Re: Docket No. PCN 5 – In the Matter of Idaho Power Company's Petition for Certificate of Public Convenience and Necessity.

Attention Filing Center:

Attached for filing in the above-referenced docket is Idaho Power Company's Reply Testimony and Exhibits of Dr. Jeffrey M. Ellenbogen (Idaho Power/1200-1220).

Please note that, because the only confidential information contained in Dr. Ellenbogen's testimony and exhibits is confidential medical information, there are only two versions of the testimony and exhibits—the public version, which contains redactions, and the confidential version. The confidential version is being sent via encrypted zip file only to the Filing Center and Mr. Greg Larkin pursuant to Administrative Law Judge Mellgren's February 17, 2023 Ruling.

Please contact this office with any questions.

Thank you,

Alisha Till

I. INTRODUCTION

Q. Please state your name, your place of employment, and your position.

A. My name is Dr. Jeffrey M. Ellenbogen and I am a physician, scientist and teacher in the state of Maryland. I am the Director of The Sound Sleep Project and President of Ellenbogen Scientific, LLC.

Q. Please describe your educational experience.

A. I received a Bachelor of Arts ("BA") from the University of Michigan, a Master of Medical Sciences degree ("MMSc") from Harvard Medical School, and a Medical Doctor degree ("MD") from Tufts University. After completing medical school, I went to the University of Pennsylvania where I completed an internship in medicine, residency in neurology, and fellowship in clinical electrophysiology. I then completed a two-year post-doctoral fellowship in Sleep, Circadian, and Respiratory Neurobiology at Harvard Medical School. A comprehensive list of my training, experience, and education is included in my resume, which is attached as an exhibit to this testimony.[1]

Q. Please describe your clinical, academic, and leadership experience as a physician.

A. I am a licensed and practicing physician and have been for more than 20 years. My clinical work experience includes practice as a neurologist and sleep-medicine specialist at the following hospitals: Massachusetts General Hospital ("MGH"), Johns Hopkins Hospital, and Walter Reed National Military Medical Center ("WRNMMC"). I was Division Chief and Lab Director of Sleep Medicine at MGH. I was an Assistant Professor of Neurology at Harvard Medical School and at Johns Hopkins University. Then, I was an Associate Professor of Neurology and of Military & Emergency Medicine, and Vice Chair of Neurology at the Uniformed Services University. At WRNMMC, I saw inpatients with neurological emergencies, and outpatients in three areas: Neurology Department;

[1] Idaho Power/1201 (Curriculum Vitae of Dr. Jeffrey Ellenbogen).

Otolaryngology Department (i.e., ENT: ear, nose, and throat); and the National Intrepid Center of Excellence ("NICoE"), which included work on traumatic brain injury, other neurological diseases, and on sleep medicine.

Q. Please discuss your specific background and expertise regarding noise impacts on health.

A. When I was Director of the Sleep Division at Harvard's MGH, I ran a sleep-research acoustical laboratory. The purpose of this lab was to help people suffering from noise-induced sleep loss.[2] I also spent several years working with the acoustics engineering firm, Bose Corporation.

Q. One of the parties in this matter has raised concerns regarding the impact of noise on his insomnia and tinnitus. Do you have specific education, training, or experience to address these topics as a subject-matter expert?

A. Yes. Regarding insomnia, I am a fellowship-trained, board-certified specialist in sleep medicine, and have been recognized as a Fellow of the American Academy of Sleep Medicine. Regarding tinnitus, I have worked directly with patients with tinnitus, mostly active-duty members of the military returning from combat. I have also seen patients with problems of the inner ear (including tinnitus and vertigo) as an outpatient doctor. Both of these experiences were at the WRNMMC.

As a neurologist and sleep-medicine specialist for the past 15 years, I frequently treat insomnia. Most recently, at the NICoE (in Bethesda, Maryland), it was my responsibility to join a multi-disciplinary team whose goal was to provide medical and related services to active-duty service members returning to the United States from combat. Most of these service members had tinnitus and insomnia. I participated in the

M. et al., Sleep Disruption Due to Hospital Noises: A Prospective Evaluation (2012)); Idaho Power/1203 (McKinney, S. et al., Covert Waking Brain Activity Reveals Instantaneous Sleep Depth (2011)); Idaho Power/1204 (Dang-Vu, T. T. et al., Spontaneous Brain Rhythms Predict Sleep Stability in the Face of Noise (2010)).

care of both. During this time, I also saw outpatients at the WRNMMC. This included outpatients in the Otolaryngology Clinic who came for treatment from our multidisciplinary team dealing with inner-ear problems that included vertigo, dizziness, tinnitus, and hearing loss.

Q. Do you have any industry experience related to noise and human health?

A. Yes. I worked as a scientific consultant for the consumer-related, acoustical, electrical-engineering company, Bose Corporation, for approximately three years. I have also provided expert testimony concerning topics such as noise-induced sleep loss, including for the wind energy company Invenergy.

Q. Do you have experience with municipal organizations related to noise and human health?

A. Yes. In 2011, the Department of Public Health and Department of Environmental Protection of the Commonwealth of Massachusetts appointed me to a panel of professionals (the "Panel") to perform an independent evaluation of the scientific and medical literature regarding wind turbines (including noise generated by them), and their potential impact on human health, as well as to solicit information from the public to hear about any potential issues not already reflected in the literature. The Panel's findings and conclusions were published in 2012.[3]

Q. Do you have experience with architectural acoustics and/or noise mitigation?

A. Yes. I helped develop two sleep laboratories for the purpose of studying sleep and noise. My role included insights concerning how to minimize noise intrusion for the purpose of optimizing sleep. One laboratory was at MGH, and the other at Walter Reed Army Institute of Research.

[3] Idaho Power/1205 (Ellenbogen, J. M. et al., Wind Turbine Health Impact Study: Report of Independent Expert Panel (2012)).

Q. In developing your testimony, have you relied on the testimony of any other Idaho Power witness in this case?

A. Yes. I relied on the noise modeling and weather data included in the Reply Testimony of Mark Bastasch.[4]

Q. What is the purpose of your testimony?

A. I was retained by representatives of Idaho Power to evaluate the testimony of Greg Larkin regarding potential health-related consequences of living near the Boardman to Hemingway Transmission Line Project ("B2H" or the "Project"), and to evaluate and to provide an expert opinion concerning Mr. Larkin's specific concerns regarding the impact of corona noise from B2H on his health.

II. GENERAL BACKGROUND ON NOISE AND HUMAN HEALTH

Q. What are the topics you will be addressing in this section of your testimony?

A. First, I will address noise characteristics and how they may be perceived by the hearer, otherwise referred to in this testimony as the "receiver" or "receptor." Second, I will discuss the levels and types of noises that can have impacts on health. Third, I will discuss noise mitigation strategies. And fourth, given that Mr. Larkin has raised his own insomnia and tinnitus as concerns, I will discuss how these conditions might be impacted by corona noise.

A. Noise Characteristics and Perception

Q. Please provide a general discussion regarding noise characteristics and human perception.

A. When considering how a particular sound might be perceived by a receptor, three variables are among the ones most important to note: steady-state vs. impulse; broadband vs. narrow band; and high amplitude vs. low amplitude.

[4] *See generally* Idaho Power/1100 (Feb. 21, 2023).

- ***Steady-state vs. impulse noise.*** Noise is generally characterized as steady-state (i.e., continuous) or impulse (i.e., comes and goes, abruptly). An example of a source of steady-state noise is a bedroom fan. An example of a source of impulse noise is the discharging of a firearm.

  Our brains are primarily change detectors. So steady-state noises are less likely to be detected than impulse noise, particularly when they contain a wide range of frequencies (i.e., broadband, see below). In fact, steady-state noises are often introduced into quiet spaces to help people not to notice annoying or unwanted noises, including impulse noises around or below the energy of the introduced noise. This is referred to as "masking" in my testimony below.

  Neither the crackling nor the hum-like features of corona noise are considered impulse noises.

- ***Broadband vs. narrow band noise.*** The frequency composition of a noise can be broadband (i.e., including many pitches) or narrow band (e.g., as narrow as a single pitch). Frequencies are reported in cycles per second, called Hertz ("Hz"). Our brains tend to find single pitches or narrow bands (i.e., just a few pitches) to be more noticeable than broadband. Examples of broadband include "white" or "brown" noise. It is also important to note that the human ear is not infinitely capable of hearing all the pitches in the physical universe. In fact, just like our eyes cannot see infrared or ultraviolet light, our ears have great difficulty hearing frequencies lower than about 20 Hz or higher than about 20,000 Hz.

  The crackling feature of corona noise is not considered a narrowband noise. While the hum is not technically tonal, it can have a narrow spectrum.

- ***High amplitude vs. low amplitude noise.*** For any given noise, it can be high or low energy, what we casually refer to as volume, which is the experience by a person of a noise's sound pressure level ("SPL").[5] This measure is often reported in some form of decibel ("dB"), typically A-weighted decibel ("dBA"), to account for the specifics of human hearing ranges. If you play a single piano key softly, the sound from the piano has a low SPL. Play the exact same key harder and the noise from the piano will have more energy—a higher SPL. That is, if you are playing a single piano key harder, the noise from the piano has the same frequency as the sound from the piano when you play the same key softly, but the noise has a higher energy or SPL. The less energetic a noise is (i.e., a lower SPL), the less likely a person will perceive that noise. In fact, there are known minimum thresholds beyond which our ear cannot hear at all. Furthermore, people with hearing loss require a higher energy or high SPL sound in order to perceive the sound.

The crackling and hum-like features of corona noise are of low amplitude in fair weather and rise to higher levels in foul weather. With respect to the noise sensitive receptors ("NSRs") in this case, and the data presented in Mr. Bastasch's testimony, under foul weather conditions, for the average person, the noise might be audible depending on the ambient background from the environment (i.e., the higher the ambient background sound level, for example from foul weather conditions, the less likely an individual will hear the corona noise) and also depending on whether the individual is indoors or outdoors (i.e., if an individual is indoors rather than outdoors, the individual is less likely to hear corona noise).

B. Noise and Human Health

Q. Are you aware of any studies on the health impacts of noise, and in particular of the impacts of corona noise?

[5] *See generally* Idaho Power/1206 (Vér, I. L. & Beranek, L. L., Noise and Vibration Control Engineering: Principles and Applications (2006)) (provides precise definitions of acoustical-engineering terms and concepts, including power, pressure, intensity, tonality, etc., as referenced in my testimony).

A. I am unaware of any health studies that have focused specifically on corona noise. However, of particular relevance to this case is a study that was published by Health Canada—the department of the Government of Canada responsible for national health policy—regarding wind turbine noise. This study provides the largest, and most rigorous and objective set of scientific data on the general issue of wind turbine noise (hereinafter, referred to in this testimony as the "Health Canada Study"). Data analysis and findings from the Health Canada Study became publicly available in several publications in 2016, all in well-regarded, peer-reviewed, clinically minded, scientific journals.[6]

While corona noise and wind turbine noise are not identical, they are similar enough that the findings of the Health Canada Study are worth considering here.

The purpose of the Health Canada Study was to rigorously examine a large population of people living near wind turbines in order to establish whether human exposure to noise from wind turbines leads to negative health-related consequences. Topics addressed in the Health Canada Study included sleep, stress, cardiovascular disease, and a number of other health-related issues, including headaches and tinnitus. The 2013 Health Canada Study took place among people living in either Prince Edward Island or southwestern Ontario.[7] These locations were chosen because of their relative similarities among people, similarities of the topography, and the wind turbines which were present and operating.[8]

This large, cross-sectional, epidemiological study examined well over 1,200

[6] *See* Idaho Power/1207 (Michaud, D. S. et al., Self-Reported and Measured Stress Related Responses Associated with Exposure to Wind Turbine Noise (2016)); Idaho Power/1208 (Michaud, D. S. et al., Exposure to Wind Turbine Noise: Perceptual Responses and Reported Health Effects (2016)); Idaho Power/1209 (Michaud, D. S. et al., Effects of Wind Turbine Noise on Self-Reported and Objective Measures of Sleep (2016)).

[7] *See, e.g.*, Idaho Power/1208, Ellenbogen/3 (Michaud, D. S. et al., Exposure to Wind Turbine Noise: Perceptual Responses and Reported Health Effects (2016)).

[8] *See, e.g.*, Idaho Power/1208, Ellenbogen/3 (Michaud, D. S. et al., Exposure to Wind Turbine Noise: Perceptual Responses and Reported Health Effects (2016)).

people living near wind turbines.[9] Participants were asked a range of health-related questions (subjective measures) and were physically examined for a range of health-related metrics (objective measures).[10] Specifically, the Health Canada Study was an "exposure-response" design.[11] Pursuant to this design method, examiners look to see if any health problems had more of a causal relationship to sound levels from wind turbines than others. Health problems are a part of life and will be discovered in any large population. The objective of the Health Canada Study was to see if any health problems resulted from or were associated with wind turbine noise. The Health Canada Study assumed that there was a dose-response relationship between wind turbine noise and the health condition.[12] Simply put, the Health Canada Study assumed that if wind turbine noise caused a health problem, that health problem should be more and more severe as the level of the noise got higher and higher.

The participants in the Health Canada Study were exposed to a range of noise from wind turbines, from less than 25 dBA up to 46 dBA.[13] A control group of persons being exposed to less than 25 dBA having similar demographics to the remaining participants in the study was utilized. Sound levels were calculated based on the location of the dwelling.[14] Health Canada's Scientific Advisory Board reviewed the design of the study, as did experts from the World Health Organization ("WHO"). The study design was also subjected to a 60-day public consultation, and review by the Research Ethics Board.

---

[9] *See, e.g.*, Idaho Power/1209, Ellenbogen/2 (Michaud, D. S. et al., Effects of Wind Turbine Noise on Self-Reported and Objective Measures of Sleep (2016)).

[10] *See, e.g.*, Idaho Power/1209, Ellenbogen/3-4 (Michaud, D. S. et al., Effects of Wind Turbine Noise on Self-Reported and Objective Measures of Sleep (2016)).

[11] *See, e.g.*, Idaho Power/1209, Ellenbogen/7 (Michaud, D. S. et al., Effects of Wind Turbine Noise on Self-Reported and Objective Measures of Sleep (2016)).

[12] *See, e.g.*, Idaho Power/1209, Ellenbogen/7 (Michaud, D. S. et al., Effects of Wind Turbine Noise on Self-Reported and Objective Measures of Sleep (2016)).

[13] *See, e.g.*, Idaho Power/1209, Ellenbogen/5-6 (Michaud, D. S. et al., Effects of Wind Turbine Noise on Self-Reported and Objective Measures of Sleep (2016)).

[14] *See, e.g.*, Idaho Power/1209, Ellenbogen/2-3 (Michaud, D. S. et al., Effects of Wind Turbine Noise on Self-Reported and Objective Measures of Sleep (2016)).

The subjective measures considered in the Health Canada Study included questions about a wide range of conditions, including migraines, tinnitus, dizziness, sleep disturbance, sleep disorders, quality of life, and perceived stress.[15] The objective measures examined in the Health Canada Study included stress (via hair cortisol measures); cardiovascular outcomes (heart rate, blood pressure); and sleep.[16]

None of the subjective measures nor objective measures of human health were found to be related to noise levels from wind turbines, demonstrating no relationship between noise from wind turbines and any adverse health impacts.[17] With respect to Mr. Larkin's concerns, it is important to point out that wind turbine noises up to 46 dBA did not impact any health conditions, including tinnitus, stress (objectively measured or subjectively reported), blood pressure (objectively measured), and sleep (objectively measured or subjectively reported). The highest modeled noise level at Mr. Larkin's property during foul weather conditions is 43 dBA and this assumes a conservative late-night ambient background of 31 dBA—a background ambient value that was calculated for periods of low winds (less than 10 mph) and without foul weather conditions.[18]

Q. In his testimony, Mr. Larkin has raised a concern that corona noise from B2H could cause hearing loss.[19] Are there known thresholds for noise induced hearing loss?

---

[15] *See, e.g.*, Idaho Power/1207, Ellenbogen/7 (Michaud, D. S. et al., Self-Reported and Measured Stress Related Responses Associated with Exposure to Wind Turbine Noise (2016)).

[16] *See, e.g.*, Idaho Power/1207, Ellenbogen/7 (Michaud, D. S. et al., Self-Reported and Measured Stress Related Responses Associated with Exposure to Wind Turbine Noise (2016)).

[17] *See, e.g.*, Idaho Power/1207, Ellenbogen/11-12 (Michaud, D. S. et al., Self-Reported and Measured Stress Related Responses Associated with Exposure to Wind Turbine Noise (2016)).

[18] Mr. Larkin's property is NSR 125. Idaho Power's Supplement to Petition for CPCN, Attachment 1 (Final Order, Attachment X-4, Revised Tabulated Summary of Acoustic Modeling Results by Receptor Location) at 10557 of 10603 (Oct. 7, 2022) [hereinafter, "Final Order, Attachment X-4"].

[19] Greg Larkin's Amended Opening Testimony and Exhibits (Greg Larkin/100, Larkin/20) (Feb. 1, 2023) ("On Page 28 of this document it indicates that there are three broad categories of health effects from exposure to noise. a. Subjective effects such as annoyance which can mean a significant degradation in the quality of life; b. Sleep, communication and concentration impacts; c. physiological effects such as anxiety, hearing loss and tinnitus. For individuals who already have underlying health issues, the addition of the corona noise will clearly exacerbate existing hearing, tinnitus, sleep and anxiety issues.").

