implementation plan includes:

a. A description of the area to be regulated.

b. An emissions inventory.

c. A monitored or simulated inventory of noise levels.

d. A comparison of the plan with emissions and noise standards or guidelines.

e. An inventory of the health effects.

f. A causal analysis of the health effects and their attribution to individual sources.

g. An analysis of control measures and their costs.

h. An analysis of transportation and land-use planning.

i. Enforcement procedures.

j. An analysis of the effectiveness of the noise management procedures.

k. An analysis of resource commitment.

l. Projections for the future.

As the LNIP also addresses the effectiveness of noise control technologies and policies, it is very much in line with the Noise Control Assessment Programme (NCAP) proposed recently (Finegold et al. 1999).

5.8. Conclusions on Noise Management

Successful noise management should be based on the fundamental principles of precaution, the polluter pays and prevention. The noise abatement strategy typically starts with the development of noise standards or guidelines, and the identification, mapping and monitoring of noise sources and exposed communities. A powerful tool in developing and applying the control strategy is to make use of modeling. These models need to be validated by monitoring data. Noise parameters relevant to the important sources of noise must be known. Indoor noise exposures present specific and complex problems, but the general principles for noise management hold. The main means for noise control in buildings include careful site investigations, adequate building designs and building codes, effective means for addressing occupant complaints and symptoms, and building diagnostic procedures.

Noise control should include measures to limit the noise at the source, to control the sound transmission path, to protect the receiver's site, to plan land use, and to raise public awareness. With careful planning, exposure to noise can be avoided or reduced. Control options should take into account the technical, financial, social, health and environmental factors of concern. Cost-benefit relationships, as well as the cost-effectiveness of the control measures, must be considered in the context of the social and financial situation of each country. A framework for a political, regulatory and administrative approach is required for the consistent and transparent promulgation of noise standards. Examples are given for some countries, which may guide others in their development of noise policies.

Noise management should:

a. Start monitoring human exposures to noise.

b. Have health control require mitigation of noise emissions. The mitigation procedures should take into consideration specific environments such as schools, playgrounds, homes and hospitals; environments with multiple noise sources, or which may amplify the effects of noise; sensitive time periods, such as evenings, nights and holidays; and groups at high risk, such as children and the hearing impaired.

c. Consider noise consequences when making decisions on transport-system and land-use planning.

d. Introduce surveillance systems for noise-related adverse health effects.

e. Assess the effectiveness of noise policies in reducing noise exposure and related adverse health effects, and in improving supportive "soundscapes."

a. Adopt these Guidelines for Community Noise as long-term targets for improving human health.

g. Adopt precautionary actions for sustainable development of acoustical environments.

6. Conclusions And Recommendations

6.1. Implementation of the Guidelines

The potential health effects of community noise include hearing impairment; startle and defense reactions; aural pain; ear discomfort speech interference; sleep disturbance; cardiovascular effects; performance reduction; and annoyance responses. These health effects, in turn, can lead to social handicap; reduced productivity; decreased performance in learning; absenteeism in the workplace and school; increased drug use; and accidents. In addition to health effects of community noise, other impacts are important such as loss of property value. In these guidelines the international literature on the health effects of community noise was reviewed and used to derive guideline values for community noise. Besides the health effects of noise, the issues of noise assessment and noise management were also addressed. Other issues considered were priority setting in noise management; quality assurance plans; and the cost-efficiency of control actions. The aim of the guidelines is to protect populations from the adverse health impacts of noise.

The following recommendations were considered appropriate:

a. Governments should consider the protection of populations from community noise as an integral part of their policy for environmental protection.

b. Governments should consider implementing action plans with short-term, medium-term and long-term objectives for reducing noise levels.

c. Governments should adopt the health guidelines for community noise as targets to be achieved in the long-term.

h. Governments should include noise as an important issue when assessing public health matters and support more research related to the health effects of noise exposure.

f. Legislation should be enacted to reduce sound pressure levels, and existing legislation should be enforced.

g. Municipalities should develop low-noise implementation plans.

h. Cost-effectiveness and cost-benefit analyses should be considered as potential instruments when making management decisions.

i. Governments should support more policy-relevant research into noise pollution (see section 6.3).

6.2. Further WHO Work on Noise

The WHO Expert Task Force proposed several issues for future work in the field of community noise. These are:

a. The WHO should consider updating the guidelines on a regular basis.

b. The WHO should provide leadership and technical direction in defining future research priorities into noise.

c. The WHO should organize workshops on the application of the guidelines.

d. The WHO should provide leadership and co-ordinate international efforts to develop techniques for the design of supportive sound environments (e.g. 'soundscapes").

e. The WHO should provide leadership for programmes to assess the effectiveness of health-related noise policies and regulations.

f. The WHO should provide leadership and technical direction for the development of sound methodologies for EIAP and EHIAP.

g. The WHO should encourage further investigation into using noise exposure as an indicator of environmental deterioration, such as found in black spots in cities.

a. The WHO should provide leadership, technical support and advice to developing countries, to facilitate the development of noise policies and noise management.

6.3. Research Needs

In the publication entitled "Community Noise", examples of essential research and development needs were given (Berglund & Lindvall 1995). In part, the scientific community has already addressed these issues.

A major step forward in raising public awareness and that of decision makers is the recommendation of the present Expert Task Force to concentrate more **on variables which have monetary consequences. This means that research should consider the dose-response relationships between sound pressure levels and politically relevant variables, such as noise-induced social handicap, reduced productivity, decreased performance in learning, workplace and school absenteeism, increased drug use and accidents.**

There is also a need for continued efforts to understand community noise and its effects on the health of the world population. Below is a list of essential research needs in non-prioritized order. Research priorities may vary over time and by place and capabilities. The main goal in suggesting these research activities is to improve the scientific basis for policy-making and noise management. This will protect and improve the public health with regard to the effects of community noise pollution.

Research related to measurement and monitoring systems for health effects

- Development of a global noise impact monitoring study. The study should be designed to obtain longitudinal data across countries on the health effects on communities of various types of environmental noise. A baseline survey could be undertaken in both developed and developing countries and monitoring surveys conducted every 3-5 years. Since a national map of noise exposure from all sources would be prohibitively expensive, periodic surveys of a representative sample of about 1000 people (using standard probability techniques) could be reliably generalized to the whole population of a country with an accuracy of plus-or-minus 3%. A small number of standard questions could be used across countries to obtain comparative data on the impact of all the main types of noise pollution.

- Development of continuous monitoring systems for direct health effects in critical locations.
- Development of standardized methods for low-cost assessment of local sound levels by measurement or model calculations.
- Development of instruments appropriate for local/regional surveys of people's perceptions of their noise/sound environments.

- Protocols for reliable measurements of high-frequency hearing (8000 Hz and above) and for evaluation of such measures as early biomarkers for hearing impairment/deficits.

Research related to combined noise sources and combined health effects

- Research into the combined health effects of traffic noise, with emphasis on the distribution of sound levels over time and over population sub-environments (time-activity pattern).
- Comprehensive studies on combined noise sources and their combinations of health effects in the 3 large areas of transport (road, rail and aircraft).
- Procedures for evaluating the various health effects of complex combined noise exposures over 24 hours on vulnerable groups and on the general population.
- Methods for assessing the total health effect from noise immission (and also other pollution) in sensitive areas (for example, airports, city centers and heavily-trafficked highways)

Research related to direct and/or long-term health effects (sensitive risk groups, sensitive areas and combined exposures)

- Identification of potential risk groups, including identification of sensitive individuals (such as people with particular health problems; people dealing with complex cognitive tasks; the blind; the hearing impaired; young children and the elderly), differences between sexes, discrimination of risk among age groups, and influence of transportation noise on pregnancy course and on fetal development.
- Studies of dose-response relationships for various effects, and for continuous transportation noise at relatively low levels of exposure and low number of noise events per unit time (including traffic flow composition).
- Studies on the perception of control of noise exposure, genetic traits, coping strategies and noise annoyance as modifiers of the effects of noise on the cardiovascular system, and as causes of variability in individual responses to noise.
- Prospective longitudinal studies of transportation noise that examine physiological measures of health, including standardized health status inventory, blood pressure, neuro-endocrine and immune function.
- Knowledge on the health effects of low-frequency components in noise and vibration.
-

Research related to indirect or after-effects of noise exposure

- Field studies on the effects of exposure to specific sounds such as aircraft noise and loud music, including effects such as noise-induced temporary and permanent threshold shifts, speech perception and misperception, tinnitus and information retrieval.
- Studies on the influence of noise-induced sleep disturbance on health, work performance, accident risk and social life.
- Assessment of dose-response relationships between sound levels and politically relevant variables such as noise-induced social handicap, reduced productivity, decreased performance in learning, workplace and school absenteeism, increased drug use and accidents.
- Determination of the causal connection between noise and mental health effects, annoyance and (spontaneous) complaints in areas such as around large airports, heavy-trafficked highways, high-speed rail tracks and heavy vehicles transit routes. The connections could be examined by longitudinal studies, for example.
- Studies on the impact of traffic noise on recovery from noise-related stress, or from nervous system hyperactivity due to work and other noise exposures.

Research on the efficiency of noise abatement policies which are health based

- Determination of the accuracy and effectiveness of modern sound insulation (active noise absorption), especially in residential buildings, in reducing the long-term effects of noise on annoyance/sleep disturbance/speech intelligibility. This can be accomplished by studying sites that provide data on remedial activities and changes in behavioral patterns among occupants.
- Evaluation of environmental (area layout, architecture) and traffic planning (e.g. rerouting) interventions on annoyance, speech interference and sleep disturbance.
- Comparative studies to determine whether children and the hearing impaired have equitable access to healthier lives when compared with normal adults in noise-exposed areas.
- Development of a methodology for the environmental health impact assessment of noise that is applicable in developing as well as developed countries.

Research into positive acoustical needs of the general population and vulnerable groups

- Development of techniques/protocols for the design of supportive acoustical environments for the general population and for vulnerable groups. The protocols should take into account time periods that are sensitive from physiological, psychological and socio-cultural perspectives.
- Studies to characterize good "restoration areas" which provide the possibility for rest without adverse noise load.
- Studies to assess the effectiveness of noise policies in maintaining and improving soundscapes and reducing human exposures.

Appendix 2 : Examples Of Regional Noise Situations

REGION OF THE AMERICAS

Latin America (Guillermo Fuchs, Argentina).

As more and more cities in Latin America surpass the 20 million inhabitants mark, the noise pollution situation will continue to deteriorate. Most noise pollution in Latin American cities comes from traffic, industry, domestic situations and from the community. Traffic is the main source of outdoor noise in most big cities. The increase in automobile engine power and lack of adequate silencing results in LAeq street levels >70 dB, above acceptable limits. Vehicle noise has strong low-frequency peaks at ~13 Hz, and at driving speeds of 100 Km/h noise levels can exceed 100 dB. The low-frequency (LF) noise is aerodynamic in origin produced, for example, by driving with the car windows open. Little can be done to mitigate these low-frequency noises, except to drive with all the windows closed. Noise exposure due to leisure activities such as carting, motor racing and Walkman use is also growing at a fast rate. Walkman use in the street not only contributes to temporary threshold shifts (TTS) in hearing, but also endangers the user because they may not hear warning signals Construction sites, pavement repairs and advertisements also contribute to street noise, and noise levels of 85–100 dB are common.

The Centro de Investigaciones Acústicas y Luminotécnicas (CIAL) in Córdoba, Argentina has investigated noise pollution in both the field and in the laboratory. The most noticeable effect of excessive urban noise is hearing impairment, but other psychophysiological effects also result. For example, tinnitus resulting from sudden or continuous noise bursts, can produce a TTS of 20–30 dB, and prolonged exposures can result in permanent threshold shifts (PTS). By analyzing sound spectra down to a few Hertz, and at levels of up to 120 dB, discrete frequencies and bands of infrasound were found which damage hearing. With LF sounds at levels of 120 dB, TTS resulted after brief exposure, and PTS after only 30 min of exposure. The effects of noise on hearing can be especially detrimental to children in schools located downtown. Field studies in Córdoba city schools located near streets with high traffic density showed that speech intelligibility was dramatically degraded in classrooms that did not meet international acoustical standards. This is a particularly worrying problem for the younger students, who are in the process of language acquisition, and interferes with their learning process.

In general, community noise in Latin America remains above accepted limits. Particularly at night, sleep and rest are affected by transient noise signals from electronically amplified sounds, music and propaganda. Field research was carried out in four zones of Buenos Aires, to determine the effects of urban noise on the well-being, health and activities of the inhabitants. The effects of confounding variables were taken into consideration. It was concluded that night-time noise levels in downtown Buenos Aires were barely lower than daytime levels. The results showed that sleep, concentration, communication and well-being were affected in most people when noise levels exceeded those permitted by international laws. The reactions of the inhabitants to protect themselves from the effects of noise varied, and included changing rooms, closing windows and complaining to authorities.

Individual responses to noise also vary, and depend on factors such as social, educational and economic levels, individual sensibility, attitudes towards noise, satisfaction with home or neighborhood, and cognitive and affective parameters. For example, at CIAL, two pilot studies were carried out with a group of adolescents to determine the influence of environmental conditions on the perception of noise. When music was played at very high sound levels (with sound peaks of 119 dBA) in a discotheque, judged to be a pleasant environment, the subjects showed less TTS than when exposed to the same music in the laboratory, which was considered to be an unpleasant environment.

At the municipal level Argentinean Ordinances consider two types of noises: unnecessary and excessive. Unnecessary noises are forbidden. Excessive noises are classified according to neighboring activities and are limited by maximum levels allowed for daytime (7 am to 10 pm) and night-time (10 pm to 7 am). This regulation has been relatively successful, but control has to be continuous. Similar actions have been prescribed at the provincial level in many cities of Argentina and Latin America. Control efforts aimed at reducing noise levels from individual vehicles are showing reasonably good improvements. However, many efforts of municipal authorities to mitigate noise pollution have failed because of economic, political and other pressures. For example, although noise control for automobiles has shown some improvement, efforts have been counteracted by the growth in the number and power of automobiles.

CIAL has designed both static and dynamic tests that can be used to set annual noise control limits. For roads and freeways where permitted speeds are above 80 Km/h, CIAL has also designed barriers which protect buildings lining the freeways. Considerable improvements have been obtained using these barriers with noise reductions of over 20 dB at buildings fronts. The most common types of barrier are concrete slabs or wooden structures, made translucent or covered with vegetation. Planted vegetation does not act as an efficient noise shield for freeway noise, except in cases of thick forest strips. In several cities, CIAL also designed ring roads to avoid heavy traffic along sensitive areas such as hospitals, schools and laboratories.

Efforts have not been successful in reducing the noise pollution from popular sports such as carting, motorboating and motocross, where noise levels can exceed 100 dB. In part, this is because individuals do not believe these activities can result in hearing impairment or have other detrimental effects, in spite of the scientific evidence. Argentinean and other Latin American authorities also have not been successful in reducing the sound levels from music centres, such as discotheques, where sound levels can exceed 100 dB between 11 pm and 6 am. However, public protest is increasing and municipal authorities have been applying some control. For instance, in big cities, discotheque owners and others are beginning to seek advice on how to isolate their businesses from apartment buildings and residential areas. Some improvements have been observed, but accepted limits have not yet been generally attained.

United States of America (Larry Finegold)

Noise Exposure.

In the United States, there have only been a few major attempts to describe broad environmental noise exposures. Early estimates for the average daily exposure of various population groups were reported in the U.S. Environmental Protection Agency's *Levels Document* (US EPA 1974), but these were only partially verified by subsequent large-scale measurements. Another EPA publication the same year provided estimates of the national population distribution as a function of outdoor noise level, and established population density as the primary predictor of a community's noise exposure (Galloway et al. 1974). Methodological issues that need be considered when measuring community noise, including both temporal and geographic sampling techniques, have been addressed by Eldred (1975). This paper also provided early quantitative estimates of noise exposure at a variety of sites, from an isolated spot on the North rim of the Grand Canyon to a spot in downtown Harlem in New York City. Another nationwide survey focused on exposure to everyday urban noises, rather than the more traditional approach of measuring exposure to high-level transportation noise from aircraft, traffic and rail (Fidell 1978). This study included noise exposure and human response data from over 2 000 participants at 24 sites.

A comprehensive report, *Noise In America: The Extent of the Problem,* included estimates of occupational noise exposure in the US in standard industrial classification categories (Bolt, Beranek & Newman, Inc. 1981). A more recent paper reviewed the long-term trends of noise exposure in the US and its impact over a 30-year time span, starting in the early 1970's. The focus was primarily on motor vehicle and aircraft noise, and the prediction was for steadily decreasing population-weighted day-night sound exposure (Eldred 1988). However, it remains to be seen whether the technological improvements in noise emission, such as changing from Chapter 2 to Chapter 3 aircraft, will be offset in the long run by the larger carriers and increased operations levels that are forecast for all transportation modes. Although never implemented in its entirety, a comprehensive plan for measuring community environmental noise and associated human responses was proposed over 25 years ago in the US (Sutherland et al. 1973).

Environmental Noise Policy in the United States

One of the first major breakthroughs in developing an environmental noise policy in the United States occurred in 1969 with the adoption of the National Environmental Policy Act (NEPA). This Congressional Act mandated that the environmental effects of any major development project be assessed if federal funds were involved in the project. Through the Noise Control Act (NCA) of 1972, the U.S. Congress directed the US Environmental Protection Agency (EPA) to publish scientific information about the kind and extent of all identifiable effects of different qualities and quantities of noise. The US EPA was also requested to define acceptable noise levels under various conditions that would protect the public health and welfare with an adequate margin of safety. To accomplish this objective, the 1974 US EPA *Levels Document* formally introduced prescribed noise descriptors and prescribed levels of environmental noise exposure. Along with its companion document, *Guidelines for Preparing Environmental Impact Statements on Noise*, which was published by the U.S. National Research Council in 1977, the

Levels Document has been the mainstay of U.S. environmental noise policy for nearly a quarter of a century. These documents were supplemented by additional Public Laws, Presidential Executive Orders, and many-tiered noise exposure guidelines, regulations, and Standards. Important examples include *Guidelines for Considering Noise in Land Use Planning and Control*, published in 1980 by the US Federal Interagency Committee on Urban Noise; and *Guidelines for Noise Impact Analysis*, published in 1982 by the US EPA.

One of the distinctive features of the US EPA *Levels Document* is that it does not establish regulatory goals. This is because the noise exposure levels identified in this document were determined by a negotiated scientific consensus and were chosen without concern for their economic and technological feasibility; they also included an additional margin of safety. For these reasons, an A-weighted Day-Night Average Sound Level (DNL) of 55 dB was selected in the *Levels Document* as that required to totally protect against outdoor activity interference and annoyance. Land use planning guidelines developed since its publication allow for an outdoor DNL exposure in non-sensitive areas of up to 65 dB before sound insulation or other noise mitigation measures must be implemented. Thus, separation of short-, medium- and long-term goals allow noise-exposure goals to be established that are based on human effects research data, yet still allow for the financial and technological constraints within which all countries must work.

The US EPA's Office of Noise Abatement and Control (ONAC) provided a considerable amount of impetus to the development of environmental noise policies for about a decade in the US. During this time, several major US federal agencies, including the US EPA, the Department of Transportation, the Federal Aviation Administration, the Department of Housing and Urban Development, the National Aeronautics and Space Administration, the Department of Defense, and the Federal Interagency Committee on Noise have all published important documents addressing environmental noise and its effects on people. Lack of funding, however, has made the EPA ONAC largely ineffective in the past decade. A new bill, the *Quiet Communities Act* has recently been introduced in the U.S. Congress to re-enact and fund this office (House of Representatives Bill, H.R. 536). However, the passage of this bill is uncertain, because noise in the US, as in Europe, has not received the attention that other environmental issues have, such as air and water quality.

In the USA there is growing debate over whether to continue to rely on the use of DNL (and the A-Weighted Equivalent Continuous Sound Pressure Level upon which DNL is based) as the primary environmental noise exposure metric, or whether to supplement it with other noise descriptors. Because a growing number of researchers believe that "Sound Exposure" is more understandable to the public, the American National Standards Institute has prepared a new Standard, which allows the equivalent use of either DNL or Sound Exposure (ANSI 1996). The primary purpose of this new standard, however, is to provide a methodology for modeling the Combined or Total Noise Environment, by making numerical adjustments to the exposure levels from various noise sources before assessing their predicted impacts on people. A companion standard (ANSI 1998) links DNL and Sound Exposure with the current USA land use planning table. The latter is currently being updated by a team of people from various federal government agencies and when completed should improve the capabilities of environmental and community land-use planners. These documents will complement the newly revised ANSI standard on acoustical terminology (ANSI 1994).

To summarize progress in noise control made in the USA in the nearly 25 years since the initial national environmental noise policy documents were written, the Acoustical Society of America held a special session in Washington, D.C. in 1995. The papers presented in this special session were then published as a collaborative effort between the Acoustical Society of America and the Institute of Noise Control Engineering (von Gierke & Johnson 1996). This document is available from the Acoustical Society of America, as are a wide range of standards related to various environmental noise and bioacoustics topics from the ANSI.

A document from the European Union is now also available, which includes guidelines for addressing noise in environmental assessments (EU 1996). Policy documents from organizations such as ISO, CEN, and ICAO have shown that international cooperation is quite possible in the environmental noise arena. The ISO document, entitled *Acoustics - Description and Measurement of Environmental Noise* (ISO 1996), and other international standards have already proven themselves to be invaluable in moving towards the development of a harmonized environmental noise policy. The best way to move forward in developing a harmonized environmental noise policy is to take a look at the various national policies that have already been adopted in many countries, including those both from the European member states and from the USA, and to decide what improvements need to be made to the existing policy documents. A solid understanding of the progress that has already been achieved around the world would obviously provide the foundation for the development of future noise policies.