A. Yes, depending on the level of the noise, and whether or not it is steady-state or impulse, noise can cause hearing loss. In fact, noise-related hearing loss is the most common health-related consequence of noise exposure. With respect to noise levels, the United States Department of Labor, Occupational Safety and Health Administration ("OSHA") has longstanding guidelines that allow up to eight hours of steady-state noise exposure at 90 dBA (see Table 1 below).

Table 1. Permissible Noise Exposure[20]

Duration Per Day (Hours)	Sound Level Slow Response (dBA)
8	90
6	92
4	95
3	97
2	100
1½	102
1	105
½	110
¼ or less	115

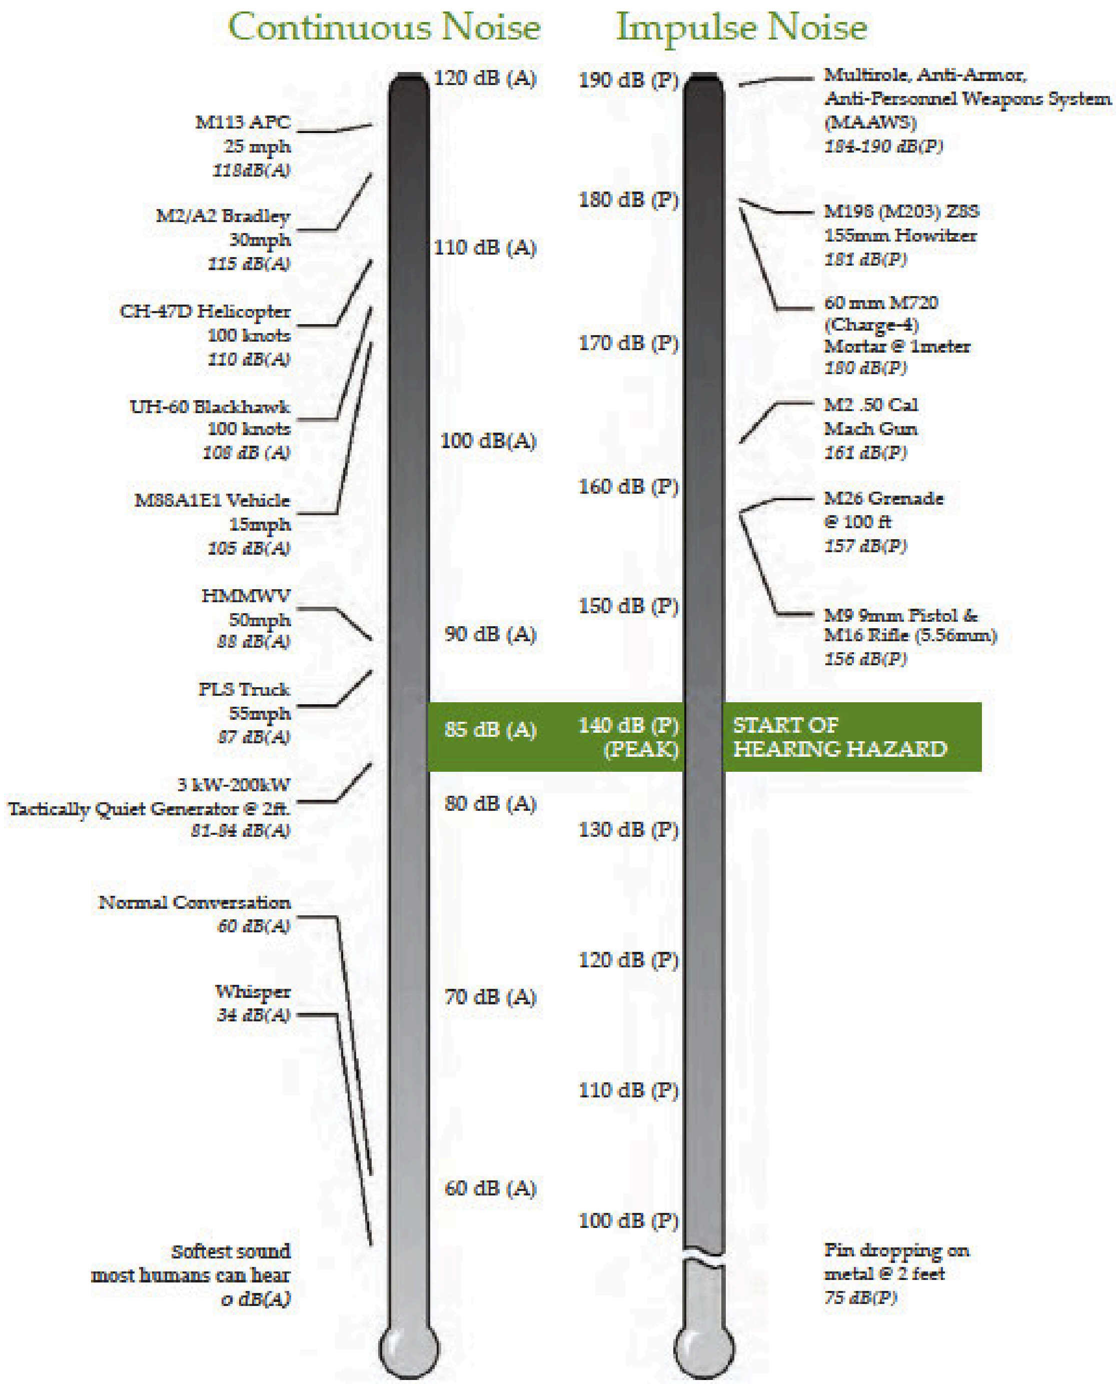
When daily noise exposure is composed of two or more periods of noise exposure of different levels, their combined effect should be considered, rather than the individual effect of each. If the sum of the following fractions: *C1/T1* + *C2/T2Cn/Tn* exceeds unity, then, the mixed exposure should be considered to exceed the limit value. *Cn* indicates the total time of exposure at a specified noise level, and *Tn* indicates the total time of exposure permitted at that level.

Exposure to impulsive or impact noise should not exceed 140 dB peak sound pressure level.

It is further well understood that impulse noises of very high energy (i.e., higher than 140 dB peak sound pressure or "dBP") can lead to hearing loss as well (see Table 1 above and Figure 1 below).

[20] 29 CFR 1910.95(b) (Table G-16 – Permissible Noise Exposure).

1 **Figure 1. Comparison of Continuous Noise and Impulse Noise**[21]



[21] Idaho Power/1210, Ellenbogen/3 (U.S. Army Public Health Command, Readiness Through Hearing Loss Prevention (July 2014)).

It should be noted that, based on the sound monitoring performed by Idaho Power's expert acoustical engineers as described in the Reply Testimony of Mr. Bastasch, the B2H transmission line noise as it relates to the NSRs in this case is nowhere near the threshold of noise necessary to cause or worsen hearing loss.[22]

C. Mitigation for Noise Impacts

Q. What about sound mitigation—is there anything to do to make the impact of corona noise less of a problem for nearby residents?

A. Yes. There are many things that can be done to reduce the impact of a noise on a person. Doing so is often referred to as "noise mitigation."

Generally speaking, noise mitigation leverages psychological and physical principles under a couple of different disciplines within acoustics, including psychoacoustics (i.e., the discipline addressing how people perceive sound) and architectural acoustics (i.e., the discipline addressing how sound is handled in and around spaces, including everything from concert halls to bedrooms).

The item that makes noise is often referred to as the "noise source." And the item that hears the noise is referred to as the noise "receiver" or "receptor." A source of noise can be plucking the string of a guitar or revving the engine of a car. The receptor can be many things, including a studio microphone or a human ear. For the purpose of this discussion, a receiver will be a person in their bedroom.

Broadly speaking, there are three categories of how one might mitigate noise. These categories address: (1) the noise source (i.e., the item that makes the noise); (2) the path the noise takes through the atmosphere; and (3) the receiver (e.g., the listener in a home). Manipulating any of these variables, sometimes a combination of these variables, can reduce the impact of noise on human health, safety, and welfare. Moreover,

[22] Final Order, Attachment X-4 at 10553-58 of 10603.

perception of a noise might be masked by similar or higher ambient background sound levels.

- ***Source.*** It is often optimal to deal with a noise by resolving it at the source. Providing lubrication to a squeaking wheel, for example, might help reduce the friction that causes a noise. In other words, addressing the source of the noise might make the noise reduced or even eliminated.
- ***Path.*** For noise to travel from the source to the receiver, the vibration energy needs to be transmitted from the source to the receiver. This is achieved by energy that sequentially vibrates molecules in the atmosphere along that pathway. Because there are no molecules in space, this is why noise does not travel in space. Conversely, because liquid water is more densely packed with molecules compared to the air in our atmosphere, noise travels faster in water than in air. But there is a catch to this movement of vibration energy. It is imperfectly efficient. More specifically, along the way of the path, there are energy losses due to friction as each molecule passes its energy to the next. The further the noise has to travel, the more and more friction it encounters, making its energy less and less along the way. We have all intuitively experienced this phenomenon. The further we are from a noise, the less we hear it.

As a result of this loss of energy due to friction (and other physical principles), setting the noise source further away from the receiver will reduce the level of the sound at the receiver. Also, placing barriers between the noise source and the receiver can not only cause a great deal of friction and energy loss, but can also cause the energy to be reflected and travel in a different direction than the receiver. The result of a barrier—which can be trees, a wall, or a window—is that the SPL of the noise is reduced by the time it reaches the receiver, if it reaches the receiver at all. And if the noise reaches the receiver at a similar SPL to the ambient background sound level or less, then the receiver's perception of the noise will likely be reduced, or the receiver might not notice the noise at all.

Earplugs are another example of attempting to obstruct the path of a noise getting to the receiver's eardrum from the noise source.

- ***Receiver or receptor.*** Once a noise has been produced and has traveled all the way to a human ear, whatever frequency and energy that remains will cause the eardrum to transmit that energy through the acoustic nerve and to the auditory portion of the brain where it is then brought to the attention of the person via attention mechanisms in the brain. That is, if the noise is made of a frequency too high or too low for human perception (below 20 Hz or above 20,000 Hz), or if the noise is of such a low level that it is whisper-quiet, the noise does not generate a signal from the ear to the brain such that it is perceivable.
- ***Masking.*** Even if a noise is able to generate a signal that is transmitted to the brain, there are a number of different conditions and mitigation measures that would reduce the receiver's perception of the noise, or even allow the noise to go unnoticed by the receiver. First, as discussed above, if the noise reaches the receiver at a similar SPL to the ambient background sound level or less, then the receiver's perception of the noise will likely be reduced, or the receiver might not notice the noise at all. For example, if a broadband sound is of modest SPL (like a breeze through trees or rain at night), that broadband ambient background sound makes it difficult to hear a novel noise of similar or lesser level. When one deliberately introduces a background sound, with the goal of not hearing unwanted noise, that process is referred to as "sound masking." Sound masking can be done with a wearable device, like a programmable hearing aid or earbuds with a feed of music or noises. Sound masking can also be achieved without contact to the body, such as turning on a fan in a bedroom. A fan running in the bedroom at a modest SPL would produce a steady-

state, broadband noise and a mild energy state that will make it difficult to perceive other noises at or below the SPL of the fan.

- ***Other.*** If a novel noise is not reduced or eliminated at the noise source or path, and the noise reaches and is perceived by the receiver, then another important variable to consider beyond sound masking is to reduce the receiver's attention to the noise and vigilance of it. Any noise that produces a fear response, for instance, will be attended to with vigilance. A fear response to a novel noise is adaptive and helpful if the noise source is threatening. Conversely, a fear response is maladaptive if the noise source is not threatening. Importantly, in his testimony, Mr. Larkin has raised the concern that noise can impact anxiety.[23] Disorders such as anxiety [redacted] might lead to distortions of significance and threat level, triggering the receiver's fear response and resulting in maladaptive hyper-attention to a non-threatening noise. Therefore, it is important to treat disorders that may trigger a maladaptive fear response and cause unnecessary stress to the receiver. To prevent or reduce a maladaptive fear response, it is equally important for the receiver to be adequately informed of what noise constitutes a threat, and what does not. This information might come in the form of a broader cognitive-behavioral therapy ("CBT") strategy, which can be therapeutic for people with anxiety [redacted].

[23] Greg Larkin/100, Larkin/20 (Feb. 1, 2023) ("For individuals who already have underlying health issues, the addition of the corona noise will clearly exacerbate existing hearing, tinnitus, sleep and anxiety issues.").

D. Insomnia and Tinnitus

Q. What is insomnia, and how might it relate to noise?

A. Insomnia is the inability to fall asleep or stay asleep, or both, and an overall concern regarding insomnia is the sleep disorder's impact on daily life. In this response, I will first address the topic of insomnia, in general, including terminology and diagnosis. I will then relate insomnia to noise.

To the general public, the term insomnia is sometimes used with a relaxed definition to mean anything that impairs good sleep. To a medical provider, however, the term "insomnia" does not merely mean the inability to sleep. Instead, the field of sleep medicine has criteria that forge the definition of chronic insomnia as a disorder. The six criteria below defining insomnia are from the International Classification of Sleep Disorders, ICSD-3,[24] and similar criteria have been adapted by the psychiatry field in the Diagnostic and Statistical Manual of Mental Disorders, DSM-5-TR.[25]

A. The patient reports one or more of the following:

1. Difficulty initiating sleep.

2. Difficulty maintaining sleep.

3. Waking up earlier than desired.

4. Resistance to going to bed on appropriate schedule.

5. Difficulty sleeping without parent or caregiver intervention.

B. The patient reports one or more of the following related to the night-time sleep difficulty:

1. Fatigue/malaise.

2. Attention, concentration or memory impairment.

[24] American Academy of Sleep Medicine, International Classification of Sleep Disorders (3d ed. 2014)).

[25] American Psychiatric Association Publishing, Diagnostic and Statistical Manual of Mental Disorders: DSM-5-TR (5th ed. 2022).

3. Impaired social, family, occupational or academic performance.

4. Mood disturbance/irritability.

5. Daytime sleepiness.

6. Behavioral problems (e.g. hyperactivity, impulsivity, aggression).

7. Reduced motivation/energy/initiative.

8. Proneness for errors/accidents.

9. Concerns about or dissatisfaction with sleep.

C. The reported sleep/wake complaints cannot be explained purely by inadequate opportunity (i.e. enough time is allotted for sleep) or inadequate circumstances (i.e. the environment is safe, dark, quiet and comfortable) for sleep.

D. The sleep disturbance and associated daytime symptoms occur at least three times per week.

E. The sleep disturbance and associated daytime symptoms have been present for at least 3 months.

F. The sleep/wake difficulty is not better explained by another sleep disorder.

For purposes of our discussion—in considering whether the noise from the transmission line causes or worsens insomnia—it is important to highlight two components of this clinical definition of insomnia. First is Criterion C, which requires adequate opportunity and circumstances, such as quiet environments to sleep. In other words, if I were unable to fall asleep at night due to a very loud noise from a neighbor, I would not have a diagnosis of insomnia; rather, I would have inadequate circumstances conducive for sleep. Such circumstances still result in lost sleep and are still a problem, but do not constitute insomnia. The diagnosis of insomnia requires difficulty initiating or maintaining sleep under reasonable circumstances, such as quiet environments. This distinction is important when discussing an individual's concerns regarding their inability to sleep, as inability to initiate or maintain sleep might be due to either the circumstance (e.g., noise) or the disorder (i.e., insomnia)—knowing which is the real cause of the patient's inability to sleep will optimize problem solving.

The second component of this clinical definition of insomnia that is worth noting is Criterion F, which requires that the patient's inability to initiate or maintain sleep is not best explained by another factor, such as a different medical condition. For example, when a person has [redacted] pain, that individual can have difficulty initiating or maintaining sleep. The signal of pain to the brain is an alerting signal, like a flashing light or loud noise. While this person can be said to lack adequate sleep due to pain, they would not be given the separate diagnosis of insomnia as well. Efforts to treat the pain would be more suitable than efforts to generically treat insomnia. A particularly problematic treatment plan would be to exclusively address the alleged insomnia without consideration of a patient's pain. [redacted]

Separately, when a person has insomnia, they have, by definition, difficulty initiating or maintaining sleep, or both. In those situations, people will often become frustrated or anxious while awake. A patient is more likely to become frustrated or anxious under such circumstances if they already have a disorder, such as anxiety [redacted]. Furthermore, while lying in bed awake, an individual with insomnia might attribute their inability to initiate or maintain sleep to subtle sensory experiences. For example, a subtle sound at night like a dripping faucet. To a person with insomnia, this is often a mistaken attribution. The individual's insomnia is keeping them awake, not the noise from the dripping faucet. At least, that is the case initially. But then the patient with insomnia unintentionally conditions themselves to find the signal (dripping faucet, in this example) to be the cause of their insomnia. Hearing the faint dripping sound—a noise that might not disturb the average person—can create an anxious and awakening response in the patient with insomnia. In fact, this phenomenon is particularly robust when the person ***feels*** the signal is dangerous. And the interesting thing is that the signal does not need to be dangerous in reality; the signal just needs to be considered dangerous in the mind of the person having trouble sleeping. Threat responses of the mind are alerting and prevent sleep.