Implementation Concepts and Tools

Development of appropriate policies, regulations, and standards, particularly in the noise measurement and impact assessment areas, is a necessary foundation for implementing effective noise abatement policies and noise control programs. A well-trained cadre of environmental planners will be needed in the future to perform land-use planning and environmental impact analysis. These professionals will require both a new generation of standardized noise propagation models to deal with the Total Noise Environment, as well as sophisticated computer-based impact analysis and land-use planning tools.

A more thorough description of the current noise environment in major cities, suburbs, and rural areas is needed to support the noise policy development process. A new generation of noise measurement and monitoring systems, along with standards related to their use, are already providing considerable improvement in our ability to accurately describe complex noise environments. Finally, both active and passive noise control technologies, and other noise mitigation techniques, are rapidly becoming available for addressing local noise problems. Combined with a strong public awareness and education program, land-use planning and noise abatement efforts certainly have the potential to provide us with an environment with acceptable levels of noise exposure.

AFRICAN REGION

South Africa (Etienne Grond, South Africa)

Introduction

Cultural and developmental levels diverge greatly in South Africa, and the country can be divided into a first world sector, a developing sector and a third world sector. This contributes to huge variations in both the awareness of noise pollution and in population exposure to noise pollution. Noise-related health problems will in all probability show the same large variations.

Legal requirements

Noise control in South Africa has a history dating back about three decades. Noise control began with codes of practice issued by the South African Bureau of Standards (SABS) to address noise pollution in different sectors. Since then, Section 25 of the Environment Conservation Act (Act 73 of 1989) made provision for the Minister of Environmental Affairs and Tourism to regulate noise, vibration and shock at the national level. These regulations were published in 1990 and local authorities could apply to the Minister to make them applicable in their areas of jurisdiction. However, a number of the bigger local authorities did not apply for the regulations since they already had by-laws in place, which they felt were sufficient. By the middle of 1992 only 29 local authorities had applied the regulations and so the act was changed to make it obligatory for all authorities to apply the regulations. However, by the time the regulations were ready to be published, the new Constitution of South Africa came into effect and this listed noise control as an exclusive legislative competence of provincial and local authorities. This meant that the national government could not publish the regulations. However, provincial governments have agreed to publish the regulations in their respective areas. The regulations will apply to all local authorities as soon as they are published in the provinces, and will give local authorities both the power and the obligation to enforce the regulations.

The Department of Environmental Affairs and Tourism also published regulations during 1997 to make Environmental Impact Assessments mandatory for most new developments, as well as for changes in existing developments. This means that any impact that a development might have on its surrounding environment must be evaluated and, where necessary, the impact must be mitigated to acceptable levels. The noise control regulations also state that a local authority may declare a "controlled area," which is an area where the average noise level exceeds 65 dBA over a period of 24 h period. This means that educational and residential buildings, hospitals and churches may not be situated within such areas.

Occupational noise exposure is regulated by the Department of Manpower, under the Occupational Health and Safety Act (Act 85 of 1993). These regulations states that workers may not be exposed to noise levels of higher than 85 dBA and that those exposed to such levels must make use of equipment to protect their hearing. The problem, however, is that most workers tend not to make use of the provided equipment, either because the equipment is not comfortable, or because they are not aware of the risks high noise levels pose to their hearing. A further problem is that small industries often do not supply the workers with the necessary equipment, or supply inferior equipment that is less costly.

Codes of practice

The codes of practice issued by the SABS were for the most part replaced by IEC (International Electrotechnical Commission) standards and adopted as SABS ISO codes of practice. They are still being used in South Africa and are regularly updated. A relevant list can be found in the references. The SABS has also published a number of recommended practices (ARP). These include the ARP 020: "Sound impact investigations for integrated environmental management" that is currently being upgraded to a code of practice. Such codes of practice can be referred to as requirements in legislation and will be known as SABS 0328: "Methods for environmental noise impact assessments." The codes of practice published in South Africa cover hearing protection; measurement of noise; occupational noise; environmental noise; airplane noise; and building acoustics, etc.

Courses

Local authorities responsible for applying regulations published by the Department of Environmental Affairs and Tourism must employ a noise control officer who has at least three years tertiary education in engineering, physical sciences or health sciences, and who is registered with a professional council. Alternatively, a consultant with similar training may be employed. Most of the universities in South Africa provide the relevant training, with at least part of the training in acoustics. Universities and technical colleges also provide a number of special acoustics courses. Over the last couple of years awareness of environmental conservation has expanded dramatically within the academic community, and most universities and colleges now have degree courses in environmental management. At the very least, these courses include a six-month module in acoustics, and usually also include training in basic mathematics; the physics of sound; sound measuring methodologies; and noise pollution.

Community awareness and exposure to noise pollution

This topic should be discussed with respect to three separate population sectors: the first-world sector (developed), the developing sector and the third-world sector (rural).

Developed sector

This sector of the population is more-or-less as developed as their European and American counterparts. They have been exposed to noise pollution for a considerable time and, for the most part, are aware of the health consequences of high noise levels. People in this group are also aware of the existence of legal measures by which noise pollution can be addressed. Not surprisingly, most of the complaints and legal action regarding noise pollution are received from this group. Information about noise-related health problems is very limited, but because this group is highly aware of the risks posed by high noise levels, future studies will probably show that people in this category have the fewest health problems. The majority of people in this group are less exposed to high noise levels at work, and they live in more affluent neighborhoods with large plots and separating walls. Their houses tend to be built with materials that are noise reducing. They also live further away from major noise-producing activities, such as highways, airports and large industries.

Developing sector

This sector of the population has the greatest exposure to high noise levels, both at home and in the workplace. Overall, they are relatively poor and cannot afford to live in quiet areas, or afford large plots or solid building materials. A large component of this sector resides in squatter communities where building are made of any material available, from plastic to corrugated sheets and wood. The buildings are right next to each other and there is almost no noise attenuation between residencies.

People in this category usually live close to major access routes into the cities, because they make use of public transportation and taxis to get to their places of work. Often, too, they live close to their places of work, which are usually big industries with relatively high levels of noise pollution. These people usually work in high noise areas, and because of their lack of awareness of the effects of high noise levels, often do not make use of available hearing protection equipment. Because of a lack of funds, these people also cannot get out of high noise areas and go to recreational areas for relaxation and lower noise levels. Not much information is available on the adverse health problems in this sector. However, workers in this sector should undergo regular medical examinations and the results can be obtained from the industries involved.

Rural sector

As the name suggests, people in this sector live in rural surroundings and for the most part are not subjected to noise levels that could be detrimental to their health. However, they are almost totally unaware of the risks posed by high noise levels. Some of these people work on farms and work with machinery that emits relatively high noise levels, but because of their lack of awareness they do not make use of hearing protection equipment. One advantage they do have is that they return to homes in quiet surroundings and their hearing has a chance to recover. To date, no studies have been carried out to determine the state of their hearing and it would be impossible to state that they have no health problems related to high noise levels.

EASTERN MEDITERRANEAN REGION (Shabih H. Zaidi)

Scope

In the Eastern Mediterranean region some countries have highly developed industries, while others have none. In other cases, the agricultural economy is inseparably mixed with high-technology industries, such as the oil industry, which can be seen in nearly the whole of the Arabian Peninsula. Other examples of where agriculture and industry are intertwined can be seen in Pakistan, Jordan and Egypt. The main focus of this paper is community noise, but because industry is so widely distributed, some discussion of industrial noise is inevitable. The scope of this paper is to document the available scientific data on community noise in the WHO Regional Office of the Eastern Mediterranean (EMRO) region, including preventive strategies, legislation, compensation and future trends.

Sources of Noise Pollution

Sources of noise pollution in the Eastern Mediterranean region include noise from transportation, social and religious activities, building and civil works, roadside workshops, mechanical floor shops and others. During civil works and building booms, noise levels in all countries of the Eastern Mediterranean region could easily reach 85dBA during the daytime over an 8 h work period. In Pakistan, unprotected construction work goes on at all times of the day and night and uses outdated machinery; and the noise is compounded by workers shouting. On a typical building site noise levels reach 90–100 dBA.

In Karachi, the main artery for daily commuters is a long road that terminates at the harbor. In the densest area of this road there are a hundred small and large mechanical workshops, garages, metal sheet workers, dent removers, painters, welders and repair shops, all of which create a variety of noises. In the middle of this area at the Tibet Centre the LAeq,8h is 90dBA (Zaidi 1989). A similar picture is seen elsewhere in cities like Lahore, Peshawar, etc. Fortunately, the same is not true for other newly built cities in the EMRO region, such as Dubai, or Tripoli, where strict rules separate industrial zones from residential areas.

A special noise problem is Karachi harbour. This port serves the whole of Pakistan as well as Afghanistan and several Asian states, such as Kyrgyzstan, Kazakhstan and Uzbekistan. The noise level at the main wharf of Karachi Port ranges between 90–110 dBA on any given day. Other special sources of noise are the Eastern Mediterranean airports, and indeed most of the airports in the Middle East. Most northbound air traffic originates in Pakistan, Dubai, Sharjah etc. and flights usually depart after midnight so as to arrive in Europe during the daytime. A study is currently underway in Karachi to identify the damage caused by these nocturnal flights to those living under the flight path (SH Zaidi, GH Shaikh & AN Zaidi, personal communication).

Sadly, violence has become part of Eastern culture and is a significant source of noise pollution. Wars generate a lot of noise, and although noise-induced hearing loss is a secondary issue compared with the killing, after the wars many people are hearing impaired. This has been seen following conflicts in Balochistan, Peshawar and Afghanistan, where perforated ear drums, profound hearing loss and stress-related psychosomatic illnesses are common in the refugee camps. The noise levels during a recent mass demonstration in Karachi, which included the firing of automatic weapons, reached 120 dBA at a distance of 50 m from the scene.

The Effects of Noise on Health

There is good evidence that environmental noise causes a range of health effects, including hearing loss, annoyance, cardiovascular changes, sleep disturbance and psychological effects. Although the health effects of noise pollution have not been documented for the entire EMRO region, data are available for Pakistan and can be used to illustrate the general problem. In this report, noise exposure is mainly expressed as LAeq,24h values.

Noise-induced hearing loss (NIHL).

It is believed that exposure to environmental noise in the EMRO countries is directly related to the living habits, economic prosperity and outdoor habits of people. It has been estimated that no more than 5% of the people are exposed to environmental sound levels in excess of 65dBA over a 24-h period. Similarly, for indoor noise, it is believed that the average family is not exposed to sound levels in excess of 70 dBA over a 24-h period. However, it is difficult to generalize for all countries in the EMRO region, because of ancient living styles and different cultural practices, such as taking siestas between 13:00–16:00 and stopping work at 20:00.

Exposure to noise while travelling to schools, offices or workplaces may vary tremendously between cities in the region. In Karachi, for example, traffic flow is undisciplined, erratic and irrational, with LAeq,8h values of 80–85 dBA. In Riyadh, by contrast, traffic flow is orderly with LAeq levels of 70 dBA during a normal working day. In Karachi, noise levels show significant diurnal variation, reaching levels in excess of 140 dB during the peak rush hour at around 5.00 p.m. (Zaidi 1989). At the Tibet Centre, located at a busy downtown junction, noise levels were 60–70 dB at 9 am, but reached levels in excess of 140 dB between 5-7 p.m. A study conducted on a day that transportation workers went on strike established that road traffic is the most significant source of noise pollution in this city: in the absence of buses, rickshaws, trucks and other public vehicles the LAeq level declined from 90dB to 75dB (Zaidi 1990). Motor engines, horns, loud music on public buses and rickshaws generate at least 65% of the noise in Karachi (Zaidi 1997; Shams 1997). Rickshaws can produce noise levels of 100–110 dBA and do not have silencers. On festive occasions, such as national holidays or political rallies, motorbikes running at high speeds along the Clifton beach in Karachi easily make noise exceeding 120 dBA. (Zaidi 1996).