This concept of conditioning can perpetuate the symptoms of insomnia, and even make them worse. And while fixing the dripping faucet might help, the real problem is the patient's underlying insomnia and anxiety, and those disorders should be the primary focus of treatment. If the underlying insomnia and anxiety are not the primary focus of treatment, then even when the faucet is fixed, the person with insomnia will condition themselves to another stimulus they mistakenly attribute as the cause of their inability to sleep.

This approach to insomnia is commonly referred to as the "3P" model of insomnia: predisposing, precipitating, and perpetuating of insomnia symptoms.[26] Factors that predispose a patient to insomnia include, among other inherent health conditions, genetics. Precipitating factors, such as life events, initiate insomnia symptoms. Precipitating factors might specifically include a traumatic event, or an onset of a disorder, such as anxiety [redacted]. Perpetuating factors are conditions that maintain the

[26] *See, e.g.*, Idaho Power/1211, Ellenbogen/5-7 (Riemann, D. et al., Insomnia Disorder: State of the Science and Challenges for the Future (2022)).

patient's insomnia. For example, these factors can include fixed and false beliefs that produce anxiety, or an alerting response. If, as stated by Mr. Larkin in his testimony,[27] an individual believes that the very faint sound of a transmission line will render their house uninhabitable by causing a serious health condition, such as high blood pressure, then the faint sound of a transmission line might impair sleep, even if it would not do so for the average person.

To be sure, noise can and does awaken people from sleep—particularly people who are "light sleepers," meaning they tend to have difficulty achieving deep stages of sleep that prevent sensory awareness. This can become a problem if noises are of high amplitude and significantly above ambient background sound levels, and if these noises have certain characteristics such as sudden rise and fall (i.e., impulse noise), tonality (i.e., narrow bandwidth), or other alerting acoustical properties.

In some circumstances, noise can be a major contributor to a person's inability to sleep. Noise-induced sleep loss can be an aggravating and important problem. This is rarely the case unless the noise has the features discussed above, namely, that it has an energy level well above ambient background sound levels, and has alerting features to it, such as impulse and narrow bandwidth. A smoke-detector siren, for example, has such features.

With respect to treatment of insomnia, one of the most effective forms of treatment available today is cognitive behavioral therapy for insomnia, CBT-I. This therapy has been demonstrated to be as or more effective than many current medications for insomnia, and so CBT-I is felt by many sleep doctors to be a first-line treatment for most people with insomnia.[28]

[27] Greg Larkin/100, Larkin/18-19 (Feb. 1, 2023).
[28] Idaho Power/1211, Ellenbogen/7-10 (Riemann, D. et al., Insomnia Disorder: State of the Science and Challenges for the Future (2022)).

Treatment of insomnia must include approaches to sleep that are healthful. These approaches include regular nighttime routines such as a disciplined sleep schedule; reduced electronics in bed; and other strategies collectively referred to as “sleep hygiene.” [redacted]

Q. What is tinnitus and how might it relate to noise?

A. Tinnitus is the perception of sound that has no external source.[29] There are many causes to tinnitus, but the most common-known cause is noise-induced hearing loss. It is no surprise, then, that the highest associated cause of tinnitus is occupational noise exposure at a very high SPL since such exposure is also one of the most common causes of noise-induced hearing loss. Tinnitus and hearing loss can result from impulse noise like the discharging of a firearm, or from sustained noise like large engines at close range for long periods of time. Other considerations besides noise exposure that cause tinnitus, however, include neurological diseases, infection, and medications that can either cause tinnitus or make it worse.[30]

While tinnitus affects approximately 50 million people in the United States, “the majority of people with tinnitus are minimally bothered by the sensation.”[31] [redacted]

[29] *See generally* Idaho Power/1212 (Bauer, C. A., Tinnitus (2018)).
[30] Idaho Power/1213, Ellenbogen/20-23 (Dinces, E. A., Etiology and Diagnosis of Tinnitus (2023)).
[31] Idaho Power/1212, Ellenbogen/3 (Bauer, C. A., Tinnitus (2018)).

[redacted] anxiety are among the two key variables that can make the experience of tinnitus worse. The mechanism of this worsening is unclear. One model points to these [redacted] disorders leading to inappropriate attention to the sensation, and excessive worry about its impact on health and well-being.

The medical management of tinnitus includes numerous treatment strategies, none of which are cures. The first is acoustic stimulation. By exposing the patient to noises below the threshold for causing noise-induced hearing loss, their ambient background sound levels are increased, and thus they are less apt to notice the tinnitus sensation. This can be as simple as turning on broadband masking noise, such as turning on a quiet fan in the room. Or, as discussed above, sound masking can be achieved through hearing devices in the ear, such as hearing aids that can be programmed to generate sound or more simply just amplify existing sounds in the room. Finally, mental health is essential in dealing with tinnitus. Accordingly, if the patient presents with [redacted] anxiety, then therapy for these disorders is necessary. Additionally, people with tinnitus often benefit from CBT [redacted].

III. B2H AND HEALTH IMPACTS

Q. Are you familiar with the Reply Testimony of Mark Bastasch—specifically those portions of his testimony where he describes corona noise and the results of Idaho Power's sound monitoring studies?

A. Yes, I am familiar with the Reply Testimony of Mr. Bastasch concerning the Project in which he discusses: (1) the characteristics of corona noise; (2) how corona noise is produced, and what conditions trigger corona noise; (3) how often corona noise occurs during foul weather events, both regionally and across the entire analysis area for the Project; (4) what the modeled noise levels in terms of dBA are at NSRs during fair and foul weather; and (5) what level of increases from ambient sound levels are expected at NSRs during foul weather.

Q. Please summarize the aspects of Mr. Bastasch's testimony that are salient to your opinions as to the potential of corona noise from B2H to impact the people who live near B2H.

A. There are many details in Mr. Bastasch's Reply Testimony that are worth consideration. With respect to health, there are a few notable things to consider.

The average ambient sound levels in the regions B2H crosses are remarkably low, which is reflected in the representative ambient sound levels used for many of the NSRs. From a non-medical perspective, I can appreciate the desire to maintain that low ambient background. In normal operations, during fair weather conditions, the corona noise from B2H is similarly of low sound-pressure levels for all NSRs. I understand that B2H's normal operations (i.e., operating at a voltage less than 550-kV) and fair-weather conditions to be occurring the majority of the time. During these fair-weather conditions and normal operations, I doubt corona noise will be heard at residences in the vicinity of this Project, and even if perceived faintly, corona noise from the Project does not pose any health effect.

During foul weather, the corona noise will be elevated and possibly be heard at NSRs. In these instances, the highest sound-pressure level that is expected to occur along the route when corona noise occurs (during foul weather conditions) is reported to be 46 dBA.[32] Despite this level of corona noise being potentially audible, this is a fairly quiet noise level and does not pose a health risk, as discussed elsewhere in my testimony.

As reported in Mr. Bastasch's testimony, foul weather events—which correlate to a potential for exceedance—are expected to occur 1.3 percent of the hours in a year

[32] This NSR is NSR-115. Final Order, Attachment X-4 at 10557 of 10603.

averaged across the entire Project area.[33] If looking at specific regions, foul weather events in the La Grande region are anticipated to occur 2.7 percent of the hours in the year, and this frequency is the highest out of all four regions.[34] If one then considers Idaho Power's sensitivity analysis focusing on late-night data when exceedances are most likely to occur because of the lower ambient background sound levels, the frequency of calendar days with one hour or more of foul weather during the late night is four percent for the entire Project area and seven percent for LaGrande (with the regional frequencies ranging between two and seven percent).[35] I have no specific medical opinion regarding the methods for predicting whether Oregon's ambient antidegradation standard is met or not. But it struck me that Idaho Power may be overestimating NSR exceedances of the ambient antidegradation standard based on the Company's overly conservative assumptions and inputs.[36] It is reasonable to expect that the volume of corona noise would increase during foul weather events. But I would also expect that the ambient background sound level would also increase during foul weather, and Idaho Power did not appear to account for elevated ambient background sound levels when considering whether an NSR is in exceedance or not.

Specifically, if I understood correctly, the ambient background sound levels were measured or calculated during quiet, calm, good-weather situations (i.e., optimal conditions).[37] However, I would not expect these ambient background sound levels to maintain those low numbers in foul-weather conditions. Wind, rain, and other natural features would be expected to reduce the gap between the actual ambient background sound level and modeled corona noise during foul weather. Such conditions, however,

[33] Idaho Power/1100, Bastasch/16-17 (Feb. 21, 2023).
[34] Idaho Power/1100, Bastasch/16-17 (Feb. 21, 2023).
[35] Idaho Power/1100, Bastasch/17-18 (Feb. 21, 2023).
[36] Idaho Power/1100, Bastasch/18-20 (Feb. 21, 2023).
[37] Idaho Power/1100, Bastasch/19 (Feb. 21, 2023).

might not be enough to create a masking sound sufficient to narrow the gap between ambient background sound level and modeled corona noise during foul weather, such that the difference would fall below the exceedance threshold for the ambient antidegradation standard. As such, corona noise might still be audible for some receptors.

Further still, on foul-weather nights when corona noise is expected to occur at its worst, I would anticipate residents to be indoors, with windows partly or fully closed. This process would substantially reduce noise-pressure levels of corona noise indoors, independent of the ambient background sound level outdoors. Specifically, in their 2018 report, the World Health Organization or WHO explained that “the differences between indoor and outdoor levels are usually estimated at around 10 dB for open, 15 dB for tilted or half-open and about 25 dB for closed windows.”[38]

Taken together—during most hours of the year, corona noise is faint and likely inaudible. During foul-weather conditions, the noise might be audible, and might exceed the ambient antidegradation standard, but even in these circumstances, corona noise for the Project is not at a level posing a health risk, even among the 41 NSRs that exceed the ambient antidegradation standard. While my opinion here is not linked to any specific amount of time of the year that the predicted exceedances take place, it is worth noting that the exceedances themselves are infrequent.

Q. In general, how can the corona noise from B2H be expected to impact someone with or without underlying conditions?

A. Given the predicted corona noise levels from B2H, the overly conservative ambient background sound levels, the assumption that people close their windows during foul weather (i.e., when corona noise is predicted to be at its worst), and that Idaho Power will mitigate noise impacts at NSRs with predicted exceedances, I expect that corona noise

[38] Idaho Power/1214, Ellenbogen/29 (WHO, Environmental Noise Guidelines for the European Region (2018)).

from the transmission line will have no impact on human health, even among those with underlying conditions. It might be possible for a person to hear the transmission line, in foul weather conditions, particularly those landowners anticipated to experience corona noise levels well above the ambient background sound levels. But with mitigation measures in place, even this perception can be substantially reduced.

Q. In general, how would corona noise be expected to impact someone with tinnitus? Please discuss the expected impact both indoors and outdoors.

A. I would not expect that corona noise would impact someone's tinnitus, neither favorably nor unfavorably. At the noise levels produced by B2H, even in worst-case scenario conditions, there is no reasonable concern that corona noise will provoke or worsen an individual's tinnitus.

Q. In general, how would corona noise be expected to impact someone with insomnia?

A. The expected noise from B2H in normal-operating, fair-weather conditions is well below the conservative ambient background sound levels for the NSRs.[39] As such, I expect that B2H will not be perceived at all during these conditions. Accordingly, it is my opinion that during fair weather, corona noise would not have any impact on sleep, even among those who are light sleepers.

Even in foul weather, it is still unlikely that corona noise would have any impact on sleep, even among those who are light sleepers, because predicted corona noise levels are not high. This is particularly true given that Idaho Power is required to provide mitigation in those cases where an exceedance of the ambient antidegradation standard is predicted.

However, for those individuals with insomnia, anxiety, [redacted] it is possible for a resident to learn or develop the false belief that corona noise is dangerous for their

[39] Final Order, Attachment X-4 at 10557-58 of 10603.

health, resulting in the potential worsening of their sleep, mood, or anxiety. In addition to mitigation strategies, there are a number of considerations here that I discuss below.

Q. How would you expect that corona noise would impact someone with [redacted] stress, or anxiety?

A. As a general rule, the impact of noise on people with stress, anxiety, [redacted] is highly specific to the person and to the underlying cause of the stress, anxiety, [redacted] As with insomnia, discussed above, people who have anxiety can condition themselves to a non-threatening stimulus, believing it is, in fact, threatening.

The very nature of anxiety as a disorder is that a person with anxiety is prone to have exaggerated responses, even to items that pose no threat whatsoever. As such, it is possible for someone with anxiety to become more anxious, merely at the perception of corona noise, even if the noise is faint as a whisper—or, even if not perceived at all. The mere thought of a threat to personal safety—however inaccurate—is enough to provoke a worsening anxious response.

As a general rule, there are several, non-exclusive approaches to a person with anxiety who is having anxious thoughts, anxious feelings, or anxious responses to a stimulus that is not actually a threat, such as corona noise from the B2H transmission line. In all situations, the starting point of treatment is for the provider to have compassion for the anxious person. This person inhabits a world even more threatening than is warranted, and that is challenging for their daily living. This distinguishes anxious thoughts we all have, particularly from threatening stimuli. For someone with an anxiety disorder, the response is exaggerated, sometimes irrational.

Beyond compassion, the next most common step for a provider is to take effort to educate the patient about the non-threat. In short, a provider should educate the individual such that they are able to become aware of their automatic thoughts, unrealistic concerns, or unsubstantiated worries. A provider should further provide the patient with a mental process that helps them to overcome these anxious responses to non-threatening stimuli. Collectively, this and related processes are referred to as CBT.

CBT has been demonstrated to be effective for the treatment of anxiety, as have some anxiolytic medications, and the combination of the two (CBT plus medication) appears to be most potent.[40] The decision concerning which of these treatments—or combination of treatments—is most effective for any individual should be tailored to the patient. If a patient were to focus on pharmacological therapy for anxiety, it is important that they work with a healthcare provider who is familiar with which medications are effective for anxiety, at what dose, and how to deal with potential side effects.

It is essential that the patient work with a mental-health care provider to resolve these matters of anxiety. It might seem to an outsider that the person is having an anxious feeling about a particular stimulus; and that may be true. But while anxiety may manifest with something particular in the moment, removing the stimulus causing the anxiety will likely lead to the anxious person finding a new stimulus to be anxious about. Exceptions may exist when an anxious person has a particular phobia, like snakes. Therefore, generally speaking, it is most important to focus on treatment of the underlying anxiety disorder rather than exclusively focusing on the non-threatening stimulus.

IV. NOISE MITIGATION PLANS FOR B2H

Q. Have you reviewed the mitigation strategies that Idaho Power is required to undertake to reduce the impact of corona noise on persons living near B2H? How would you expect these strategies to affect the impact of corona noise on people living near the transmission line?

A. Yes, I have reviewed the mitigation strategies that Idaho Power is required to undertake to reduce the impact of corona noise on persons living near B2H. There are numerous

[40] *See generally* Idaho Power/1215 (Walkup, J. T. et al., Cognitive Behavioral Therapy, Sertraline, or a Combination in Childhood Anxiety (2008)).

mitigation strategies that are capable of addressing the corona noise produced by B2H such that there should be limited or no perception of the noise, and no risk to health or safety.

First, it should be re-emphasized that none of the residents (NSR property owners) are exposed to noise in excess of the Oregon Department of Environmental Quality's ("ODEQ") fixed Table 8 noise level standards of 55 dBA (L_{50}) daytime or 50 dBA (L_{50}) at night. The exceedances we are discussing that would require mitigation are exceedances of ODEQ's ambient antidegradation standard in which a generated noise may not be more than 10 dBA above ambient background sound levels. Idaho Power's predicted exceedances at certain NSRs are due to the ambient background sound levels for many of these NSRs being exceedingly quiet, making it more likely that a resident might hear a faint sound of the B2H transmission line even if it is under 50 dBA. In these situations, there appears to be a robust mitigation requirement of Idaho Power.

As I noted above, exceedances of ODEQ's ambient antidegradation standard will be infrequent. Moreover, the corona noise levels, as experienced in residents' homes, will be low. And, in all cases where exceedances are expected, Idaho Power is required to offer robust mitigation measures. The full mitigation process contained in Noise Control Conditions 1 and 2 can be read in detail in Idaho Power's site certificate for B2H.[41] I will briefly note a few key elements of the mitigation conditions that I found to be impressive, and that give me confidence that the mitigation process will lead to resolution of any nearby resident's concerns regarding health, safety, or welfare.

1. ***Idaho Power is required to be proactive in notifying landowners.*** Idaho Power will send notices to all landowners that might be at risk for an exceedance of the

[41] Idaho Power's Supplement to Petition for CPCN, Attachment 1 (Final Order, Attachment 1, Site Certificate) at 785-89 of 10603 (Oct. 7, 2022) (Noise Control Conditions 1 and 2) [hereinafter, "Final Order, Attachment 1"].

ambient antidegradation standard at their property (Attachment X-7). In other words, the process will not require the NSR property owner to reach out to Idaho Power. Rather, Idaho Power is required to initiate contact and inform residents of the potential noise exceedances.