Another study conducted at 14 different sites in Karachi showed that, in 11 of the sites, the average noise level ranged between 79–80 dB (Bosan & Zaidi 1995). The maximum noise levels at all these sites exceeded 100 dB. Speech interference, measured by the Preferred Speech Interference Level and the Articulation Index, was significant (Shaikh & Rizvi 1990). The study results indicated that two people facing each other at a distance of 1.2 m would have to shout to be intelligible; and the Articulation Indexes demonstrated that communication was unsatisfactory. Of perhaps greater concern are the results of a survey of 587 males between the ages of 17 and 45 years old, who worked as shopkeepers, vehicle drivers, builders and office assistants. Audiograms showed that 14.6% of the subjects had significant hearing impairment at 3 000–4 000 Hertz (Hasan et al., 2000).

Noise pollution from leisure activities can vary from country to country in the EMRO region. The Panthans in northern Pakistan, for example, like to shoot in the air on festive occasions, such as weddings, without using any noise protection devices. A minimum of 1 000 shots are fired on such occasions; and at a traditional tribal dance called the 'Khattak" the noise level recorded during a particularly enthralling performance in a sports arena was 120dBA. The hunting of wild boar is a common sport in the hinterlands of Sindh. With the rifle shots and the noise made by the beaters, noise levels can easily reach 110 –120 dBA. In some EMRO countries, the younger crowd has taken up the Western habit of listening to Pop music for many hours. Discos and floorshows are confined to a few countries, such as Egypt. Open-air concerts are usually held in stadiums. The noise level recorded at a particularly popular concert was 130 dBA at a distance of 20 m from the stage and 35 m from the amplifiers.

In a study of road traffic at 25 different sites in Peshawar, the third most populous city in Pakistan, 90 traffic constables were taken as cohorts to investigate the extent of NIHL. Of these, 50 did not have any previous history of noise exposure and were taken as controls. Detailed evaluation and audiological investigations established that constables exposed to a noise level of 90 dBA for 8 hours every day suffered from NIHL. Compared to the control subjects, the constables had significant hearing impairment at 3 000 Hz, measured by Pure Tone Audiometry (Akhter 1996).

A similar study of traffic constables in Karachi showed that 82.8% of the constables suffered from NIHL (Itrat & Zaidi 1999). The study also showed that 33.3% of rickshaw drivers, and 56.9% of shopkeepers who worked in noisy bazaars, had hearing impairment. If these findings can be extrapolated to the total populations, there are 1 566 traffic constables (out of a total of 1 890 constables), and 4 067 rickshaw drivers (out of a total of 12 202 drivers) who suffer from NIHL. As has been reported by other researchers, the study also found evidence of acclimatization in the subjects: following an initial, rapid decline, hearing loss stabilized after prolonged noise exposure.

Annoyance.

The citizens of Karachi commonly complain that noise causes irritability and stress. The main sources have been identified as traffic noise, industrial noise and noise generated by human activity. Unfortunately no data are available for the level of annoyance caused by noise exposure in the EMRO region. From limited research around the world, it can be estimated that 35–40% of employees in office buildings are seriously annoyed by noise at sound levels in excess of 55–60 dBA. In countries such as Pakistan, Iran, Jordan and Egypt that level is often seen in most offices. Annoyance is a non-tangible entity and cannot be quantified scientifically. It is a human reaction and perhaps its parameters could include irritability, apprehension, fear, anger, frustration, uneasiness, apathy, chaos and confusion. If such are the parameters, then on a scale of 0–10, with 10 being the greatest annoyance, many EMRO countries could easily score 6 or higher.

Effects of noise on sleep and the cardiovascular system.

In the Eastern Mediterranean region no specific data are available on the effects of noise on sleep or the cardiovascular system. However, factory workers, traffic constables, rickshaw drivers and shopkeepers frequently complain about fatigue, irritability and headaches; and one of the most common causes of poor performance in offices is sleep disturbance. The rising incidence of tinnitus in cities like Karachi is also related to noise exposure, and tinnitus itself can lead to sleep deprivation. Although the effects of noise on the cardiovascular system have been well documented for other countries (Berglund & Lindvall 1995), data are lacking for the EMRO region. However, the prevalence of cardiovascular diseases are on the rise in the EMRO countries, particularly hypertension. While most of the increase in these diseases is due to a rich diet and lack of exercise, the relationship between noise and cardiovascular changes is worth investigating.

The risk to unborn babies and newborns.

Although evidence from other countries indicates that noise may damage the hearing of a fetus, there are no data from the EMRO countries to confirm this. With newborn babies, however, noise from incubators is a major cause of hearing loss in the EMRO region, particularly as 20–27% of them are born underweight (Razi et al. 1995). Once exposed to noise in an incubator, the chances of hearing impairment rapidly rises compared with cohorts in developed countries. Several other factors have also been identified as causing deafness and hearing impairment in newborns in the Eastern Mediterranean region (Zaidi 1998; Zakzouk et al. 1994). They are:

a. Discharge from the ears.

b. Communicable infections.

c. Ototoxicity.

d. Noise.

e. Consanguinity.

f. Iodine deficiency.

Noise Control

Although noise control legislation exists in several EMRO countries, it is seldom enforced, particularly in Pakistan and some neighboring countries. Noise control begins with education, public awareness and the appropriate use of media in highlighting the effects of noise. In Calcutta, for instance, public orientation and mass media mobilization have produced tangible results, and this can easily be done in other countries. Three strategies have been devised for noise control, all of which are practicable in EMRO region countries. They are control at the source, control along the path and control at the receiving end.

There are many ways noise can be controlled at the source. For example, most of the equipment and machinery used in EMRO countries is imported from the West. Noise control could begin by importing quieter machinery, built with newer materials like ceramics or frictionless parts. And at the local level, the timely replacement of parts and proper maintenance of the machines should be carried out. Vehicles like the rickshaw should be banned, or at least be compelled to maintain their silencers, and all vehicles must be put to a road worthiness test periodically. This already occurs in some EMRO countries, but not all. Horns, hooters, music players and other noise making factors must also be controlled. The use of amplifiers and public address systems should also be banned, and social, leisure and religious activities should be restricted to specific places and times.

Along the sound path, barriers can be used to control noise. There are three kinds of barriers available, namely, space absorbers made out of porous material, resonant absorbers and panel absorbers. Architects, for example, use hollow blocks of porous material. The air gaps between building walls not only keep the buildings cool in hot weather, but also reduce the effects of noise. Ceilings and roofs are often treated with absorbent material. In large factories, architects use corrugated sheets and prefabricated material, which are helpful in reducing noise levels. In Pakistan, some people use clay pots in closely ranked positions on rooftops to reduce the effect of heat as well as noise. For civic works and buildings, special enclosures, barriers and vibration controlling devices should be used. Public halls, such as cinemas, mosques and meeting places should have their walls and floors carpeted, and covered with hangings, mats etc. An effective material is jute, which is grown in many countries, mainly Bangladesh, and it is quite economical. Some of the old highways and most of the busy expressways need natural noise barriers, such as earth banks, trees and plants.

SOUTH-EAST ASIAN REGION. (Sudhakar B. Ogale)

Introduction

The ability to hear sound is a sensory function vital for human survival and communication. However, not all sounds are wanted. Unwanted sounds, for which the term "noise" is normally used, often originate from human activities such as road traffic, rail traffic, aircraft, discos, electric power generators, festivals, firecrackers and toys. In general, however, data on noise pollution in South east Asian countries are not available. For example, there are no comprehensive statistical data regarding the incidence and etiology of hearing impairment. Consequently, it is difficult to estimate the exact percentage of the population affected by community noise.

Excessive noise is the major contributor to many stress conditions. It reduces resistance to illness by decreasing the efficiency of the immune system, and is the direct cause of some gastrointestinal problems. Noise also increases the use of drugs, disturbs sleep and increases proneness to accidents. An increased incidence of mental illness and hospital admissions, increases in absenteeism from work and lethargy from sleep disturbance all result from noise pollution and cause considerable loss of industrial production.

Noise Exposure in India

India is rapidly becoming industrialized and more mechanized, which directly affects noise levels. However, no general population study regarding the magnitude of the noise problem in India has been performed.

Road Traffic Noise

Exposure. A study by the Indian Institute of Road Traffic (IRT) reported that Delhi was the noisiest city in India, followed by Calcutta and Bombay (IRT 1996; Santra & Chakrabarty 1996). The survey examined whether road-traffic noise affected people with respect to annoyance, sleep disturbance, interference with communication and hearing impairment. It showed that 35% of the population in four major cities have bilateral sensory neural hearing loss at noise emission levels above 82 dBA. This is of particular concern in light of a second study, showing that LAeq,24h levels at 24 kerbside locations in Calcutta were 80–92 dBA (Chakrabarty et al. 1997) The mean noise emission levels of four different vehicle categories are presented in Table A2.1.

Table A2.1: Mean noise emission levels of vehicles

Type of vehicle	Mean sound pressure level
2 wheelers (motor cycle)	82 dBA
3 wheelers (auto rickshaw)	87 dBA
Motor car (taxi, private cars)	85 dBA
Heavy vehicles (trucks)	92 dBA

Control Measures. Only recently has noise pollution been considered an offence in India, under the Environmental (Protection) Act 1986. Several measures are being taken to reduce traffic-noise exposure. These include:

a. Planting trees, shrubs and hedges along roadsides.

b. Mandatory, periodic vehicle inspections by road traffic control.

c. Reintroduction of silent zones, such as around schools, nursing homes and hospitals that face main roads.

d. Regulation of traffic discipline, and a ban on the use of pressure horns.

e. Enforcement of exhaust noise standards.

f. Mandating that silencers be effective in three-wheeled vehicles.

g. The use and construction of bypass roads for heavy vehicles.

h. Limiting night-time access of heavy vehicles to roads in residential neighbourhoods

i. Installation of sound-proof windows.

j. Proper planning of new towns and buildings.

Air Traffic Noise

Many airports were originally built at some distance from the towns they served. But due to growing populations and the lack of space, buildings are now commonly constructed alongside airports in India.

Exposure. A survey revealed that aircraft produced a high level of noise during take-off, with sound pressure levels of 97–109 dBA for the Airbus, and 109 dBA for Boeing aircraft (SB Ogale, unpublished observations). During landing, the aircraft produced a sound pressure level of 108 dBA. Although exposure to aircraft noise is considered to be less of a problem than exposure to traffic noise, the effects of air-traffic noise are similar to those of road traffic, and include palpitations and frequent awakenings at night.

Control measures. The use of ear muffs must be made obligatory at the airport. This can reduce noise exposure to a safe level. An air-traffic control act should also enforce the use and introduction of low-noise aircraft, and mandate fewer night-time flights.

Rail Traffic Noise

Very little attention has been paid to the problems of railway noise.

Exposure. In Bombay, where the majority of residential buildings are situated on either side of railway tracks, residents are more prone to suffer from acoustic trauma. More than 14% of the population in Bombay suffer from sleep disturbances during night, due to high-speed trains and their whistling. A study on surface railways (SB Ogale, unpublished observations) revealed that platform noise was 71–73 dBA in the morning and 78–83 dBA in the evening. The noise from loudspeakers mounted in the platform was 87–90 dBA. At a distance of 1 m from the engine, the whistle noise was 105–108 dBA for a train with an electric engine, up to 110 dBA for a train with diesel engine and 118 dBA for steam engine trains. Vacuum brakes produced noise levels as high as 95 dBA. This suggests that unprotected railway staff on platforms are at risk of permanent noise induced hearing loss.

Festival noise

Festival noise in India was first surveyed in Bombay in late 1970, during the Ganpati festival period. A similar study (Santra et al. 1996) was conducted soon after in Calcutta at the Durga Pooja festival during evening hours (18:00–22:00). The music from loudspeakers produces sound pressure levels of more than 112 dBA. During the festival period the residents experienced a noisy environment for 8–10 h at a stretch, with noise level of 85–95 dBA. This level is above the 80 dBA limit set by WHO for industrial workers exposed to noise for a maximum period of 8 hours.

Control measures. In a religious country, it is politically difficult to restrict religious music, even in the interests of public health. A ban on all music from loudspeakers after 22:00 would decrease the sound pressure levels to below the permissible legal limit. A preventive programme is advocated to measure noise levels with sound level metres.

Fire crackers and toy weapons noise

Exposure. A study conducted by Gupta & Vishvakarma (1989) at the time of Deepawali, an Indian festival of fireworks, determined the auditory status of 600 volunteers from various age groups, before and after exposure to firecrackers. The study also measured the acoustical output of representative samples of toy weapons and firecrackers, and the noise intensity level at critical spectator points. The average sound level at a distance of 3 m from the noise source was 150 dBA, exceeding the 130 dBA level at which adults are at risk for hearing damage. On average, 2.5% of the people surveyed during Deepawali had persistent sensory neural hearing loss of 30 dBA, with those in the 9–15 year old age group being most affected.

Control Measures. A judicious approach in the manufacture and use of toy weapons and firecrackers is encouraged, in addition to legal restraints. Fireworks should be more a display of light, rather than sound.

Generator Noise

Diesel generators are often used in India to produce electric power. Big generators produce sound pressure levels exceeding 96 dBA (SB Ogale, unpublished observations).

Conclusions

No comprehensive statistical data are available for community noise in India, however, the main sources of environmental noise are road traffic, air traffic, rail traffic, festivals, firecrackers and diesel generators. The adverse effects of noise are difficult to quantify, since tolerance to noise levels and to different types of noise varies considerably between people. Noise intensity also varies significantly from place to place. It should also be noted that noise data from different countries are often not obtained by the same method, and in general models have been used which are based on data from a limited number of locations. Noise control measures could be taken at several levels, including building design, legal measures, and educating the people on the health dangers of community noise. In India, what is needed now is noise control legislation and its strict enforcement, if a friendly, low-noise environment is to be maintained.

Noise Exposure in Indonesia

According to a report by the WHO, the noise exposure and control situation in Indonesia is as follows (Dickinson 1993).

Exposure. No nationwide data are available for Indonesia. However, during the last three decades there has been rapid growth in transportation, industry and tourism in Indonesia.

Control Measures. With the large majority of people having little income, protection of the physical environment has not been a first-order priority. The following recommendations have been made with respect to community noise (Dickinson 1993):

a. The cities of Indonesia have relatively large populations and each provincial government will need the staff and equipment to monitor and manage the environment.

b. Sound level meters with noise analysis computer programmes should be purchased.

c. Training courses and adequate equipment should be provided.

d. Noise management planning for airports should be promoted.

e. Reduction measures should be taken for road-traffic noise.

Noise Exposure in Bangladesh

Exposure. In Bangladesh no authentic statistical data on the effects of community noise on deafness or hearing impairment are available (Amin 1995).

Control Measures. Governments have meager resources, a vast population to contend with and high illiteracy rates; consequently, priorities are with fighting hunger, malnutrition, diseases and various man-made and natural calamities. The governments are unable to give the necessary attention towards the prevention, early detection and management of noise disabilities in the country. Close cooperation is needed between the national and international organizations, to exchange ideas, skills and knowledge (Amin 1995).

Noise Exposure in Thailand

Exposure. Noise from traffic, construction, and from factories and industry has become a big problem in the Bangkok area. The National Environmental Board of Thailand was set up two decades ago and has been active in studying the pollution problems in Thailand. Indeed, a committee on noise pollution control was set up to study the noise pollution in Bangkok area and its surroundings. Although regulations and recommendations were made for controlling various sources of noise, the problem was not solved due to a lack of public awareness, the difficulty of proving that noise had adverse effects on health and hearing, and the difficulty of getting access to control noise. A general survey revealed that 21.4% of the Bangkok population is suffering from sensory neural hearing loss (Prasanchuk 1997). Noise sources included street noise, traffic noise, industrial noise and leisure noise.

Control Measures. In 1996, regulations for noise pollution control set LAeq,24h levels at 70 dBA for residential areas, and less than 50 dBA to avoid annoyance. The National Committee on Noise Pollution Control has been asked to study the health effects of noise in the Bangkok area and its surroundings, and determine whether these regulations are realistic and feasible.

WESTERN PACIFIC REGION.

In this section, information on noise pollution and control will be given for three countries in the Western Pacific Region, namely Australia, the People's Republic of China and Japan. From a noise pollution point of view China may be viewed as a developing country, whereas Japan and Australia, with their high level of industrialization, represent developed countries.

Australia (Andrew Hede & Michinori Kabuto)

Exposure. Australia has a population of 18 million with the majority living in cities that have experienced increasing noise pollution from a number of sources. The single most serious source of noise is road traffic, although in major cities such as Sydney, Melbourne and Perth, large communities are exposed to aircraft noise as well. Other important sources of noise pollution are railway noise and neighbourhood noise (including barking dogs, lawn mowers and garbage collection). A particular problem in Australia is that the climate encourages most residents to live with open windows, and few houses have effective noise insulation.

A study of road-traffic noise was conducted at 264 sites in 11 urban centres with populations in excess of 100 000 people (Brown et al. 1994). Noise was measured one metre from the façade of the most exposed windows and at window height. From the results, it was estimated that over 9% of the Australian population is exposed to LA10,18h levels of 68 dB or greater, and 19% of the population is exposed to noise levels of 63 dB or greater. In terms of LAeq values for daytimes, noise exposure in Australia is worse than in the Netherlands, but better than in Germany, France, Switzerland or Japan.

Control. In the mid-1990's, when a third runway was built at Sydney Airport, the government funded noise insulation of high-exposed dwellings. Increasingly, too, major cities are using noise barriers along freeways adjacent to residential communities. In most states barriers are mandatory for new freeways and for new residential developments along existing freeways and major motorways. There has been considerable testing of noise barriers by state agencies, to develop designs and materials that are cost effective.

China (Chen Ming)

Introduction

Urban noise pollution has become a contemporary world problem. Urban noise influences people's living, learning and working. People exposed to noise feel disagreeable and cannot concentrate on work. Rest and sleep are also disturbed. People exposed to high-intensity noise do not hear alarm signals and cannot communicate with each other. This can result in injury and, indeed, with the modernization of China, construction accidents related to noise are increasing. According to statistics for several cities in China, including Beijing, Shanghai, Tientsin and Fuzhou, the proportion of total accidents that were noise related was 29.7% in 1979, 34.6% in 1980, 44.8% in 1981 and 50% in 1990. It is therefore very important to control noise pollution in China.

Long-term exposure to urban environmental noise can lead to temporary hearing loss (assessed by temporary threshold shift), permanent hearing loss (assessed by permanent threshold shift) or deafness. Microscopy studies have shown that in people exposed to noise for long periods, hair cells, nerve fibers and ganglion cells were absent in the cochleae, especially in the basal turns. The primary lesion is in the 8–10 mm region of the cochlea, which is responsible for detecting sound at a frequency of 4 000 Hz. People chronically exposed to noise may first complain about tinnitus and, later on, about hearing loss. This is especially true for patients who have bilateral hearing loss at 4 000 Hz, but who have relatively good hearing other frequencies. Non-auditory symptoms of noise include effects on the nervous system, cardiovascular system and blood system. These symptoms were rarely observed in China in the past, but today more and more people complain about hearing damage and non-auditory physiological effects.

Urban environmental noise has thus become a common concern of all members of society. A key to resolving the complex noise issue lies in the effective control of urban noise sources. Control measures include reducing noise at its source, changing noise transmission pathways, building design, community planning and the use of personal hearing protection.

Urban environmental noise sources can be divided into industrial noise, traffic noise, building architecture noise and community district noise sources. Only the last three types are of concern here.

Traffic Noise

There are four sources of traffic noise: road traffic, railway transport, civil aviation and water transport; of these, road traffic is the main source of urban noise. The sound emission levels of heavy-duty trucks are 82–92 dBA and 90–100 dBA for electric horns; air horns are even worse, with sound emission levels of 105–110 dBA. Most urban noise from automobiles is in the 70–75 dB range, and it has been estimated that 27% of all complaints are about traffic noise. When a commercial jet takes off, speech communication is interrupted for up to 1 km on both sides of the runway, but people as far away as 4 km are disturbed in their sleep and rest. If a supersonic passenger plane flies at an altitude of 1 500 m, its sound pressure waves can be heard on the ground in a 30–50 km radius.

Building Noise

As a result of urban development in China, construction noise has become an increasingly serious problem. It is estimated that 80% of the houses in Fuzhou were built in the past 20 years. According to statistics, the noise from ramming in posts and supports is about 88 dB and the noise from bulldozers and excavators is about 91 dB, 10 m from the equipment. About 98% of industrial noise is in the 80–105 dB range, and it is estimated that 20% of all noise complaints is about industrial noise.

Community Noise

The main sources of community noise include street noise, noise from electronic equipment (air conditioners, refrigerators, washing machines, televisions), music, clocks, gongs and drums. Trumpets, gongs, drums and firecrackers, in particular, seriously disturb normal life and lead to annoyance complaints.

In conclusion, urban noise pollution in China is serious and is getting worse. To control noise pollution, China has promulgated standard sound values for environmental noise. These are summarized in table A2.2.

Table A2.2: LAeq standard values in dB for environmental noise in urban areas.

Applied area	day	night
Special residential quarters[1]	45	35
Residential and cultural education area[2]	50	40
Type 1 mixed area[3]	55	45
Type 2 mixed area[4] or commercial area	60	50
Industrial area	65	55
Arterial roads[5]	70	55

1 Special residential quarters: quiet residential area
2 Residential and cultural education area: residential quarters, cultural, educational offices
3 Type 1 mixed area: mixture of commercial area and residential quarters
4 Type 2 mixed area: mixture of industrial area, commercial area, residential quarters and others
5 Roads with traffic volume of more than 100 cars per hour

The peak sound levels for frequent noises emitted during the night-time are not allowed to exceed standard values by more than 10 dBA. Single, sudden noises during the night-time are not allowed to exceed standard values by more than 15dBA.