2. ***Mitigation measures are robust.*** The requirements for noise mitigation include a primary intervention, alternative options, requirement of mutual agreement among the parties, and allowances for specific instances and circumstances of individual landowner preferences and relevant health conditions.

3. ***Mitigation measures are required to be in place prior to operation.*** Site-specific noise mitigation plans are required to be in effect prior to operation. So there is no window of time in which corona noise from B2H would be anticipated to impact the health, safety, or wellness of nearby residents without mitigation.

4. ***A system is in place to receive and respond to complaints if they arise.*** If a situation were to arise in which a landowner experiences a noise exceedance after B2H begins operating (which is not contemplated by the exception to and variance from ODEQ's ambient antidegradation standard under Noise Control Conditions 4 and 5),[42] or the landowner was not initially identified as an NSR with an exceedance, it is important that they have a means to voice that complaint, an expectation that their complaint will be responded to in a timely fashion, and that there is objective, agency oversight of the complaint process—especially if a disagreement should occur between the complainant and Idaho Power. Idaho Power is required to have this process in place, and to notify potentially impacted landowners within one mile of the Project's site boundary (Attachment X-7) of the

[42] Final Order, Attachment 1 at 812 of 10603 (Noise Control Conditions 4 and 5).

site certificate conditions prescribing this complaint process in a plain language summary.

V. RESPONSE TO MR. GREG LARKIN'S CONCERNS ABOUT HIS OWN HEALTH

Q. Mr. Greg Larkin has provided testimony regarding his concerns that corona noise generated by B2H would exacerbate his pre-existing health conditions and has provided medical records attesting to his health conditions. Are you familiar with Mr. Larkin's testimony and his medical records that he provided?

A. Yes. I have reviewed the medical records of Mr. Larkin that were made available to me through representatives of Idaho Power.[43] I also reviewed the portion of Mr. Larkin's testimony in which he raised general concerns and specific concerns that B2H may affect his health, and his related claims concerning the habitability of his home resulting from these potential health effects.[44]

Q. [redacted]

A. [redacted]

[43] [redacted]

[44] Greg Larkin/100, Larkin/16-21 (Feb. 1, 2023); Greg Larkin's Opening Testimony (Greg Larkin/100, Larkin/11-14) (Jan. 17, 2023).

[redacted]

Q. In Mr. Larkin's testimony, did he raise specific concerns about his health that might be affected by corona noise from B2H?

A. Yes. In Mr. Larkin's testimony, he raises concerns that both his insomnia and his tinnitus would be affected by noise from B2H: "My medical records document that my current medical conditions make me particularly sensitive to noise."[46]

[redacted]

[45] [redacted]

[46] Greg Larkin/100, Larkin/19 (Feb. 1, 2023).

[47] [redacted]

[48] [redacted]

Mr. Larkin continues in his testimony: "A lack of sleep can make my tinnitus worse, and I am to be 'cautious about additional exposure to loud noise, as additional damage to the inner ear may aggravate my tinnitus.'"[49]

I agree that additional damage to Mr. Larkin's inner ear might aggravate his tinnitus further. However, as I discussed above, the corona noise from the B2H transmission line at Mr. Larkin's home—or any of the 41 NSRs expected to experience an exceedance of the ambient antidegradation standard—are noises of orders of magnitude below any concern for noise-induced hearing loss.

As pointed out in Table 1 of this testimony, hearing loss is felt to be of potential concern with continuous exposures at or above 90 dBA (or 140 dBP).[50] None of the receptors for this project are predicted to be exposed to sound levels from corona noise above 46 dBA. Note that dB is not an arithmetic scale where it only takes twice as much noise to reach levels of concern in this example. Since dB is a logarithmic scale, the acoustical energy doubles every 3 dB. So, in this example, to reach 90 dBA from 46 dBA, that would require several thousand of these transmission lines to approach 90 dBA in order to be concerned regarding causes or contributions to noise-induced hearing damage to the inner ear.

Similar criteria to OSHA's guidelines have been implemented by the Environmental Protection Agency, National Institute of Occupational Safety and Health, and the United States Department of Defense branches.[51]

[redacted]

---

[49] Greg Larkin/100, Larkin/19 (Feb. 1, 2023).

[50] 29 CFR 1910.95(b) (Table G-16 – Permissible Noise Exposure); *see also* Idaho Power/1210, Ellenbogen/3 (U.S. Army Public Health Command, Readiness Through Hearing Loss Prevention (July 2014)).

[51] *See* Idaho Power/1206, Ellenbogen/444-60 (Vér, I. L. & Beranek, L. L., Noise and Vibration Control Engineering: Principles and Applications (2006)).

[redacted]

Q. Would you expect the corona noise from B2H to disrupt Mr. Larkin's sleep or worsen insomnia?

A. There are not absolute thresholds of noise by which one would certainly be awakened or not. However, there are certain key principles that I touched on above that are worth examining here in the case of B2H.

First, the character of a noise is most alerting when it is impulse noise, has frequency composition optimized for human hearing, and has substantial amplitude modulation. These characteristics can be found in emergency responder sirens, for example.

Second, it depends on the depth of the sleep, with increasing depth of sleep being more resistant to disruption.

Third, it is worth noting that even healthy sleepers awaken briefly numerous times during the night. If during these brief moments, a noise is perceived, and that noise is felt to be a threat to one's health, safety, or welfare, then the person is more likely to be alerted by the noise and therefore less likely to return to sleep. They may feel the noise awaken them, but in this scenario, it is their feeling about the noise that prevents them from

---

52 [redacted]

returning to sleep. This is adaptive when the noise is an actual threat, but maladaptive when the noise is not, [redacted]

In Mr. Larkin's circumstance, [redacted]

[53] [redacted]

[54] Greg Larkin/100, Larkin/19 (Feb. 1, 2023).

[55] Greg Larkin/100, Larkin/19-20 (Feb. 1, 2023) ("I also developed high blood pressure due to the stress that has occurred over the years with the threat of losing my home.").

[56] [redacted]

[redacted]

Mr. Larkin's [redacted] stress can be best appreciated by the following two statements from his testimony:

- "I also developed high blood pressure due to the stress that has occurred over the years with the threat of losing my home. I developed heart issues which necessitated me wearing a heart monitor for a period of time during the [Energy Facility Siting Council ("EFSC")] Contested Case Process."[59]
- "The corona noise predicted to occur at my home will make my residence uninhabitable for me."[60]

Mr. Larkin's concerns deserve compassion. Part of that compassion includes empathy, and another includes providing him accurate information—that the corona noise is not a risk to his health [redacted]

Q. [redacted]

[57] [redacted]

[58] [redacted]

[59] Greg Larkin/100, Larkin/19 (Feb. 1, 2023).

[60] Greg Larkin/100, Larkin/18 (Feb. 1, 2023).

A. [redacted]

Q. Would you expect that the corona noise levels from B2H would worsen Mr. Larkin's [redacted] tinnitus?

A. No. [redacted] The noise from B2H will be library-room quiet, and well away from any level of concern for [redacted] provoking or worsening tinnitus, as noted above. Corona noise from B2H will not worsen Mr. Larkin's tinnitus.

Q. [redacted]

A. [redacted]

---

[75] [redacted]

[76] [redacted]

[77] [redacted]

[78] [redacted]

[79] [redacted]

[80] Greg Larkin/100, Larkin/19 (Feb. 1, 2023)

[redacted]

Q. Please specifically address Mr. Larkin's statement that he has developed high blood pressure due to the stress that has occurred over the years with the threat of losing his home.[83]

A. [redacted]

Q. Please specifically address Mr. Larkin's claim that once B2H is constructed, his home will become "uninhabitable."[84] [redacted] **How would you recommend that this** [redacted] **stress be addressed?**

A. Once B2H is constructed, it is possible that on occasion (i.e., during foul weather conditions) an average healthy person living in Mr. Larkin's home would faintly hear the corona noise generated by B2H. An individual's perception of the corona noise will be further reduced, however, by noise-mitigation required of Idaho Power. In short, the

[81] 29 CFR 1910.95(b) (Table G-16 – Permissible Noise Exposure).
[82] [redacted]
[83] Greg Larkin/100, Larkin/19 (Feb. 1, 2023).
[84] Greg Larkin/100, Larkin/18 (Feb. 1, 2023).

average healthy person might hear the faint sound of B2H. [redacted]

Q. Have you reviewed the report that Mr. Larkin references in his testimony, the Oregon Health Authority report entitled "Strategic Health Impact Assessment on Wind Energy Development in Oregon"? Does that report support Mr. Larkin's view that his health will be significantly impacted by corona noise from B2H? If not, are there more updated scientific studies to consider?

A. I am familiar with the report referenced by Mr. Larkin, "Strategic Health Impact Assessment of Wind Energy Development in Oregon," published in 2013.[86] The report

[85] [redacted]

[86] Greg Larkin/119 (Public Health Division of the Oregon Health Authority, Strategic Health Impact Assessment of Wind Energy Development in Oregon (Mar. 2013)).

does not support Mr. Larkin's view that his health will be significantly impacted by corona noise from B2H. Mr. Larkin makes the following statement in his testimony:

> It is well documented that elevated noise levels can create a variety of health concerns for individuals including exacerbating tinnitus (Strategic Health Impact Assessment on Wind Energy Development in Oregon, March 2013, Public Health Division, Oregon Health Authority, March 2013, Prepared by the Public Health Division, Oregon Health Authority includes Section B on Noise. Exhibit 119) This section provides general information regarding the impacts of noise. It states, "This section begins with an overview of sound and noise, the impacts of noise on human health, and methods to measure and assess community noise." On Page 25 it states that noise from a lineal object (such as a transmission line) appear to have lower rates of decrease (attenuation) because of the contribution of sound from multiple sources. On Page 28 of this document it indicates that there are three broad categories of health effects from exposure to noise. a. Subjective effects such as annoyance which can mean a significant degradation in the quality of life; b. Sleep, communication and concentration impacts; c. physiological effects."[87]

Since the publication of this review and recommendation, written by the Public Health Division of the Oregon Health Authority, there have been significant developments with respect to the science of wind energy, noise, and its potential for impacting health. The Health Canada Study I discuss above is one such example.

Q. Mr. Larkin also cites a 2009 report by the WHO that recommends nighttime noise levels below 40 decibels.[88] Can you place that report in context?

A. Yes. There are many organizations that have attempted to evaluate and create guidelines concerning the potential for noise to impact human health. None are perfectly suited for comparison to corona noise from the B2H transmission line.

Institutions like the WHO have attempted to broadly address concerns from a variety of noises, and their impact on human health. In its most recent and updated guidelines, published in 2018, the WHO addresses a range of noises and potential health implications. Noises evaluated include road-traffic noise, railway noise, airplane noise,

---

[87] Greg Larkin/100, Larkin/19-20 (Feb. 1, 2023).
[88] Greg Larkin/100, Larkin/21 (Feb. 1, 2023).

noise from wind turbines, and leisure noises. Health implications evaluated included sleep loss, ischemic heart disease, hypertension, cognitive impairment, hearing impairment, tinnitus, metabolic outcomes, mental health, etc.

This report produced by the WHO in 2018 was not merely a supplement to their prior reports on noise. The WHO published community noise guidelines and night noise guidelines for Europe in 1999 and 2009, respectively.[89] Since then, significant new evidence has accumulated on the health effects of environmental noise. As a result, the WHO's 2018 report was meant to be the more comprehensive and more updated version of the institution's policy recommendations for noises, including at night in which this new report proposed "an updated set of public health recommendations on exposure to environmental noise."[90] Based on the defined scope and key questions, the WHO's guidelines reviewed the pertinent literature in order to incorporate significant research undertaken in the area of environmental noise and health since the community noise guidelines and night noise guidelines for Europe were issued.[91]

In addition, it is essential to understand that the WHO's recommended levels are ***yearly averages***. Corona noise levels are well below WHO-recommended levels most of the time. Therefore, the yearly average for corona noise from B2H will be below the thresholds of concern raised by WHO for other noise sources—notably air, rail, road, wind or leisure noise.[92] This applies to health concerns raised by the WHO as possible outcomes of noise, including ischemic heart disease, hypertension, sleep loss, etc.

---

[89] Idaho Power/1214, Ellenbogen/21 (WHO, Environmental Noise Guidelines for the European Region (2018)); *see also* Idaho Power/1219, (WHO, Night Noise Guidelines for Europe (2009)); Idaho Power/1220 (WHO, Guidelines for Community Noise (1999)).

[90] Idaho Power/1214, Ellenbogen/21 (WHO, Environmental Noise Guidelines for the European Region (2018))

[91] Idaho Power/1214, Ellenbogen/17 (WHO, Environmental Noise Guidelines for the European Region (2018))

[92] Idaho Power/1214, Ellenbogen/19-20 (WHO, Environmental Noise Guidelines for the European Region (2018))

Finally, the WHO's recommendations are not only highly restrictive, but at times their conservative restrictions are outdated and unreliable. For instance, when it comes to wind turbine noise, the WHO recommends a 45 L_{den} yearly maximum.[93] Yet the largest, most rigorous, and most objective study on the potential health impacts of wind-turbine noise—i.e., the Health Canada Study—demonstrated that at 46 dBA there were no known health outcomes of concern.[94] Since 46 dBA is the equivalent of about 52 L_{den}, that new information should place an updated average noise exposure recommendation at 52 L_{den}. In either case, these numbers are equal to or exceed modeled corona noise produced by the B2H transmission line at NSRs.

Q. Mr. Larkin has suggested that prior to mitigation discussions, the Company should have evaluated the owners of all NSRs for health conditions that may be exacerbated by noise.[95] Do you believe that approach is superior to the approach required by EFSC's site certificate conditions?

A. It appears to me that the requirements of EFSC's site certificate conditions are robust and sufficient. Among other things, Noise Control Condition 1 requires that Idaho Power proactively approach landowners who may be impacted by exceedances of the ambient antidegradation standard and develop together site-specific noise mitigation plans tailored to the landowners' specific health issues and/or individual preferences. In other words, the site certificate conditions do not require the landowner to initiate the negotiation process, and specifically take into account a landowner's preexisting health conditions in

Sleep Disruption due to Hospital Noises

A Prospective Evaluation

Orfeu M. Buxton, PhD*; Jeffrey M. Ellenbogen, MD*; Wei Wang, PhD; Andy Carballeira, BM; Shawn O'Connor, BS; Dan Cooper, BS; Ankit J. Gordhandas, SB; Scott M. McKinney, BA; and Jo M. Solet, PhD

Background: Sleep plays a critical role in maintaining health and well-being; however, patients who are hospitalized are frequently exposed to noise that can disrupt sleep. Efforts to attenuate hospital noise have been limited by incomplete information on the interaction between sounds and sleep physiology.

Objective: To determine profiles of acoustic disruption of sleep by examining the cortical (encephalographic) arousal responses during sleep to typical hospital noises by sound level and type and sleep stage.

Design: 3-day polysomnographic study.

Setting: Sound-attenuated sleep laboratory.

Participants: Volunteer sample of 12 healthy participants.

Intervention: Baseline (sham) night followed by 2 intervention nights with controlled presentation of 14 sounds that are common in hospitals (for example, voice, intravenous alarm, phone, ice machine, outside traffic, and helicopter). The sounds were administered at calibrated, increasing decibel levels (40 to 70 dBA [decibels, adjusted for the range of normal hearing]) during specific sleep stages.

Measurements: Encephalographic arousals, by using established criteria, during rapid eye movement (REM) sleep and non-REM (NREM) sleep stages 2 and 3.

Results: Sound presentations yielded arousal response curves that varied because of sound level and type and sleep stage. Electronic sounds were more arousing than other sounds, including human voices, and there were large differences in responses by sound type. As expected, sounds in NREM stage 3 were less likely to cause arousals than sounds in NREM stage 2; unexpectedly, the probability of arousal to sounds presented in REM sleep varied less by sound type than when presented in NREM sleep and caused a greater and more sustained elevation of instantaneous heart rate.

Limitations: The study included only 12 participants. Results for these healthy persons may underestimate the effects of noise on sleep in patients who are hospitalized.

Conclusion: Sounds during sleep influence both cortical brain activity and cardiovascular function. This study systematically quantifies the disruptive capacity of a range of hospital sounds on sleep, providing evidence that is essential to improving the acoustic environments of new and existing health care facilities to enable the highest quality of care.

This article was published at www.annals.org on 12 June 2012.

Sleep is essential for the restoration of health and well-being (1). However, in hospitals, where healing is paramount, noise frequently disrupts patients' sleep. In a recent national survey, patients identified the noise levels in and around rooms at night as the quality-of-care factor with the most need for improvement (2). Acoustic measurements from a major urban hospital document a crescendo of nighttime hospital noise over the past 45 years from an average level of 42 dBA (decibels, adjusted for the range of normal hearing) to more than 55 dBA in 2005 (3). Hospitals are exposed to external noise sources known to disrupt sleep, such as traffic and airplane sounds (4), with documented dose-related consequences for next-day cognitive performance (5). Patient care also produces noise specific to treatment and protection, such as intravenous and cardiac monitor alarm signals (6). Improving acoustics in environments of care to protect sleep and enhance outcomes for the more than 37 million patients who are hospitalized annually in the United States (7) has become a transdisciplinary priority (8–11).