Environmental Quality Standards

Noise standards for both general and roadside areas were set in Japan in 1967, through the "Basic Law for Environmental Pollution." This law was updated in September 1999. Each standard is classified according to the type of land use and the time of day. In ordinary residential areas, the night-time standard is 45 dB LAeq, but in areas that require even lower noise exposure, such as hospitals, this is lowered to 40 dB LAeq. In contrast, the daytime levels for commercial and industrial areas is as high as 60 dBA. Standards for roadside areas are 70 dB LAeq for daytime and 65 dB LAeq for nighttime. Between 1973–1997 noise standards for aircraft noise, super-express train noise and conventional railway train noise were also implemented. Standards for aircraft noise were set in terms of the weighted equivalent continuous perceived noise level (WECPNL). For residential areas, the WECPNL standard is 70 dBA, and is 75 dBA for areas where it is necessary to maintain a normal daily life.

For super-express trains, the Environmental Agency required noise levels to be below 75 dBA in densely populated residential areas, such as along the Tokaido and Sanyo Shinkansen lines, as well as in increasingly populated areas, such as along the Tohoku and Joetsu Shinkansen lines. The standards were to be met by 1990, but by 1991 this level had been achieved at only 76% of the measuring sites on average. Noise countermeasures included the installation of new types of sound-proof walls, and laying ballast mats along densely populated stretches of the four Shinkansen lines. Noise and vibration problems can also result from conventional trains, such as occurred with the opening of the Tsugaru Strait and Seto Ohashi railway lines in 1988. Various measures have since been taken to address the problems.

Complaints About Community Noise.

In Japan, complaints to local governments about environmental problems have been summarized annually and reported by Japan Environmental Agency. Thirty-seven percent of all complaints was due to factory (machinery) noise; 22% to construction noise; 3% to road traffic noise; 4% to air traffic noise; 0.8% to rail traffic noise; 9% to night-time business; 6% to other commercial activities; 2.5% to loudspeaker announcements; 9% to domestic noise; and 8% was due to miscellaneous complaints.

Sources of Noise Exposure and their Effects

Road-traffic noise. The number of automobiles in Japan has increased from 20 million in 1971 to 70 million in 1994, a 3.5-fold increase. One-third of this increase was due to heavy-duty vehicles. Since 1994, out of a total of 1 150 000 km of roads in Japan, only 29 930 km have been designed according to noise regulations. According to 1998 estimates by the Environmental Agency, 58% of all roads passed through residential areas. Daytime noise limits were exceeded in 92% of all cases, and night-time limits were exceeded in 87% of all cases. The study also estimated that 0.5 million houses within 10 m of the roads were exposed to excessive traffic noise. In a recent lawsuit, the Japanese Supreme Court ruled that people should be compensated when exposed to night-time noise levels exceeding 65 dB Laeq. This would apply to people living alongside 2 000 km of roads in Japan.

A recent epidemiological study examined insomnia in 3 600 women living in eight different roadside areas exposed to night-time traffic. Insomnia was defined as one or more of the following symptoms: difficulty in falling asleep; waking up during sleep; waking up too early; and feelings of sleeplessness one or more days a week over a period of at least a month. The data were adjusted for confounding variables, such as age, medical care, whether the subjects had young children to care for, and sleep apnea symptoms. The results showed that the odds ratio for insomnia was significantly correlated with the average night-time traffic volume for each of the eight areas and suggested that insomnia could be attributed solely to night-time road traffic.

From the most noisy areas in the above study 19 insomnia cases were selected for a further in-depth examination. The insomnia cases were matched in age and work with 19 control subjects. Indoor and outdoor sound levels during sleep were measured simultaneously at 0.6 s intervals. For residences facing roads with average night-time traffic volume of 6 000 vehicles per hour, the highest sound levels observed were 78–93 dBA. The odds ratios for insomnia in each of the quartiles for LAmax,1min; L50,1min; L10,1min and LAeq,1min generally showed a linear trend and ranged between 1 (lowest quartile) and 6–7 (highest quartile). It was concluded that insomnia was likely to result when night-time indoor LAeq, 1min sound levels exceeded 30 dBA.

Air-traffic noise At the larger Japanese airports (Osaka, Tokyo, Fukuoka), jet airplanes have rapidly increased in number and have caused serious complaints and lawsuits from those living nearby. Complaints about jet-fighter noise are also common from residents living in the vicinity of several U.S. airbases located in Japan. In the case of Kadena and Futemma airbases on Okinawa, a recent study by the Okinawa Prefecture Government suggested that hearing loss, child misbehaviour and low birth-weight babies were possible health effects of the noise associated with these bases (RSCANIH 1997). Using measurements taken in 1968 during the Vietnam War, it was estimated that the WECPNL was 99–108 dBA at the Kadena village fire station. Similar WECPNL estimates of 105 dBA were also obtained for Yara (Kadena-cho) and Sunabe (Chatan-cho) bases. These levels correspond to a LAeq,24h value of 83 dB, and are of serious concern in light of recommendations by the Japan Association of Industrial Health that occupational noise exposure levels should not exceed 85 dB for an 8-h work day if hearing loss is to be avoided.

Audiogrammes of subjects living in areas surrounding Kadena airport indicated that they had progressive hearing loss at higher frequencies. Eight subjects had hearing impairment in the 3–6 kHz range, which strongly suggested that the hearing loss was due to excessive noise exposure. Since the examiners confirmed the subjects had not been exposed to repeated intense noise at their residences or workplaces, the most likely cause of their hearing loss was the intense aircraft noise during take-offs, landings and tune-ups at Kadena airport.

The effects of noise were examined in children from nursery schools and kindergartens in towns surrounding Kadena airport. The children were scored with respect to seven variables: cold symptoms, emotional instability, discontentment-anxiety, headache-stomachache, passivity, eating problems and urination problems. Confounding factors, such as sex, age, birth order, the number of parents living together, the mother's age when the child was born, reaction to noise and the extent of noise exposure, were taken into account. The results showed that children exposed to noise had significantly more problems with respect to their behaviour, physical condition, character and reaction to noise, when compared to a control group of children that had not been exposed to airport noise. This was especially true of for children exposed to a WECPNL of 75 or more. Thus, small children acquire both physical and mental disorders from chronic exposure to aircraft noise.

Chronic exposure to aircraft noise also affects the birth-weight of children. The birth-weights of infants were analyzed using records from 1974 to 1993 in the Okinawa Prefecture. Confounding factors such as the mother's age, whether there were single or multiple embryos, the child's sex, and the legitimacy of the child were considered. The results showed that 9.1 % of all infants born in Kadena-cho, located closest to Kadena airport, had low birth-weights. This was significantly higher than the 7.6 % rate seen in other municipalities around Kadena and Futemma airfields, and much higher than the 7 % rate in cities, towns and villages on other parts of Okinawa Island.

Rail-traffic noise. Commuter trains and subway cars expose Tokyo office workers to much higher noise levels than do other daily activities (Kabuto & Suzuki 1976). Exposure to indoor noise may vary according to railway line or season (there are more open windows in good weather), but the levels range from 65–85 dBA. In general, these values exceeded the LAeq,24h level of 70 dBA for auditory protection (US EPA 1974).

Neighbourhood noise. Neighbourhood noise, including noise from late-night business operations, noise caused by loudspeaker announcements, and noise from everyday activities, have accounted for approximately 39% of all complaints about noise in recent years. At present, noise controls for late-night business operations have been enforced by ordinances in 39 cities and prefectures, and in 42 cities for loudspeaker announcements.

Appendix 3 : Glossary

Acoustic	Pertaning to sound or to the sense of hearing (CMD 1997)
Acoustic dispersion	Change of speed of sound with frequency (ANSI 1994)
Acoustic trauma	Injury to hearing by noise, especially loud noise (CMD 1997)
Adverse effect	(of noise:) A change in morphology and physiology of an organism which results in impairment of functional capacity or impairment of capacity to compensate for additional stress or increase in susceptibility to the harmful effects of other environmental influences. This definition includes any temporary or long term lowering of physical, psychological or social functioning of humans or human organs (WHO 1994)
Annoyance	A feeling of displeasure associated with any agent or condition known or believed by an individual or a group to be adversely affecting them" (Lindvall and Radford 1973; Koelega 1987). Any sound that is perceived as irritating or a nuisance (ANSI 1995)
Anxiety	A feeling of apprehension, uncertainty, and fear without apparent stimulus, and associated with physiological changes (tachycardia, sweating, tremor, etc.) (DIMD 1985). A vaguer feeling of apprehension, worry, uneasiness, or dread, the source of which is often nonspecific or unknown to the individual (CMD 1997).
Audiometry	Testing of the hearing sense (CMD 1997). Measurement of hearing, including aspects other than hearing sensitivity (ANSI 1995)
Auditory	Pertaining to the sense of hearing (CMD 1997)
Auditory threshold	Minimum audible sound perceived (CMD 1997)
A-weighting	A frequency dependent correction that is applied to a measured or calculated sound of moderate intensity to mimick the varying sensitivity of the ear to sound for different frequencies

Ambient noise	All-encompassing sound at a given place, usually a composite of sounds from many sources near and far (ANSI 1994)
Articulation index	Numerical value indicating the proportion of an average speech signal that is understandable to an individual (ANSI 1995)
Bel	Unit of level when the base of the logarithm is ten, and the quantities concerned are proportional to power; unit symbol B (ANSI 1994)
Cardiovascular	Pertaining to the heart and blood vessels (DIMD 1985)
Cochlea	A winding cone-shaped tube forming a portion of the inner ear. It contains the receptor for hearing (CMD 1997)
Cognitive	Being aware with perception, reasoning, judgement, intuition, and memory (CMD 1997)
Community noise	Noise emitted from all noise sources except noise at the industrial workplace (WHO 1995a)
Cortisol	A glucocortical hormone of the outer layer of the adrenal gland (CMD 1997)
Critical health effect	Health effect with lowest effect level
C-weighting	A frequency dependent correction that is applied to a measured or calculated sound of high intensity to mimick the varying sensitivity of the ear to sound for different frequencies
dB	Decibel, one-tenth of a bel
dBA	A-weighted frequency spectrum in dB, see A-weighting
dBC	C-weighted frequency spectrum in dB, see C-weighting
dBlin	Unweighted frequency spectrum in dB
Decibel	Unit of level when the base of the logarithm is the tenth root of ten, and the quantities concerned are proportional to power; unit symbol dB (ANSI 1994)

Ear plug	Hearing protector that is inserted into the ear canal (ANSI 1994)
Ear muff	Hearing protector worn over the pinna (external part) of an ear (ANSI 1994)
Effective perceived noise level	Level of the time integral of the antilogarithm of one tenth of tone-corrected perceived noise level over the duration of an aircraft fly-over, the reference duration being 10 s (ANSI 1994)
Emission	(of sounds). Sounds generated from all types of sources
Epinephrine	A hormone secreted by the adrenal medulla (inner or central portion of an organ) in response to stimulation of the sympathetic nervous system (CMD 1997)
Equal energy principle	Hypothesis that states that the total effect of sound is proportional to the total amount of sound energy received by the ear, irrespective of the distribution of that energy in time
Equivalent sound pressure level	Ten times the logarithm to the base ten of the ratio of the time-mean-square instantaneous sound pressure, during a stated time interval T, to the square of the standard reference sound pressure (ANSI 1994)
Exposure-response curve	Graphical representation of exposure-response relationship
Exposure-response relationship	(With respect to noise:) Relationship between specified sound levels and health impacts
Frequency	For a function periodic in time, the reciprocal of the period (ANSI 1994)
Frequency-weighting	A frequency dependent correction that is applied to a measured or calculated sound (ANSI 1994)
Gastro-intestinal	Pertaining to the stomach and intestines (CMD 1997)
Hearing impairment, hearing loss	A decreased ability to perceive sounds as compared which what the individual or examiner would regard as normal (CMD 1997)
Hearing threshold	For a given listener and specified signal, the minimum (a) sound pressure level or (b) force level that is capable of

	evoking an auditory sensation in a specified function of trials (ANSI 1994)
Hertz	Unit of frequency, the number of times a phenomenon repeats itself in a unit of time; abbreviated to Hz
Hysteria	A mental disorder, usually temporary, presenting somatic (pertaining to the body) symptoms, stimulating almost any type of physical disease. Symptoms include emotional instability, various sensory disturbations, and a marked craving for sympathy (CMD 1997)
Immission	Sounds impacting on the human ear.
Impulsive sound	Sound consisting of one or more very brief and rapid increases in sound pressure
Incubator	An enclosed crib, in which the temperature and humidity may be regulated, for care of premature babies (CMD 1997)
Isolation, insulation	(With respect to sound:) Between two rooms in a specified frequency band, difference between the space-time average sound presssure levels in the two enclosed spaces when one or more sound sources operates in one of the rooms (ANSI 1994). (With respect to vibrations:) Reduction in the capacity of a system to respond to excitation, attained by use of resilient support (ANSI 1994).
Ischaemic Heart Disease	Heart disease due to a local and temporary deficiency of blood supply due to obstruction of the circulation to a part (CMD 1997)
Loudness level	Of a sound, the median sound pressure level in a specified number of trials of a free progressive wave having a frequency of 1000 Hz that is judged equally loud as the unknown sound when presented to listeners with normal hearing who are facing the source; unit phon (ANSI 1994)
Level	Logarithm of the ratio of a quantity to a reference quantity of the same kind; unit Bel (ANSI 1994)
Maximum sound level	Greatest fast (125 milliseconds) A-weighted sound level, within a stated time interval (ANSI 1994)

Mental Health	The absence of identifiable psychiatric disorder according to current norms (Freeman 1984). In noise research, mental health covers a variety of symptoms, ranging from anxiety, emotional stress, nervous complaints, nausea, headaches, instability, argumentativeness, sexual impotency, changes in general mood and anxiety, and social conflicts, to more general psychiatric categories like neurosis, phychosis and hysteria (Berglund and Lindvall 1995).
Morphological	Pertaining to the science of structure and form of organisms without regard to function (CMD 1997)
Nausea	An unpleasant sensation usually preceding vomiting (CMD 1997)
Neurosis	An emotional disorder due to unresolved conflicts, anxiety being its chief characteristic (DIMD 1985)
Noise	Undesired sound. By extension, noise is any unwarranted disturbance within a useful frequency band, such as undesired electric waves in a transmission channel or device (ANSI 1994).
Noise induced temporary threshold shift	Temporary hearing impairment occurring as a result of noise exposure, often phrased temporary threshold shift (adapted from ANSI 1994)
Noise induced permanent threshold shift	Permanent hearing impairment occurring as a result of noise exposure, often phrased permanent threshold shift (adapted from ANSI 1994)
Noise level	Level of undesired sound
Norepinephrine	A hormone produced by the adrenal medulla (inner or central portion of an organ), similar in chemical and pharmacological properties to epinephrine, but chiefly a vasoconstrictor with little effect on cardiac output (CMD 1997)
Oscillation	Variation, usually with time, of the magnitude of a quantity with respect to a specified reference when the magnitude is alternately greater and smaller than the reference (ANSI 1994)

Ototoxic	Having a detrimental effect on the organs of hearing (CMD 1997)
Paracusis	Any abnormality or disorder of the sense of hearing (CMD 1997)
Pascal	Unit of pressure, equal to one newton per square meter, abbreviated to Pa
Peak sound pressure	Greatest absolute instantaneous sound pressure within a specified time interval (ANSI 1994)
Peak sound pressure level	Level of peak sound pressure with stated frequency weighting, within a specified time interval (ANSI 1994)
Perceived noise level	Frequency-weighted sound pressure level obtained by a stated procedure that combines the sound pressure levels in the 24 one-third octave bands with midband frequencies from 50 Hz to 10 kHz (ANSI 1994)
Permanent threshold shift, permanent hearing loss	Permanent increase in the auditory threshold for an ear (adapted from ANSI 1995) (see also: noise induced permanent threshold shift)
Presbyacusia, presbycusis	The progressive loss of hearing ability due to the normal aging process (CMD 1997)
Psychiatric disorders	Mental disorders
Psychosis	Mental disturbance of a magnitude that there is a personality disintegration and loss of contact with reality (CMD 1997)
Psychotropic drug	A drug that affects psychic function, behaviour or experience (CMD 1997)
Reverberation time	Of an enclosure, for a stated frequency or frequency band, time that would be required for the level of time-mean-square sound pressure in the enclosure to decrease by 60 dB, after the source has been stopped (ANSI 1994)
Sensorineural	Of or pertaining to a sensory nerve; pertaining to or affecting a sensory mechanism and/or a sensory nerve (DIMD 1985)

Signal	Information to be conveyed over a communication system (ANSI 1994)
Signal-to-noise ratio	Ratio of a measure of a signal to the same measure of the noise (ANSI 1995) (see also: noise –in its extended meaning)
Silencer	Duct designed to reduce the level of sound; the sound-reducing mechanisms may be either absorptive or reactive, or a combination (ANSI 1994)
Sound absorption	Change in sound energy into some other form, usually heat, in passing through a medium or on striking a surface (ANSI 1994)
Sound energy	Total energy in a given part of a medium minus the energy that would exist at that same part with no sound waves present (ANSI 1994)
Sound exposure	Time integral of squared, instantaneous frequency-weighted sound pressure over a stated time interval or event (ANSI 1994)
Sound exposure level	Ten times the logarithm to the base ten of the ratio of a given time integral of squared, instantaneous A-weighted sound pressure, over a stated time interval or event, to the product of the squared reference sound pressure of 20 micropascals and reference duration of one second (ANSI 1994)
Sound intensity	Average rate of sound energy transmitted in a specified direction at a point through a unit area normal to this direction at the point considered (ANSI 1994)
Sound level meter	Device to be used to measure sound pressure level with a standardized frequency weighting and indicated exponential time weighting for measurements of sound level, or without time weighting for measurement of time-average sound pressure level or sound exposure level (ANSI 1994)
Sound pressure	Root-mean-square instantaneous sound pressure at a point, during a given time interval (ANSI 1994), where the *instantaneous* sound pressure is the total instantaneous pressure in that point minus the static pressure (ANSI 1994)

Sound pressure level	Ten times the logarithm to the base ten of the ratio of the time-mean-square pressure of a sound, in a stated frequency band, to the square of the reference sound pressure in gases of 20 μPa (ANSI 1994)
Sound reduction index	Single-number rating of airborne sound insulation of a partition (ANSI 1994)
Sound transmission class	Single-number rating of airborne sound insulation of a building partition (ANSI 1994)
Speech interference level	One-fourth of the the sum of the band sound pressure levels for octave-bands with nominal midband frequencies of 500, 100, 2000 and 4000 Hz (ANSI 1994)
Speech intelligibility	That property which allows units of speech to be identified (ANSI 1995)
Speech perception	Psychological process that relates a sensation caused by a spoken message to a listener's knowledge of speech and language (ANSI 1995)
Speech comprehension	(a) Highest level of speech perception. (b) Knowledge or understanding of a verbal statement (ANSI 1995)
Speech transmission index	Physical methgod for measuring the quality of speech-transmission channels accounting for nonlinear distortions as well as distortions of time (ANSI 1995)
Stereocilia	Nonmotile protoplasmic projections from free surfaces on the hair cells of the receptors of the inner ear (CMD 1997)
Stress	The sum of the biological reactions to any adverse stimulus, physical, mental or emotional, internal or external, that tends to disturb the organism's homeostasis (DIMD 1985)
Temporary threshold shift, temporary hearing loss	Temporary increase in the auditory threshold for an ear caused by exposure to high-intensity acoustic stimuli (adapted from ANSI 1995) (see also: noise induced temporary threshold shift).
Tinnitus	A subjective ringing or tinkling sound in the ear (CMD 1997). Otological condition in which sound is perceived by

	a person without an external auditory stimulation. The sound may be a whistling, ringing, buzzing, or cricket type sounds, but auditory hallucinations of voices are excluded (ANSI 1995).
Vibration	Oscillation of a parameter that defines the motion of a mechanical system (ANSI 1994)

Appendix 5 : Equations and other technical information

Basic acoustical measures

Sound Pressure Level

The time-varying sound pressure will completely define a sound in a given location. The sound pressure range is wide within which human listeners can receive (10^{-5} - 10^{2} N/m^2). Therefore, it is practical to measure sound pressure level on a logarithmic scale. Sound intensity level is defined as 10 times the logarithm (to the base 10) of the ratio of the sound intensity of a target sound to the sound intensity of another (reference) sound. Sound intensity is proportional to the squared sound pressure because the static mass density of the sound medium as well as the speed of sound in this medium are invariant. The sound pressure level (L_p) of a sound may be expressed as a function of sound pressure (p) and is, thus, possible to measure:

$$L_p = 10 \log_{10} (p/p_{ref})^2$$

For the purpose of measuring sound pressure level in a comparative way, the reference pressure, p_{ref}, has an internationally agreed value of $2 \cdot 10^{-5}$ N/m^2 (earlier 20 μPa). Sound pressure level is then expressed in decibel (dB) relative to this reference sound.

Sound Pressure Level of Combined Sounds

Whereas sound intensities or energies or pressures are additive, non-correlated time-varying sound pressure levels have first to be expressed as mean square pressure, then added, and then transferred to a sound pressure value again. For example, if two sound sources are combined, each of a sound pressure level of 80 dB, then the sound pressure level of the resulting combined sound will become 83 dB:

$$L_p = 10 * \log_{10} (10^8 + 10^8) = 10 * \log_{10} (2 * 10^8) = 10 * (\log_{10} 2 + \log_{10} 10^8) = \\ 10 * (0.3 + 8) = 83$$

It is only sounds with similar sound pressure levels that when combined will result in a significant increase in sound pressure level relative to the louder sound. In the example given above, a doubling of the sound energy from two sources will only result in a 3-dB increase in sound pressure level. For two sound sources that emit non-correlated time-varying sound pressures, this represents the maximum increase possible. The sound pressure level outcome, resulting from combining two sound pressure levels in dB, is displayed in Figure A.5.1.