Web-Only
Samples of acoustic stimuli

The goal of this study was to provide essential information about the effect of sound on sleep to guide architectural, technological, and programmatic advances to facilitate sleep and improve clinical outcomes for patients who are hospitalized. We hypothesized that the capacity for sleep disruption varies by the type of sound and increases for each type as the sound level increases. We further hypothesized that the stages of sleep, characterized by diverse cortical activity patterns, are differentially vulnerable to disruption by noise. Sleep stages cycle through the night and vary in their relative proportions with age (12), medications (13), and certain medical and psychiatric disorders (14), among other factors. Therefore, a useful exploration of the responses of sleep to noises must include sleep stage during noise exposure.

Sleep stages include 2 brain state categories: rapid eye movement (REM) sleep and non-REM (NREM) sleep stages. The range of NREM sleep stages includes progressively deepening levels from drowsiness to deep sleep, termed *N1*, *N2*, and *N3* (15): N1 is the brief transition between wakefulness and sleep, N2 is typically the most abundant stage of sleep in adults, and N3 (or slow-wave sleep) is the deepest level. These REM and NREM brain states seem to be driven by different nuclei and neurotransmitters (16). They can be readily discerned through distinct patterns appearing on electroencephalograms (EEGs) (15) and neuroimaging (17). In addition, behavioral evidence demonstrates that the sleeping brain responds to auditory stimuli differently during REM than during NREM sleep (18). We sought to elaborate on this evidence by examining differential responses to hospital noise exposures between REM and NREM states and exploring variability in sleep disruption within the deepening stages of NREM.

We designed a protocol to examine the influence of graded noise exposures during all stages of sleep, through polysomnographic (PSG) assessments (combined EEG, electrooculogram, and electromyogram), a standard (19, 20) and sensitive (21, 22) system to measure sleep strongly correlated with awakenings (21). Because elevations in heart rate are known to occur during full EEG-documented awakenings from sleep (23), we used the electrocardiogram to detect the presence of clinically relevant heart rate responses to noise-induced arousals. We predicted heart rate elevations during these EEG-documented sleep arousals in participants who were exposed to common hospital sounds.

Methods

Design Overview

All study procedures were approved by the human research committees of the involved institutions. The design was a 3-day PSG study, beginning with a baseline (sham) quiet night followed by 2 noise exposure intervention nights, during which EEG arousals and electrocardiogram heart rate accelerations were documented.

Participants and Setting

Participants were recruited through flyers, Web site postings, and word of mouth and then screened by questionnaire, physical examination, and laboratory testing. Participants who reported medical or psychiatric conditions or use of substances or medications that potentially affect sleep were excluded from the study. Criteria for exclusion included history of drug or alcohol abuse; depression; anxiety; posttraumatic stress and obsessive compulsive disorders; neurologic or sleep disorders; infectious diseases; diseases of the cardiovascular system; or treatment with antidepressants, neuroleptics, or major tranquilizers. Urinalysis confirmed the absence of caffeine, nicotine, and alcohol. Standard audiometric screening confirmed normal hearing (that is, exceeding 20 dBA in both ears). The first 12 eligible and available participants were enrolled (**Figure 1**).

Participants slept at home on a regular schedule for at least 4 days before participation in the study. They reported sleeping a mean of 7.72 hours (SD, 0.27) over a mean of 6.5 days (SD, 1.1) through a time-stamped phone-answering system that was confirmed through wrist actigraphy (AW-64, Philips Respironics, Murrysville, Pennsylvania), which demonstrated a mean of 7.16 hours (SD, 0.29) of sleep over a mean of 6.7 monitored days (SD, 0.9).

Participants stayed at the Massachusetts General Hospital Sleep Laboratory for 3 days. Each night, participants were given an 8.5-hour sleep opportunity, which began at their normal bedtimes. Continuous video observation and wrist actigraphy confirmed that participants did not nap during the day. Light levels were maintained at less than 1 lux (darkness) during sleep periods and approximately 90 lux (ordinary daylight in room) during waking periods. Because of continuous air exchange (required in health care facilities), background ambient sound levels averaged between 34 and 35 dBA ($LA_{EQ,\ 10\text{-}s}$ [equivalent continuous A-weighted scale {adjusted for the range of normal human hearing} sound pressure level, averaged over the 10-second stimulus duration]). On the first night, participants slept undisturbed to allow adaptation to the PSG equipment and laboratory environment, confirm absence of sleep disorders (including sleep apnea), and establish baseline sleep recordings. On the second and third nights, recorded hospital sounds were presented to participants throughout sleep.

Intervention: Acoustic Stimuli

Recordings of hospital sounds were captured on a medical unit of Somerville Hospital, Cambridge Health Alliance, Somerville, Massachusetts. Each sound stimulus fit within 1 or more of the categories identified as salient in the American Institute of Architects Guideline on Sound and Vibration in Healthcare Facilities: external to building,

Context

The negative effects of hospital noise on sleep are among the most common concerns of inpatients and their families.

Contribution

During sleep laboratory studies of healthy volunteers, investigators found that the disruptive effect of recorded hospital noises varied by the type and level of sound emitted and by the volunteer's stage of sleep. Electronic sounds designed to be alerting were most disruptive, as were staff conversations and voice paging.

Caution

Volunteers were young and healthy. Sounds were not administered together.

Implication

Reduction of hospital noise through policies, procedures, and building design may lead to improved patient sleep.

EKG = electrocardiogram.

within hospital, and within or outside patient rooms (8). Fourteen noise stimuli were selected: "good" conversation, which was defined as 1 male and 1 female voice discussing a positive patient outcome; "bad" conversation, which was defined as the same voices discussing a negative patient outcome; male voice from an overhead paging system calling a physician by name; door opening or closing; telephone ringing; toilet flushing; ice machine disgorging; IV alarm sounding; laundry cart rolling; automatic paper towel machine dispensing; helicopter takeoff; jet engine flyover; and outside traffic flow. Samples of acoustic stimuli are available at www.annals.org. To control for differences in duration across stimuli, sounds were normalized to 10 seconds (**Appendix Table 1**, available at www.annals.org).

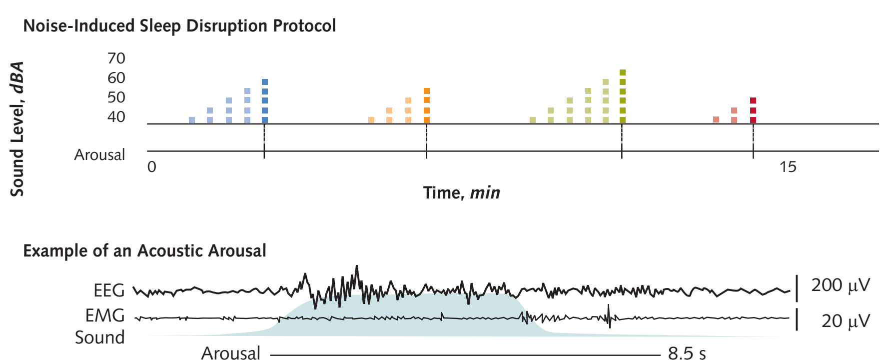
Hospital noises were presented as stimuli with 2-dimensional verisimilitude (for example, airplane sounds moved across space) through use of 4 studio monitor loudspeakers (PS6, Event Electronics, Silverwater, Australia) arrayed about the head of the sleeping participants (a modified pattern from the ITU-R BS 775-1 Recommendation, omitting the center loudspeaker). Sound levels in the participants' room were logged in 1-second increments by using an environmental sound monitor (NL-31, with type 1 microphone [Rion, Tokyo, Japan]) installed roughly 10 inches above the head of the sleeping participants and programmed to output a direct current voltage proportional to the A-weighted fast-response sound level.

Once a steady sleep stage of at least 90 seconds was recorded, as assessed in real time by a technician, stimuli were systematically presented once per 30-second sleep epoch, starting at an exposure level ($LA_{EQ,\ 10\text{-}s}$) of 40 dBA in increasing steps of 5 dBA (**Figure 2**, *top*) until either sleep was disrupted by an arousal (**Figure 2**, *bottom*), sleep stage changed, or the 70-dBA maximum exposure level was reached. Because both the equivalent sound level and the duration of the noise stimuli were held constant, all stimuli were normalized to deliver an equal "noise dose," an integration of sound intensity over time (24). All stimuli were presented in a computer-generated random order within each sleep stage on both exposure nights for every participant.

Outcomes

Standard PSG recordings (Comet XL, Grass Technologies, West Warwick, Rhode Island) were collected on all 3 nights through skin surface electrodes. Sleep stages and arousals were identified by using current criteria (15). **Figure 2** (*bottom*) depicts a standard arousal, as defined by an

Figure 2. **Schematic diagram of study protocol.**



dBA = decibels, adjusted for the range of normal hearing; EEG = electroencephalogram; EMG = electromyogram; N2 = non-REM sleep stage 2; REM = rapid eye movement. **Top.** The solid vertical lines along the *x*-axis indicate stimuli evoking EEG arousals, and a sample of 4 noises is shown. Each color represents a different sound type. Ten-second noises were evaluated for their probability to induce a cortical arousal at increasing sound levels in varying stages of sleep and presented once per 30-second sleep epoch (while sleep stage was stable) until an arousal occurred, sleep stage changed, or the 70-dBA maximum was reached. **Bottom.** A typical sound-induced arousal from stage N2 sleep, as measured by polysomnography. Arousals are defined by their appearance on the EEG (the right frontal lead F3 shown here), characterized by an abrupt shift of frequency that lasts at least 3 seconds. Arousals during REM sleep require a concurrent increase in submental EMG activity. This transient arousal lasted for approximately 8.5 seconds before sleep resumed.

abrupt shift of EEG frequency lasting at least 3 seconds. Arousals during REM sleep also require a concurrent increase in submental electromyogram activity (**Figure 2**). Body position was scored from infrared video to allow for statistical adjustment based on whether either ear was occluded, potentially attenuating arousal responses. Body position (supine or not) was assessed continuously by a sleep technician viewing the infrared video on the same screen as the EEG signals they were using to score sleep stages in real time at the initiation of each acoustic stimulus.

Experimental tasks were coordinated by 2 researchers; a sleep technician maintained PSG signal quality classification of sleep stages and identification of cortical arousals indicating sleep disruption (25), along with documentation of body position. A second technician or investigator maintained the acoustic equipment and initiated the programmed, semiautomatic presentation of escalating noise stimuli. Discrepancies with the real-time scoring were resolved by a board-certified sleep physician.

Statistical Analysis

The probability of arousal by stimulus sound level and type and sleep stage was examined descriptively (graphically). Generalized linear mixed models were applied to evaluate the effects of hospital noises on the binary outcome (arousal from sleep) with a logit link, by using PROC GLIMMIX in SAS software, version 9.2 (SAS Institute, Cary, North Carolina), for determining differences by sleep stage, with factors of study night and body position. Because of large interperson differences, the participant was treated as a random effect, incorporating participant-specific intercepts into the model. We assume that, between 2 adjacent presented stimuli levels (for example, 50 and 55 dBA), the arousal probability increases linearly for the intervening stimuli levels (for example, 51 to 54 dBA). Because an ear against the pillow could attenuate the administered sound level, body position served as a covariate in the model where supine position (reference category) corresponded to having both ears exposed. This model was used to estimate the probability of arousal while accounting for stimulus, sound level, sleep stage, and body position. We separately estimate the additional effect of the night of study (see the Results section).

To assess the effects of noise on heart rate during sleep by sleep stage, we calculated the profile of instantaneous heart rate during each arousal relative to the average heart rate during the 10 seconds preceding each corresponding sound onset. To quantify the temporal dynamics of the heart rate response, we calculated the median durations from the sound onset to the time of peak heart rate during each arousal and to the time of arousal onset.

Role of Funding Source

Nonprofit entities, the Academy of Architecture for Health, Facilities Guidelines Institute, and The Center for Health Design, contributed resources to this investigator-initiated study. They did not play a role in the study design, conduct, reporting, or the decision to submit a manuscript.

Results

Twelve healthy, white participants (8 women; mean age, 27 years [SD, 7]; mean body mass index, 21.8 kg/m^2 [SD, 3.7]) successfully completed this study.

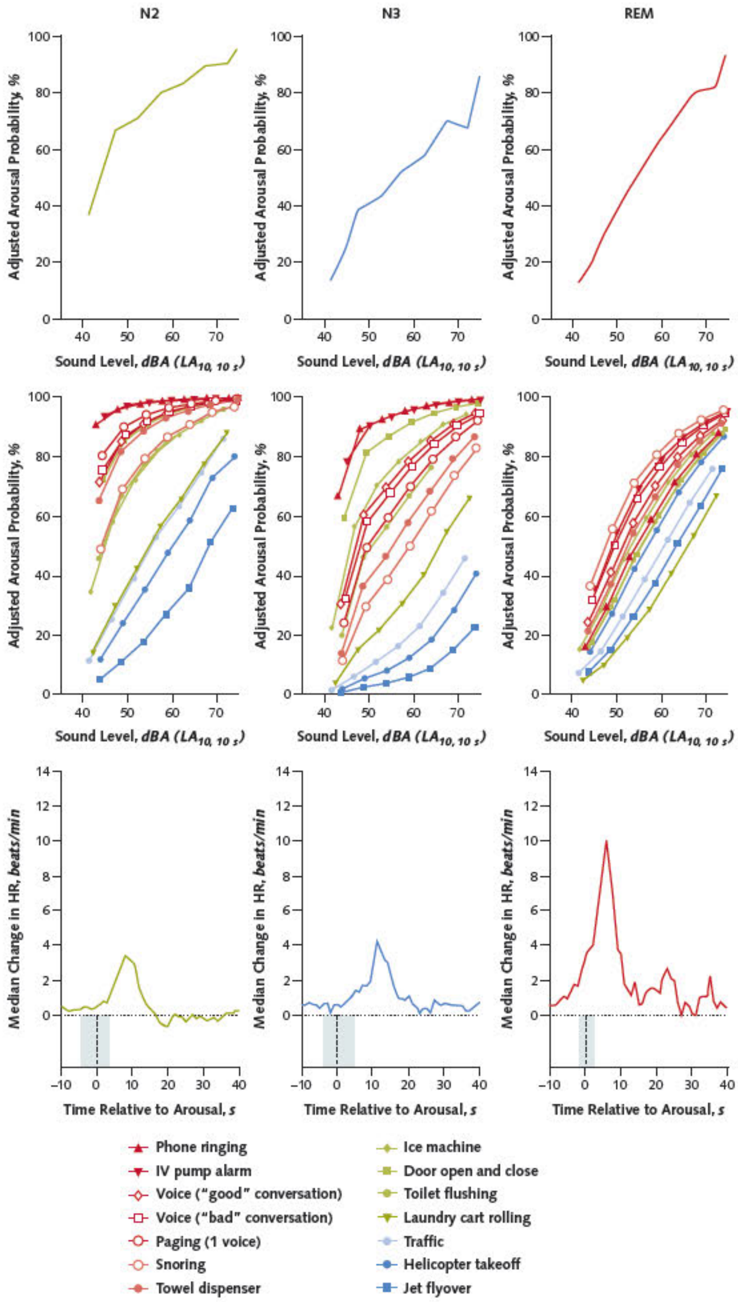
As expected, louder sounds were more apt to cause sleep disruption (**Figure 3**). Effects varied by the type of sound stimulus (for example, IV alarm vs. voices) and by the stage of sleep during which the sound stimulus was presented (for example, REM vs. N3).

We saw an effect of sleep stage on sound stimulus–evoked arousal probability (**Figure 3**, *top panels*); N2 differed from N3 and REM (both $P < 0.001$, Bonferroni-adjusted), but N3 and REM did not differ overall, using model-based probability estimates. The pattern of arousal probabilities from stages N2 to N3 were relatively consistent in terms of sound stimulus order from most to least arousing, but shifted to overall lower arousal rates during N3 compared with N2 (**Figure 3**, *middle panels*). In marked contrast, arousals from REM sleep revealed a more homogeneous and monotonic pattern across sounds presented than NREM stages (**Figure 3**, *middle panels*) not readily apparent from the mean curves alone (**Figure 3**, *top panels*). Arousals occurred at lower sound levels on the third study night compared with the second study night ($P < 0.001$). Testing for the stage–by–study-night interaction only showed a slight difference across nights among sleep stages ($P = 0.020$, adjusted for sound levels [**Appendix Table 2**, available at www.annals.org]; body position was not significant and was not included in the final interaction model). The significant interaction suggests that the arousal probability was lower on the third night for all sleep stages, but the magnitude of the difference varied across stages and may reflect some degree of sensitization of arousals to sound presentation. Depiction of arousal probabilities for individual sound stimuli by stage and sound level revealed considerable heterogeneity in the responses to the various stimuli (**Figure 4**).

We studied the change in heart rate during stimulus-induced arousals by subtracting the instantaneous heart rate from the average heart rate of the 10 seconds preceding the sound onset. The stage in which the arousal occurred substantially predicts the magnitude of the heart rate increase ($P < 0.001$); the greatest responses occurred during REM, followed by N3 and N2 (**Figure 3**, *bottom panels*). All pairwise comparisons are significant at an α level of $0.05/3 = 0.017$. Baseline (prearousal) heart rate does not predict the magnitude of the response ($P = 0.94$). Study night is not significant ($P = 0.83$), reflecting a lack of habituation of the electrocardiogram heart rate response.

Heart rate responses are aligned by their peaks in **Figure 3** (*bottom panels*). The stage in which the arousal occurred significantly predicts the duration of time from the

Figure 3. **Sleep disruption due to noise stimuli presented during sleep, by stage of sleep.**



Arousal probability of sound stimuli presented in sleep stages N2, N3, and REM. Ten-second noises were introduced during sleep stages N2, N3, and REM to evaluate their propensity to disturb sleep. Once a stable stage of at least 90 seconds was reached, noises were initiated at sound levels of 40 dBA (equivalent continuous A-weighted [adjusted for the range of normal human hearing] sound pressure level, averaged over the 10-second stimulus duration) and presented every 30 seconds in 5-dBA increments until an arousal occurred or the 70-dBA exposure level was reached. dBA = decibels, adjusted for the range of normal hearing; HR = heart rate; IV = intravenous; $LA_{10,\ 10\text{-}s}$ = sound pressure level, averaged over the 10-second stimulus duration, exceeded 10% of the time; N2 = non-REM sleep stage 2; N3 = non-REM sleep stage 3; REM = rapid eye movement. **Top.** Mean arousal probabilities for stimuli presented during sleep stages N2, N3, and REM versus presented sound level and adjusted for stimulus and body position (see Methods section). **Middle.** Mean arousal probabilities for individual noise stimuli by sleep stage, adjusted for body position. **Bottom.** Changes in the median HR during nonspontaneous, noise-induced arousals are aligned by the time of the peak HR response and expressed relative to the average HR in the 10 seconds preceding the arousals in sleep stages N2, N3, and REM. The vertical lines represent the median times of arousal onset (with CIs) before that peak.

start of the arousal to the peak of the heart rate increase ($P < 0.001$); the fastest response times to peak were found during REM, then during N2 and N3. The median time from the start of the arousal to peak heart rate in REM is significantly shorter than N2 and N3; N3 is not significantly different from N2 adjusted for several comparisons at an α level of 0.017. No differences were seen in baseline heart rate across sleep stages ($P = 0.53$).

Discussion

This study systematically quantifies the disruptive capacity of hospital-recorded sounds on sleep. Sound presentations during sleep yielded arousal response curves that varied due to sound type and level and sleep stage. As predicted, for each stimulus higher sound levels led to a greater probability of sleep disruption. Electronic sounds, such as an IV alarm designed to alert medical staff, were consistently more arousing than other sounds at the same noise dose. Overall, the effect of sound level and type were modified by sleep stage physiology, producing unique arousal probability profiles for each sleep stage. We further demonstrate that the arousal effects of noise on sleep include heart rate elevations, even when disruptions are brief and frequent. Heart rate effects may be particularly relevant to critical care settings, in which monitor alarms are very frequent (6). These arousal probability profiles have the potential to drive needed innovation in design, construction, engineering, building materials, monitoring and communication equipment, and care-giving protocols to preserve sleep and enhance environments for healing. Improved acoustic environments consistent with current guidelines in the United States (8) and European Union (26) could deliver several clinical benefits, including reduced sedation and shorter hospital stays (4, 9, 10, 21, 27–29).

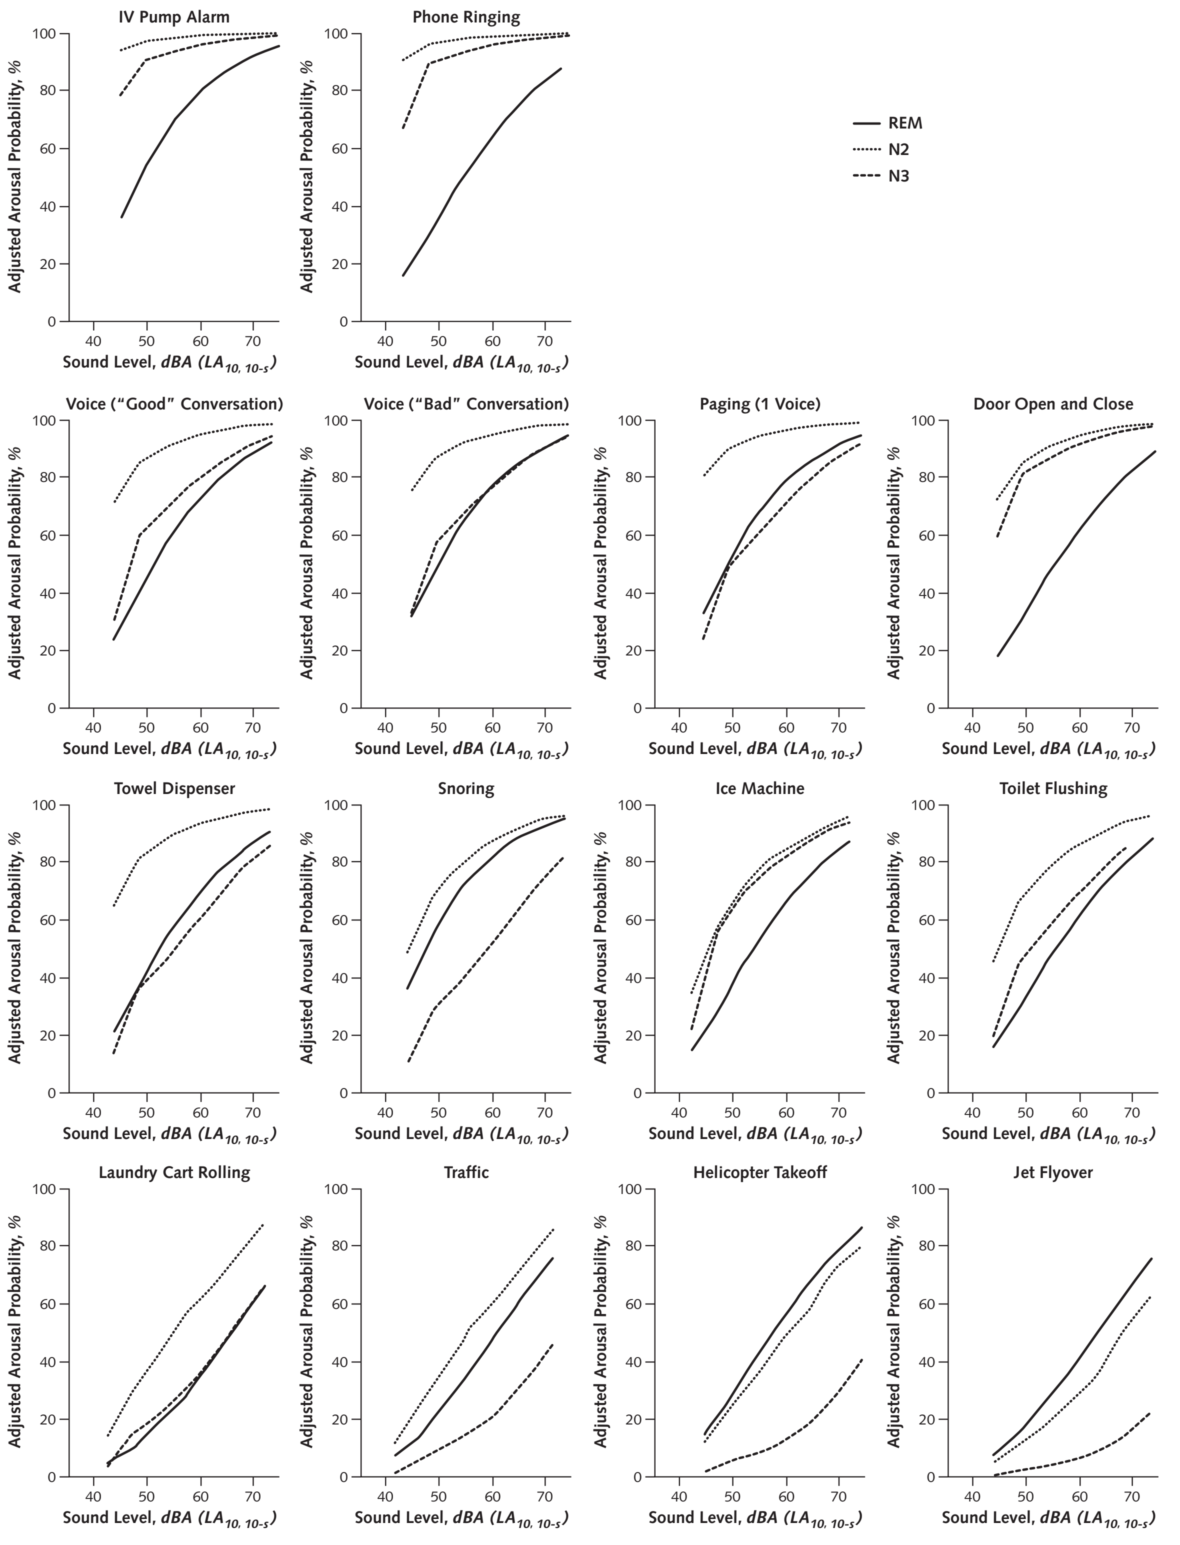
Disrupted sleep is known to be associated with hypertension (30), incidence of cardiovascular and coronary heart disease (31), impaired immune function (32), elevated stress hormone responses (33), attention and memory deficits (34), and depressed mood (35). Preservation of patients' sleep should be a priority for contributing to improved clinical outcomes for patients who are hospitalized (36). Spontaneous arousals are known to accelerate heart rate (36–39). Full awakenings evoked by noise lead to heart rate elevations of approximately 10 beats/min (36). We demonstrate that evoked arousals elicit heart rate acceleration from all stages of sleep, but a greater magnitude (10 beats/min) and faster onset of heart rate accelerations from REM, with lesser magnitude and less rapid accelerations in stages N2 and N3. Our data demonstrate that the effect of noise on sleep includes heart rate elevations, even when the disruption is brief and frequent, as might be seen in an intensive care unit setting. A recent synthesis of hospital soundscape surveillance data described a pattern of intensive care unit noise exceeding a "peak" of 60 dBA more than 50% of the time at night (40) and, thus, the frequency of sleep disruptions may be high in typical intensive care or other inpatient units, as described by patient self-reports (2), and in other units, such as the neonatal intensive care unit (41). A study of patients in the cardiac intensive care unit demonstrated that adverse acoustic environments are associated with higher pulse amplitude at night and elevated use of β-blockers. The patient group exposed to the unimproved acoustic environment also demonstrated higher rates of rehospitalization and poorer ratings of quality of care (29).

More broadly across the hospital, patients who are hospitalized frequently have delirium with immediate and long-term consequences, including an association with increased mortality rates. Sleep disruption has been proposed as a modifiable target for delirium interventions (42). A prospective and multifaceted delirium intervention study of older patients on a general medical ward—a study that included a sleep component and noise reduction—successfully reduced delirium symptoms and the rate of sleep medication use (43). Sleep is a cyclic orchestration of stages that alters with aging and can vary from person to person with specific medical, psychiatric, and situational differences (44). Older persons tend to have less N3 sleep (12, 45), and various medications can influence stage distributions (for example, antidepressants suppress REM sleep) (46). Our data provide a framework for implementing targeted strategies to mitigate noise-induced sleep disruption, which potentially contributes to delirium among patients who are hospitalized.

Approaches to mitigating noise for sleeping patients include eliminating or controlling the source of sound or blocking its path. The first approach, controlling sound at the source, includes public-policy restrictions on acceptable night noise, such as aircraft flyovers (9); substitution with quieter technologies, such as personal digital assistants in place of overhead paging; and telemetry from nurses' stations to limit intrusive oversight (11, 47). The night care intervention study at 1 hospital established a "quiet time" period, altered intrusive medication routines, and reduced sound level exposures from staff voices. This protocol resulted in a 25% reduction of unit-wide sedative medication use and improved patient satisfaction ratings (10). The second approach to mitigation focuses on "blocking" or attenuating sound along the transmission path, including hospital unit design configurations; application of advanced construction materials, such as acoustic surfaces (48); closing doors; and even supplying earplugs to patients.

As expected, the most potent sleep disruptors were electronic sounds intentionally designed to be alerting (49, 50). The arousal probability curves in **Figure 4** corresponding to these sounds (that is, phone ringing and IV alarm) reveal that these devices may not be suitably attenuated to spare sleep, even at their quietest settings: within the lowest tested ranges in this study, these sounds produced sleep disruption more than 50% of the time. Alarm signals have

Figure 4. **Electroencephalogram arousal probabilities for noise stimuli presented, adjusted for body position.**



See Methods section. dBA = decibels, adjusted for the range of normal hearing; IV = intravenous; $LA_{10,\ 10\text{-}s}$ = sound pressure level, averaged over the 10-second stimulus duration, exceeded 10% of the time; N2 = non-REM sleep stage 2; N3 = non-REM sleep stage 3; REM = rapid eye movement.

proliferated in health care settings. Monitor alarms could be better managed through enhanced algorithms, more careful patient assignment and clinically relevant configuration standards, and targeting intended responders with technologies using nonauditory channels (6).

Staff conversations and voice paging were also found to be highly alerting, producing a 50% chance of arousal at 50 dBA ($LA_{10,\ 10\text{-}s}$, sound level exceeded 10% of the time) in N2 and REM sleep. Voice transmission can be modified behaviorally (10) and diminished through design and construction solutions. Simple strategies include planning for and directing conversation to designated consulting spaces. In many health care settings, policy still includes keeping patient doors open to allow for visual monitoring and easy accessibility by caregivers, which exposes patients to excess noise from the nurses' station and other sources. Centralized patient-monitoring technology may help minimize the need for this policy—at least at night—while still addressing patient-safety concerns. Proper door hardware and gasketing could decrease the sounds generated by door closing and limit sound transmission from halls.

Other tested hospital sounds (for example, ice machines, laundry carts, and overhead paging) that emanate from sources external to patient rooms (51–53) were, as a group, arousing at relatively low sound levels. Ice machines should be architecturally isolated from patient areas or reengineered. Modifying procedures and equipment, such as selection and maintenance of carts and organizing the schedule of use and routing, is a low-tech, low-cost contribution to reducing noise. Exterior-to-building noises (for example, jet, helicopter, traffic) were the least arousing among our group of stimuli, and our findings were consistent with other studies of sleep and airplane flyovers (21). The previous work determined that statistical description of average sound level (LA_{EQ}) over 24 hours is an inadequate measure for describing the sleep-disruptive effects from noise. Examining disruption at different sound levels is the more appropriate exposure metric (9), especially for sounds with broad ranges that peak. It is, therefore, not surprising that we determined that continuous stimuli (for example, traffic noise) are less arousing than intermittent stimuli (for example, phone ringing or IV alarm). At the same adjusted noise dose, higher transient sound levels and faster rise times are more likely to induce cortical arousals. In light of our findings, broad sleep-preserving steps should include changes in the design of health care facilities, construction materials chosen for acoustic properties, improved monitoring and alerting technology, sleep-protective night care routines, and education and retraining of health care personnel on the effect of noise on patient arousal and cardiac responses to such sleep disruptions (4, 9, 10, 21, 27–29).

During REM sleep, we saw a narrower range of cortical arousals, relative to NREM stages of sleep, and across the wide range of sounds administered in this experiment. This may demonstrate that the brain, during REM sleep, has less capacity to differentiate among sounds compared with NREM sleep. This finding is unexpected because REM sleep has an abundance of cerebral activity relative to stage N3 sleep, including in auditory areas of the brain (17). Auditory-evoked potentials elicited by saying a participant's name during REM sleep also seem similar in morphology to those seen during wakefulness (18), implying that there is some higher-order processing in REM sleep. This supports the broader notion that, in REM sleep, cerebral resources are dedicated to internal processing, such as dream content, rather than to differentiating external sound sources.

Although ecologically valid in many aspects, this experiment has some limitations that may cause an underestimation of the effects of noise on sleep. We presented noises individually for up to 10 seconds and halted if arousal occurred. This procedure minimized full awakenings and increased sleep time available for more stimulus presentations. In a hospital setting, sounds often last longer than 10 seconds and several sounds occur simultaneously. We do not account for relative proportion or intermittency of stimuli in a hospital setting; our data are intended to provide a framework by which a hospital unit could assess the sleep-disrupting effects of a specific hospital environment. We studied only 12 young, healthy adults. The typical patient who is hospitalized is older, with generally less of the most protected deep sleep, N3 (54). Medical and psychiatric conditions, as well as pain and medication use, compromise sleep in patients who are hospitalized, presumably rendering deep sleep, N3, more difficult to achieve. Noise can be expected to interact with these other sleep-disrupting stressors associated with hospitalization (55). Therefore, we judge our arousal probability profiles for N2 sleep to be most relevant for predicting acoustic disruption of sleep in inpatient populations. Future studies should assess the effect of noise on sleep disruption and heart rate changes in older participants to confirm generalizability and document effects on sleep stage proportions and architecture. Together, these limitations may cause our data to underestimate the effects of noise on sleep for patients who are hospitalized. Our data should be viewed as providing reference points that demonstrate sleep disruption caused by these common hospital noises, across a range of sound levels, and should be used to set a minimum for noise-attenuating standards.

In summary, protecting sleep from acoustic assault in hospital settings is a key goal in advancing the quality of care for inpatient medicine. We characterized the vulnerability of sleep to commonly encountered hospital sounds by deriving unique arousal probability profiles to enable customized target thresholds and interventions to limit noise-induced sleep disruption. This research has already informed the first acoustic standards in the Guidelines for the Design and Construction of Health Care Facilities (8). With the leading edge of baby boomers turning 66 this year and an aging health care infrastructure, billions of dollars in health care facility renovation and new construction are anticipated in the coming decade (7). Improving the acoustics in health care facilities will be critical to ensuring that these environments enable the highest quality care and the best clinical outcomes.

Abstract

The neural correlates of the wake-sleep continuum remain incompletely understood, limiting the development of adaptive drug delivery systems for promoting sleep maintenance. The most useful measure for resolving early positions along this continuum is the alpha oscillation, an 8–13 Hz electroencephalographic rhythm prominent over posterior scalp locations. The brain activation signature of wakefulness, alpha expression discloses immediate levels of alertness and dissipates in concert with fading awareness as sleep begins. This brain activity pattern, however, is largely ignored once sleep begins. Here we show that the intensity of spectral power in the alpha band actually continues to disclose instantaneous responsiveness to noise—a measure of sleep depth—throughout a night of sleep. By systematically challenging sleep with realistic and varied acoustic disruption, we found that sleepers exhibited markedly greater sensitivity to sounds during moments of elevated alpha expression. This result demonstrates that alpha power is not a binary marker of the transition between sleep and wakefulness, but carries rich information about immediate sleep stability. Further, it shows that an empirical and ecologically relevant form of sleep depth is revealed in real-time by EEG spectral content in the alpha band, a measure that affords prediction on the order of minutes. This signal, which transcends the boundaries of classical sleep stages, could potentially be used for real-time feedback to novel, adaptive drug delivery systems for inducing sleep.

Introduction

Sleep is not uniform, and certain moments are sounder than others. Indeed, resistance to acoustic disturbance—a measure of sleep depth—displays considerable variability throughout a night of sleep, even within sleep stage [1]. The factors that influence sleep's vulnerability to sensory insult have not been fully illuminated.

The very transition from wake to sleep involves a dissociation from the external world and a crescendo of internal brain rhythms. Heralding this transition is attenuation of the alpha rhythm, an 8–13 Hz electroencephalographic (EEG) oscillation prominent over posterior brain regions, and the signature of relaxed wakefulness [2]. Diminishing during the descent into sleep, alpha amplitude shadows the decline in external awareness that accompanies sleep onset [3,4]. And while it appears to vanish as sleep begins, quantitative analysis reveals that power in the alpha band actually fluctuates dynamically throughout the night (Fig. 1A) [5].

Given alpha activity's association with wakefulness and sensory intake, we hypothesized that covert levels of alpha activity would reveal a sleeper's instantaneous sensitivity to the environment. That is, inconspicuous fluctuations in wake-like background brain activity might correspond to changes in sleep depth, even beyond sleep stage designation.

To study this question in a realistic setting, we used ecological noises to probe environmental sensitivity throughout sleep, simultaneously monitoring subjects' brain activity with EEG. The sound intensity required to disturb subjects provided an empirical measure of their instantaneous sleep depth. In this paradigm, *sleep stability* denotes resistance to disruption, while *sleep fragility* denotes vulnerability to disruption. We sought to evaluate whether these qualities could be predicted using the covert level of waking brain activity just before each stimulus.

Results

We systematically challenged sleep with auditory stimulation in thirteen healthy subjects throughout two nights of sleep. Brain activity was monitored on each night using EEG. Ten-second, ecological noises (e.g., road and air traffic, a telephone ringing) were presented during bouts of stable sleep (Fig. 2). Each sound was initiated at 40 decibels (dB) and replayed every thirty seconds in 5 dB increments until the EEG signal was perturbed according to standard guidelines (i.e., an arousal was observed [6]).

We interrogated the relationship between alpha activity and sleep fragility using Cox regression, a tool from survival analysis (see Materials and Methods). The output of Cox regression is the hazard ratio (HR): this number represents the relative hazard of

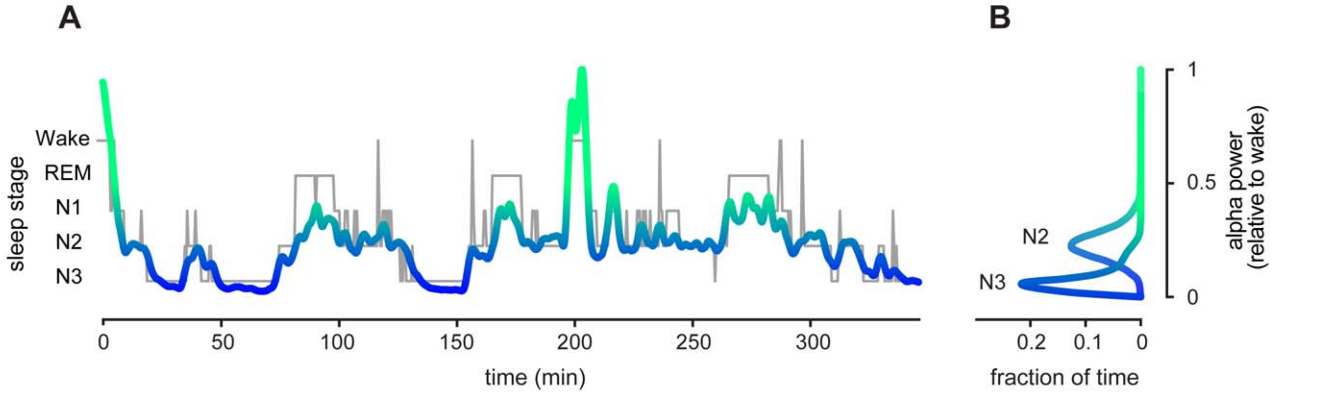

Figure 1. Alpha power fluctuates dynamically throughout the night. A. The trajectory of relative alpha power throughout a quiet night of sleep is shown from one representative subject. Simultaneous sleep stage designations run beneath the time course of alpha power. Diminishing as sleep begins, alpha power fluctuates throughout the night, in tandem with sleep depth. For display, the alpha power time-series was approximated using local linear regression in 4 minute windows, corresponding to the approximate length of each stimulation series (see Materials and Methods). This procedure removes noise and emphasizes slower fluctuations with fewer distortions than those imposed by simple low-pass filtering [42]. B. These histograms show the distribution of alpha power during NREM sleep, revealing that a range of values can be observed within each of stages N2 and N3. Power was computed in non-overlapping 10-second bins; epochs containing arousals, which may represent transient departures from stable sleep, were discarded.
doi:10.1371/journal.pone.0017351.g001

disruption in one condition compared to another. For continuous covariates, the HR represents the relative hazard of disruption incurred by a one-unit increase of the covariate. Hazard ratios greater than 1 imply that the covariate is associated with sleep fragility (vulnerability to disruption), while those less than 1 denote covariates accompanying sleep stability (resistance to disruption).

We focused our analysis on factors contributing to sleep fragility during non-rapid-eye-movement (NREM) sleep (stages N2 and N3, accounting for the majority of sleep [7]), as several difficulties arise when considering alpha activity during rapid-eye-movement (REM) sleep (see Discussion). The regression model contained two covariates, one indicating the visually scored sleep stage designation [6], the other indicating the spectral content preceding each stimulus (see Materials and Methods).

When comparing noise sensitivity across sleep stage, Cox regression yielded a HR of 0.54 ($P<0.0001$) associated with stage N3, so-called slow-wave sleep, relative to N2. In line with previous reports [1,8], this value indicates a suppressed hazard of disruption in N3 compared with N2 (the probability of tolerating noise at any loudness in N3 being roughly the square root of that in N2).

We next addressed the influence of occipital alpha activity on sleep fragility. Figure 1A shows that, on an undisturbed night of sleep, relative alpha power shadows the trajectory of qualitatively assessed sleep depth. Like the probability of disruption, alpha power is generally suppressed in N3 relative to N2 (Fig. 1B).

Although relative alpha power correlates well with sleep stage, a wide spectrum of variation still exists within each category. We therefore sought to determine whether fluctuations in this quantity—even within sleep stage—correspond to concurrent variations in sleep fragility.

To address this question, we included in the statistical model a measure of the alpha content during the ten seconds immediately preceding each sound (Fig. 2, light gray windows). Even controlling for stage, we observed a highly significant relationship between alpha power and sleep fragility ($HR = 5.74$, $P<0.001$). This suggests that, well beyond sleep stage designation, latent alpha content betrays heightened sensitivity to impending sounds.

To investigate the timescale over which alpha power predicts sleep fragility, we further characterized each sound series by a single spectral measure derived from a reference window of stable sleep preceding the sound series (Fig. 2, dark gray windows). This interval anticipated the eventual disruption by a variable latency of up to four minutes, as arousal may have occurred as late as 70 dB. Still, alpha power during this ninety-second baseline period predicted the probability of disruption in the moments that followed ($HR = 7.33$, $P<0.001$), suggesting that the brain state disclosed by alpha activity persists for several minutes (see also Results S1 and Figure S1).

Figure 3 illustrates a summary of our results, rendering the probability of sleep disruption in the face of noise as a function of

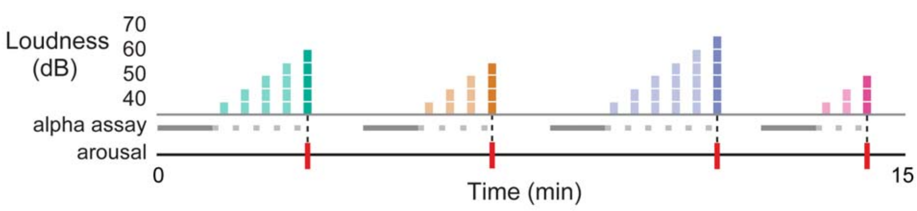

Figure 2. Sleep depth was probed with auditory stimulation. We systematically probed sleep depth with auditory stimulation during bouts of N2, N3 and REM sleep. Ten-second noises were initiated at 40 decibels (dB) and presented every thirty seconds in 5 dB increments until the EEG signal was perturbed (arousal, vertical bars on the bottom line). Each color represents a different sound type; a sample of four is shown here. The sound intensity required to disturb subjects provided an experimental measure of their immediate sleep depth. The gray windows beneath the sound level delineate periods during which alpha power was measured to predict sleep fragility.
doi:10.1371/journal.pone.0017351.g002

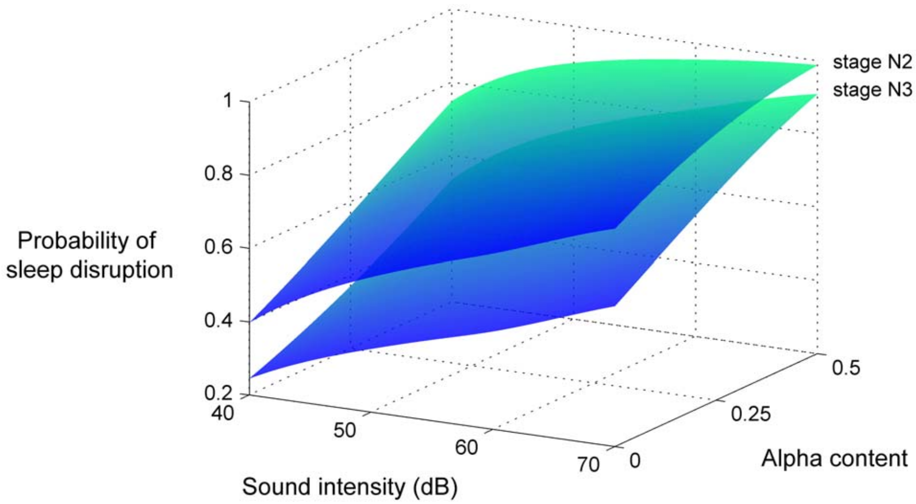

Figure 3. Alpha content reveals immediate sleep fragility. Using Cox regression, we found that alpha activity disclosed noise sensitivity during NREM sleep, even when controlling for stage. Here we reconstruct probability surfaces for sleep stages N2 and N3, rendering sleep fragility as a function of both stimulus intensity and EEG alpha content.
doi:10.1371/journal.pone.0017351.g003

both stimulus intensity and EEG alpha content. Here we depict a distinct surface for each NREM sleep stage, in which separate mechanisms may also regulate sensory perception [9,10]. Just as the probability of disruption increases monotonically with loudness, so too is sleep's vulnerability modulated by coincident alpha content.

We next explored the relationship between immediate sleep fragility and the broader EEG power spectrum. Toward this end, we estimated the power at frequencies between 0.5 and 25 Hz (in 0.5 Hz intervals) expressed over occipital electrodes during the ten seconds immediately preceding each stimulus (Fig. 2, light gray windows). To facilitate a meaningful comparison across frequencies, power values were standardized based on their waking levels and their dynamic ranges observed during NREM sleep (see Materials and Methods). The power at each frequency was then analyzed independently using Cox regression.

The resulting spectral portrait shows how power at each frequency, beyond stage designation, covaries with sleep fragility (Fig. 4). (For comparison across the entire EEG spectrum, estimates of the Cox regression coefficients reflect a change of one standard deviation in the log-power at each frequency.) The large, sustained contribution throughout the alpha band suggests that this region of the spectrum indeed contains a meaningful signal. We moreover observed strong tendencies toward sleep stability in conjunction with low-frequency power (including slow-wave, delta, and theta activity) and toward fragility in conjunction with high-frequency power (beta activity). Nonetheless, the only power value that achieved significance after a liberal correction for multiple comparisons (Holm-Bonferroni method) was that at 10.5 Hz ($P = 0.025$), centrally located within the alpha band.

As the approach just described manages to isolate the power at different frequencies, we took the opportunity to once more study

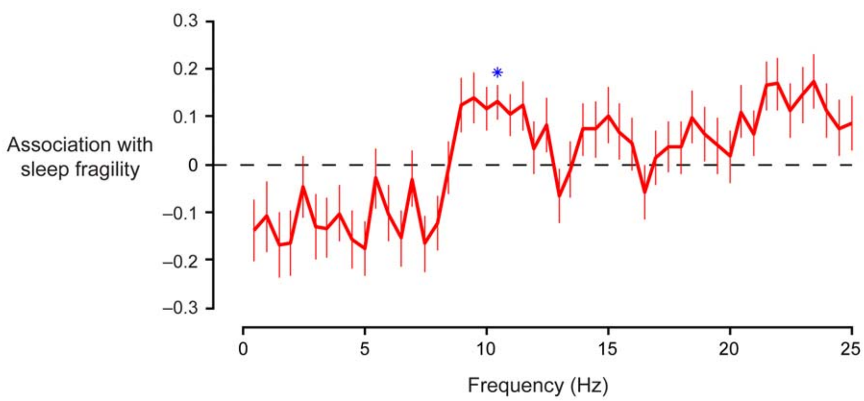

Figure 4. Alpha band power is a specific marker of sleep depth. We examined the broader relationship between EEG spectral content (beyond sleep stage designation) and NREM sleep depth. The power expressed over occipital electrodes immediately preceding each stimulus was standardized using a baseline waking spectrum and the dynamic range observed during sleep at each frequency. The relationship between spectral power values and sleep fragility was then assessed independently with Cox regression; the resulting regression coefficients (±SE) are shown for each frequency in 0.5 Hz bins. Coefficients less than zero imply an association with sleep stability (resistance to disruption), whereas coefficients greater than zero imply an association with sleep fragility (vulnerability to disruption). We observed a strong relationship between heightened sound sensitivity and spectral power throughout the alpha band. Trends toward sleep stability emerged in conjunction with low frequency (<8 Hz) power and toward fragility in conjunction with high frequency (>13 Hz) power. *$P<0.05$ after correction for multiple comparisons.
doi:10.1371/journal.pone.0017351.g004

the relationship between alpha activity and sleep fragility, this time including in our statistical model, in place of sleep stage designation, a measure of low-frequency oscillatory EEG activity (0.5–4 Hz), which may more faithfully track changes in sleep depth at the neuronal level [11]. This moreover teases apart the effects of alpha and delta activity, which may interact in the relative measure of alpha content employed earlier. In this context, slow-wave activity was associated with sleep stability (HR = 0.73; $P<10^{-11}$), and alpha activity again demonstrated a significant relationship with sleep fragility (HR = 1.13; $P = 0.002$).

Discussion

The present results show that the soundness of sleep, defined empirically and with ecological relevance, is revealed in real-time by EEG spectral content: greater vulnerability to noise-induced sleep disruption accompanies elevated alpha activity. Such spectral interrogation of sleep fragility has predictive power on the order of minutes. Furthermore, this effect transcended traditional sleep staging, imparting a greater sense of fluidity to what is typically seen as a rigid process.

From a behavioral perspective, alpha activity has been shown to resolve fine gradations in the sleep-wake continuum. On visual and auditory vigilance tasks, reduced alpha activity is associated with sluggish reaction times and an elevated probability of lapse [12,13,14,15,16]. Even during wakefulness, immediate levels of alertness are revealed by ongoing alpha activity: moments of higher parietal alpha amplitude have been associated with receptiveness to tactile stimuli and heightened attention [17]. These observations concerning alpha's relationship to sensory intake, in conjunction with several others, have emboldened some investigators to include the alpha oscillation among the neural correlates of consciousness [18]. Here we extend alpha activity's association with environmental awareness beyond wakefulness and drowsiness, and into NREM sleep.

Though the alpha oscillation was one of the first brain rhythms to be described in the human EEG [19], little is currently understood about its underlying generators or functional significance. The thalamus, which has been found to influence cortical alpha synchronization [20], might be the critical link between alpha activity and the brain's vulnerability to acoustic disruption. As the thalamus is involved in relaying sensory information to the cortex, alpha activity could be a reflection of this region's propensity for conveying external stimuli to cortical processing centers where it is capable of interrupting sleep. Intriguingly, it was recently shown that global expression of alpha power (and, to a weaker extent, beta power) is positively correlated with activity in a "tonic-alertness network," comprised of the dorsal anterior cingulate cortex, anterior insula, and thalamus [21]. The constituents of this network, with access to sensory information and broad projections throughout the cortex [22], are well positioned to support alerting functions and a "general readiness for perception and action" [21,23]. At least during wakefulness, then, elevated alpha activity seems to reflect the engagement of regions supporting sensory intake and alertness. Future studies should address the existence of a similar intrinsic connectivity network during sleep, and its connection with EEG alpha content.

The specificity of alpha power as a maker of NREM sleep depth

When we broadened the scope of our analysis to include the rest of the EEG power spectrum during NREM sleep, only an alpha frequency (10.5 Hz) remained significant after correction for multiple comparisons. Rather than suggesting that this lone frequency contains information regarding sleep fragility, we suspect that inter-individual variability in peak alpha rhythm frequency [24] undermined the effect when small slivers of the band were considered alone.

Although large scale associations between EEG power and sleep depth might be expected based on inherent correlations across frequencies in the power spectrum of the sleeping brain [5], we nonetheless observed several trends outside the alpha band that warrant attention. In particular, we noted a tendency toward sleep stability in conjunction with increased power in the frequencies below 8 Hz. This accords well with the view that low-frequency oscillatory activity (including slow-wave and delta activity) intensifies with increasing depth of NREM sleep [11]. It should be noted, however, that our analysis controlled for NREM sleep stage, so the overall relationship between sleep stability and low-frequency power, which is enhanced in stage N3 relative to N2, was necessarily blunted in this context. The association between reduced sound sensitivity and EEG spectral power in the low frequencies appeared to extend even to the theta band (4–7 Hz). In light of this observation, it is interesting to note that during vigilance tasks, theta-rich EEG has been found to be associated with reduced arousal [25] and deteriorated stimulus detection [12,26].

We further observed a tendency for increased vulnerability to disruption in conjunction with greater EEG power in higher frequencies, including the beta band (15–25 Hz). As with alpha activity, previous work has also shown a connection between variation in beta activity and fluctuations in cortical arousal and vigilance behavior [27,28]. A similar observation was made in sleep, with enhanced beta activity now thought to signify heightened arousal in patients with insomnia [29].

As might be expected, the association between alpha power and sleep fragility did not yield significance when REM sleep was considered alone ($P = 0.45$). During REM, the relative alpha power is more erratic and this activity may stem from heterogeneous brain sources. Alpha activity during REM occurs in at least two forms, conspicuous alpha bursts and background alpha activity, which are thought to be electrophysiologically distinct from one another and from that evident during wakefulness. Further, alpha amplitude may be modulated by visual imagery in the context of dreaming [2]. While the function of alpha activity during REM remains hypothetical, the present results suggest that it does not accompany heightened sensitivity to one's environment.

Future directions and applications

Previous electrophysiological studies have demonstrated that ongoing network activity profoundly influences evoked cortical responses and explains their dramatic variability [30]. Here we further emphasize the role of the immediate brain state in modulating perception by showing that beyond sleep stage [8] and the overt rhythms of sleep [31], inconspicuous background activity also varies with the soundness of sleep. In this light, alpha activity provides a potent window onto the instantaneous responsiveness of the sleeping brain. Future research should investigate the extent to which other features of EEG dynamics, such as spectral coherence [32,33], cross-frequency phase synchrony [34,35], or nested oscillations [36,37] offer useful information about empirical measures of sleep depth.

Given that real-time fluctuations in EEG parameters provide immediate information about sleep's depth and its vulnerability to disruption, it is enticing to speculate that this kind of information could be employed by adaptive hypnotic agents guided by direct feedback from neural activity. Such technology might be capable of combating the disruptive effects of environmental noise on sleep and next-day cognitive performance [38,39], while optimally preserving natural sleep physiology. At present, sleep medications are a blunt instrument. Administered before bed, conventional hypnotics last for a rigid duration fixed by their pharmacokinetic properties. These drugs dominate consciousness, inducing sleep-like sedation of unclear authenticity [40,41]. A system that allows for dynamic drug delivery based on instantaneous feedback (using a metric derived from alpha activity or the broader EEG power spectrum) could momentarily protect or facilitate sleep when vulnerable, otherwise letting natural brain rhythms run their course. Further, such an arrangement might allow for emergency interruptions or scheduled wake-times; such specificity is prohibited by the crude sleep medications used today. Besides using smaller doses, then, this system would afford enhanced precision and flexibility. The present study establishes a conceptual framework for such research, showing that sleep can be monitored in real-time and characterized along a rich continuum of depth.

Materials and Methods

The findings described here stem from an experiment conducted to study the disruptive salience of different sounds in sleep. Biomarkers for individual noise tolerance (i.e., traits) were presented in [10], whereas the current analysis seeks to elucidate moment-to-moment variations in sleep's vulnerability to disruption (i.e., states).

Ethics statement

Study procedures were approved by the Human Research Committees of the Brigham and Women's Hospital, the Massachusetts General Hospital (MGH), and the Cambridge Health Alliance. Written informed consent was obtained for all participants.

Participants

Thirteen healthy volunteers (9 females and 4 males, age 24.9±7.3; mean ± SD) were determined to be free from medical or psychiatric conditions on the basis of clinical history and a physical examination. Participants were also screened for drug, alcohol, or caffeine dependency. Subjects reported taking no medications that affect sleep or circadian rhythms. All participants demonstrated normal hearing on the basis of audiometric screening of each ear (minimum hearing level of 25 decibels [dB] at 500, 1000, 2000 and 4000 Hz).

Study conditions

Participants slept on a consistent schedule for at least 4 days prior to the study, as confirmed by wrist actigraphy (AW-64, Minimitter, Bend, OR). During the study, subjects stayed at the MGH Sleep Laboratory for 3 consecutive nights. Each night, subjects were given the opportunity to sleep for 8.5 hours at their normal bedtime. Research staff monitored the subjects 24 hours a day to ensure that they did not nap. Light levels were maintained at approximately 90 lux during waking periods, and <1 lux during sleep periods. The first night was used for adaptation; subjects adjusted to the laboratory environment and were screened for any sleep disorders visible on the polysomnogram. Acoustic stimulation was applied only on the second and third nights.

Sleep recordings

Polysomnographic recordings were collected using a Comet XL system (Grass-Telefactor, West Warwick, RI, USA). Skin surface electrodes (Beckman Instrument Company, Schiller Park, IL) captured EEG from frontal (F3 and F4), central (C3 and C4) and occipital (O1 and O2) positions; electrooculogram (EOG); submental electromyogram (EMG); and electrocardiogram (ECG). Data were conditioned by analogue filters (high-pass: 0.3 Hz; low-pass: 70 Hz), and digitally sampled at 200 Hz.

Experimental paradigm

On the second and third nights of the experiment, acoustic stimulation was applied systematically throughout stages N2, N3 and REM sleep. Once stable sleep was achieved (at least 90 consecutive seconds of the same stage scored in real time), sounds were initiated at 40 dB and replayed every thirty seconds in 5 dB increments until an arousal was observed or 70 dB was reached (Fig. 2). A 70 dB limit was imposed to minimize full awakenings from sleep and prevent significant disruption of sleep architecture. Each time an arousal was elicited, sound was withheld until stable sleep resumed, at which time a new sound was chosen.

Acoustic stimuli were each ten seconds in duration, and drawn from diverse sources. Noises included a telephone ringing, a toilet flushing, an IV alarm, a hospital intercom, a door creaking and slamming, a laundry machine, an ice machine, a towel dispenser, road traffic, snoring, a jet engine, a helicopter, and two conversations of positive and negative emotional valence. All sounds except the jet and helicopter were recorded on site in a medical unit of Somerville Hospital, Somerville, MA. Stimuli, which were repeated through each graduated sound series, were selected at random for each participant on each night.

Sound levels were measured using dBA-$L_{eq\text{-}10\ s}$, consistent with standard methods used to evaluate the clinical effects of noise. "A" refers to the weighting of sounds in ranges audible to humans, while "$L_{eq\text{-}10\ s}$" denotes an average intensity derived from the 10 seconds of the sound's duration. The sound level in the patient room was logged with an environmental sound monitor (Rion Type NL-31, with Type 1 microphone) located 10 inches above the subject's head. Stimuli were presented on a measured average background of 34–35 dB due to continuous ventilation in the room.

Stimuli were delivered in surround sound using an array of four studio-monitor loudspeakers (Event, model PS6) placed at the circumference of a circle centered around the subject's head. This arrangement enabled sounds with moving sources (e.g., the airplane) to be reproduced with apparent motion through space.

Sleep scoring

Sleep stages (in 30-second epochs) and arousals were identified in adherence with the recommendations of the American Academy of Sleep Medicine [6]. According to these criteria, an arousal consists of an abrupt increase in EEG frequency lasting at least 3 seconds, excluding that caused by a spindle, and preceded by at least 10 seconds of stable sleep. Sleep scoring was conducted by a registered polysomnographic technician under the supervision of the medical director of the MGH Sleep Laboratory.

Spectral estimation

The period preceding sound presentation was used to assay the electroencephalographic sleep depth associated with each sound. Power spectra were estimated using the multitaper method [42]. Spectra were derived from occipital electrodes (average of O1 and O2), as waking alpha tends to predominate over these posterior regions [43].

For each segment of analysis, alpha activity was computed as the integral of the power spectrum in the alpha band (8–13 Hz) divided by the total power generated in that interval. As utilized elsewhere [4,44,45,46], this metric seeks to eliminate variance resulting from non-brain-based factors (e.g., degradation of electrode contact) that occur during all-night EEG recordings. Moreover, this process facilitates an aggregate analysis across two experimental nights in each of thirteen subjects. To control for the degree to which alpha power signifies wakefulness in each individual (i.e., the subject's native alpha generation [47]), this measure was normalized to the corresponding value derived from a baseline period of eyes-closed wakefulness on the same night.

When a broader range of EEG oscillatory activity was considered (Fig. 4), the power at frequencies of 0.5 Hz to 25 Hz (in steps of 0.5 Hz) was estimated using Bartlett's method (2-second segments) and the Goertzel algorithm [48]. The quantities derived from occipital electrodes O1 and O2 were averaged for subsequent analysis. As before, the power spectral density was normalized to a baseline waking spectrum. To facilitate meaningful comparison across frequencies, which have different dynamic ranges, power values were log-transformed [42] and divided by the standard deviation of the log-spectrum observed during quiet NREM sleep (absent sound presentation) on the same night. When the power in the slow/delta band (0.5–4 Hz) and alpha band (8–13 Hz) were considered as absolute, as opposed to relative, measures, the Bartlett spectra were integrated in the corresponding ranges and the resulting power values were standardized in the manner just described.

Statistical analysis

The influence of EEG spectral content on sleep fragility was interrogated using survival analysis [49]. Each sound series defined a distinct risk period (a "lifetime") during which sleep could be disrupted—maintenance of sleep constitutes survival, disruption of sleep, a failure.

Only sound series that were preceded by three contiguous 30-second epochs of the same sleep stage and terminated in a sound-induced arousal were used for analysis. (An arousal was judged to be evoked from stimulation if the arousal occurred during the sound or within 5 seconds from its conclusion.) Among these sound series, 109 out of 724 in NREM and 45 out of 267 in REM were right-censored, meaning that sound presentation ended before arousal occurred.

In this paradigm, sleep stability, a function of loudness, describes the probability of tolerating sounds of any given intensity. Sleep fragility, the stability curve's complement, describes the probability of *disruption* due to sounds of any given intensity.

The effect of EEG spectral features on sleep fragility was evaluated with a Cox proportional hazards regression model. The model was stratified across subjects in order to account for individual differences in noise tolerance. Since our loudness scale grew in discrete, 5 dB increments, we employ the exact-partial likelihood method to handle multiple arousals at each sound intensity [50]. A categorical "stage" covariate was also included to control for the conventional measures available to characterize sleep depth.

When the power at distinct frequencies through 25 Hz were tested independently, *p*-values for each frequency were adjusted using the Holm-Bonferroni method for multiple comparisons [51].

Supporting Information

Figure S1 Alpha power is stable for minutes. This plot shows an unbiased estimate of the autocorrelation function of relative spectral content in the alpha band (8–13 Hz) measured in 10-second intervals (depicted smoothed in Figure 1A). The autocorrelogram portrays the correlation of alpha content with its subsequent values for a range of lags. The trajectory used for this figure transcended multiple sleep stages, thus portraying the global stability of alpha content that might be observed at an arbitrary time of night.

Covert Waking Brain Activity Reveals Instantaneous Sleep Depth

Scott M. McKinney, Thien Thanh Dang-Vu, Orfeu M. Buxton, Jo M. Solet,
and Jeffrey M. Ellenbogen*

SUPPLEMENTARY RESULTS

To shed further light on the timescale over which alpha power might be capable of predicting sleep fragility, we studied the natural trajectory of alpha power during an entire night of sleep from one representative subject, as shown in Figure 1A. Here we used data from the quiet night of sleep, free of sound presentation.

The representation of Figure 1B conveys the magnitude of relative alpha power variability over the course of the night. To address the stability of such a measure from one moment to the next, we employed autocorrelation. The autocorrelation function shows the correlation of a time series with its future values at any given latency. Figure S1 shows an unbiased estimate of the autocorrelation function for the relative alpha power trajectory shown in Figure 1A, for lags up to 25 minutes long. This plot portrays the persistence, or inertia, of EEG alpha content from one observation to the next, understanding that stage transitions or awakenings occur many times throughout the night. Although our protocol involving frequent sound stimulation only permitted examination of latencies up to four minutes long, this information from the baseline night suggests that prediction of sleep fragility based on alpha power is not likely valid over time horizons greater than five minutes.

Spontaneous brain rhythms predict sleep stability in the face of noise

Thien Thanh Dang-Vu[1–3], Scott M. McKinney[2], Orfeu M. Buxton[1,4], Jo M. Solet[1,5] and Jeffrey M. Ellenbogen[1,2]

Quality sleep is an essential part of health and well-being. Yet fractured sleep is disturbingly prevalent in our society, partly due to insults from a variety of noises [1]. Common experience suggests that this fragility of sleep is highly variable between people, but it is unclear what mechanisms drive these differences. Here we show that it is possible to predict an individual's ability to maintain sleep in the face of sound using spontaneous brain rhythms from electroencephalography (EEG). The sleep spindle is a thalamocortical rhythm manifested on the EEG as a brief 11–15 Hz oscillation and is thought to be capable of modulating the influence of external stimuli [2]. Its rate of occurrence, while variable across people, is stable across nights [3]. We found that individuals who generated more sleep spindles during a quiet night of sleep went on to exhibit higher tolerance for noise during a subsequent, noisy night of sleep. This result shows that the sleeping brain's spontaneous activity heralds individual resilience to disruptive stimuli. Our finding sets the stage for future studies that attempt to augment spindle production to enhance sleep continuity when confronted with noise.

The brain's response to sensory input is modulated by ongoing, spontaneous neuronal activity [4]. Indeed, during sleep, the thalamus spontaneously engages with the cortex. This interaction can produce transient fluctuations of the brain's electric field visible on the EEG as rhythmic spindles (Figure 1A). As the thalamus relays sensory information to perceptual cortices, it has been proposed that brain processes involved in spindle production gate sensory input during sleep [2]. If spindles hinder the transmission of external stimuli from the thalamus to the cortex, a higher rate of spindle production throughout the night would be expected to preserve sleep stability in the face of noise. We hypothesized that individuals who generate more spindles would require sounds of higher intensity to disrupt their naturally occurring sleep.

Twelve healthy human volunteers (age 26.3 ± 7.5, mean ± SD) were studied in the sleep laboratory for three consecutive nights. The first night was quiet, while the second and third were noisy. Brain activity was monitored each night with EEG. We detected spindles on central channels (C3, C4) during the quiet night using an automatic algorithm (Figure 1A, and Figure S1A in the on-line Supplemental Information), defining each subject's spindle rate as the number of detected events per minute during stage N2 and N3 (stages 2 and 3 of non-REM sleep). On the noisy nights we presented frequently encountered sounds — for example road and air traffic, a telephone ringing, or hospital-based mechanical sounds — during stages N2, N3 and R (REM sleep). These ten-second noises were initiated at 40 decibels (dB) and presented every thirty seconds in 5 dB increments until the EEG signal was perturbed according to standard guidelines (that is, an arousal was observed) [5] (Figure 1B). In the present analysis, sleep