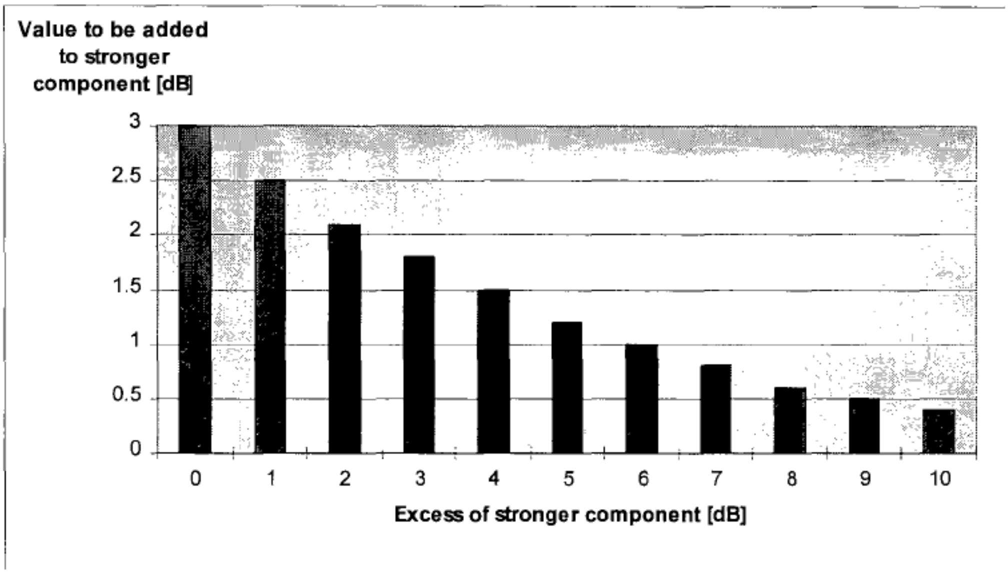

Figure A.5.1: Estimate of combined sound levels

Equivalent Continuous Sound Pressure Level

Average sound pressure level is determined for a time period of interest, T, which may be an interval in seconds, minutes, or hours. This gives a dB-value in Leq that stands for equivalent continuous sound pressure level or simply sound level. It is derived from the following mathematical expression in which A-weighting has been applied:

$$LAeq,T = 10 \log_{10}\{(1/T) \int_0^T 10^{Lp(t)/10} dt\} \text{ [dBA]}$$

Because the integral is a measure of the total sound energy during the period T, this process is often called "energy averaging". For similar reasons, the integral term representing the total sound energy may be interpreted as a measure of the total noise dose. Thus, Leq is the level of that steady sound which, over the same interval of time as the fluctuating sound of interest, has the same mean square sound pressure, usually applied as an A-frequency weighting. The interval of time must be stated.

Sound exposure level

Individual noise events can be described in terms of their sound exposure level (SEL). SEL is defined as the constant sound level over a period of 1 s that would have the same amount of energy as the complete noise event (Ford 1987). For a single noise event occurring over a time interval T, the relationship between SEL and LAeq,T is,

$$SEL = LAeq,T + 10 \log_{10} (T/T_0)$$

In this equation T_0 is 1 s.

Day and night continuous sound pressure level

There are different definition in different countries. One definition is (von Gierke 1975; Ford 1987):

L_{dn} = LAeq,16h + LAeq,8h – 10 dBA

Where LAeq,16h is the day equivalent sound pressure level and LAeq,8h is the night equivalent sound pressure level.

Sound Transmission into and within buildings

An approximate relationship between sound reduction index (R), the frequency (f), the mass per unit area of the panel (m) in kg/m^2, and the angle of incidence (θ) is given by

$$R(\theta) = 20 \log\{f m \cos(\theta)\} - 42.4, \text{ (dB)}$$

This relationship indicates that the sound reduction index will increase with the mass of a panel and with the frequency of the sound as well as varying with the angle of incidence of the sound. It is valid for limp materials but is a good approximation to the behaviour of many real building materials at lower frequencies.

The sound reduction index versus frequency characteristics are usually complicated by a coincidence dip which occurs around the frequency where the wavelength of the incident sound is the same as the wavelength of bending waves in the building façade material. The frequency at which the coincidence dip occurs is influenced by the stiffness of the panel material. Thicker, and hence stiffer materials, will have coincidence dips that are lower in frequency than less stiff materials. Figure A.5.2 plots measured sound reduction index values versus frequency for 4 mm thick glass and illustrates the coincidence dip for this glass at a frequency centered just above 3 kHz.

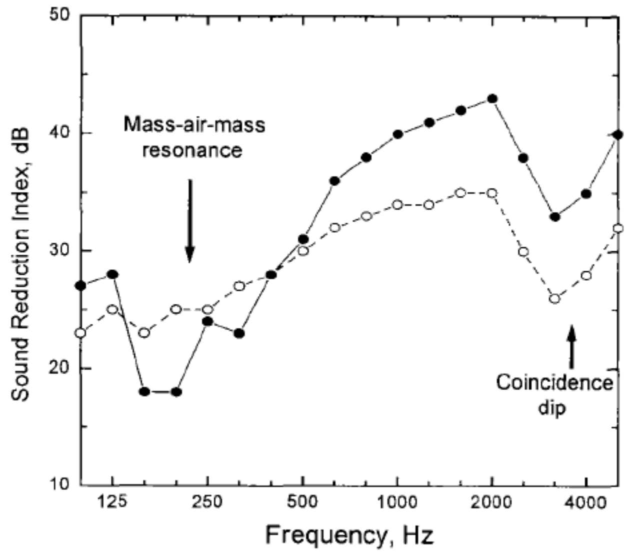

Figure A.5.2: Sound reduction index versus frequency for single and double layers of 4 mm glass (air separation 13 mm).

As also illustrated in Figure A.5.2 for two layers of 4 mm glass, the low frequency sound reduction can be severely limited by the mass-air-mass resonance. This resonance is due to the combination of the masses of the two layers and the stiffness of the enclosed air space. As the Figure A.5.2 example shows, this resonance can often dramatically reduce the low frequency sound reduction of common double window constructions.

The sound reduction of various building constructions can be calculated as the difference between the average sound levels in the two rooms ($L_1 - L_2$) plus a correction involving the area of the test panel (S) in m^2 and the total sound absorption (A) in m^2 in the receiving room,

$$R = L_1 - L_2 + 10 \log\{S/A\} \quad [\text{dB}].$$

For outdoor-to-indoor sound propagation, the measured sound reduction index will also depend on the angle of incidence of the outdoor sound as well as the position of the outdoor measuring microphone relative to the building façade,

$$R = L_1 - L_2 + 10 \log\{4S\,COS(\theta)/A\} + k \quad [\text{dB}].$$

When the outdoor incident sound level L_1 is measured with the outdoor microphone positioned against the external façade surface, measured incident sound pressures will be 6 dB higher due to pressure doubling. This occurs because the incident sound and reflected sound arrive at the microphone at the same time. If the external microphone is located 2 m from the façade, there will not be exact pressure doubling but an approximate doubling of the measured sound energy corresponding to a 3 dB increase in sound level. The table below indicates the appropriate values of k to be used in the above equation, depending on the location of the outdoor microphone, to account for sound reflected from the façade.

$k = 0$, dB	L_1 does not include reflected sound.
$k = -3$, dB	L_1 measured 2 m from façade and includes reflected energy.
$k = -6$, dB	L_1 measured at the façade surface and includes pressure doubling effect.

Appendix 6 : Participant list of THE WHO Expert Task Force meeting on Guidelines For Community Noise, 26-30 April 1999, MARC, London, UK

Professor Birgitta Berglund, Department of Psychology, Stockholm University, S-10691 Stockholm, Sweden, Tel: +46 8 16 3857, Fax: +46 8 16 5522, Email: birber@mbox.ki.se.

Dr. Hans Bögli, Bundesamt für Umwelt, Wald und Landschaft (BUWAL), Abteilung Lärmbekämpfung, CD 3003 Bern, Switzerland, Tel: +41 31 322 9370, Fax: +41 31 323 0372, Email: hans.boegli@buwal.admin.ch.

Dr. John S. Bradley, Manager, Acoustics Subprogram, Indoor Environment Program, National Research Council Canada, Ottawa, K1A OR6, Canada, Tel: +1 613 993 9747, Fax: +1 613 954 1495, Email: john.bradley@nrc.ca.

Dr. Ming Chen, Department of Otolaryngology, Fujian Provincial Hospital, N° 134 East Street, Fuzhou 350001, People's Republic of China, Tel: +86 0591 755 7768-365(258) office, 755 6952 home, Fax: +86 0591 755 6952, Email:

Lawrence S. Finegold, Air Force Research Laboratory, AFRL/HECA, 2255 H Street, Wright-Patterson AFB, OH 45433-7022, USA, Tel: +1 937 255 7559, Fax: +1 937 255-9198, Email: Larry.Finegold@he.wpafb.af.mil.

Etienne Grond, P.O. Box 668, Messina 0900, South Africa, Tel: +27 15 575 2031, Fax: +27 15 575 2025, Email: egrond@debeers.co.za.

Professor Andrew Hede, University of the Sunshine Coast, Sippy Downs, Maroochydore South, Qld. 4558, Australia, Tel: +61 7 5430 1230, Fax: +61 7 5430 1231, Email: hede@usc.edu.au.

Professor Gerd Jansen, Institut für Arbeitsmedizin der Medizinischen Einrichtungen der Heinrich-Heine-Universität Düsseldorf, Kirchfeldstraβe 35, D-40217 Düsseldorf, Germany, Tel: +49 211 919 4985 (O.), +49 201 403 123 (R.), Fax: +49 211 919 3989, Email: Jan.G2t-online.de

Dr. Michinori Kabuto, Director, Env. Risk Research Division, National Institute for Environmental Studies, 16-2 Onogawa, Tsukuba, Ibaraki 305, Japan, Tel: +81 298 50 2333, Fax: +81 298 50 2571, Email: kabuto@nies.go.jp/mkabuto@msn.com.

Professor Thomas Lindvall, National Institute of Environmental Medicine and Karolinska Institutet, PO Box 210, S-17177 Stockholm, Sweden, Tel: +46 8 728 7510, Fax: +46 8 33 22 18, Email: Thomas.Lindvall@imm.ki.se.

Dr. Amanda Niskar, CDC/NCEH, 4770 Buford Highway, NE, Mailstop F-46, Atlanta, Georgia 30341-3724, USA, Tel: +1 770 488 7009, Fax: +1 770 488 3506, Email: abn0@cdc.gov.

Dr Sudhakar B. Ogale, Professor and Head, Dept. of Otolaryngology, G.S. Medical College and KEM Hospital, Parel, Mumbai 400012, India, Tel: +91 22 413 6051 Ext ENT, Home +91 22 412 4329, Fax: +91 22 414 3435, Email:
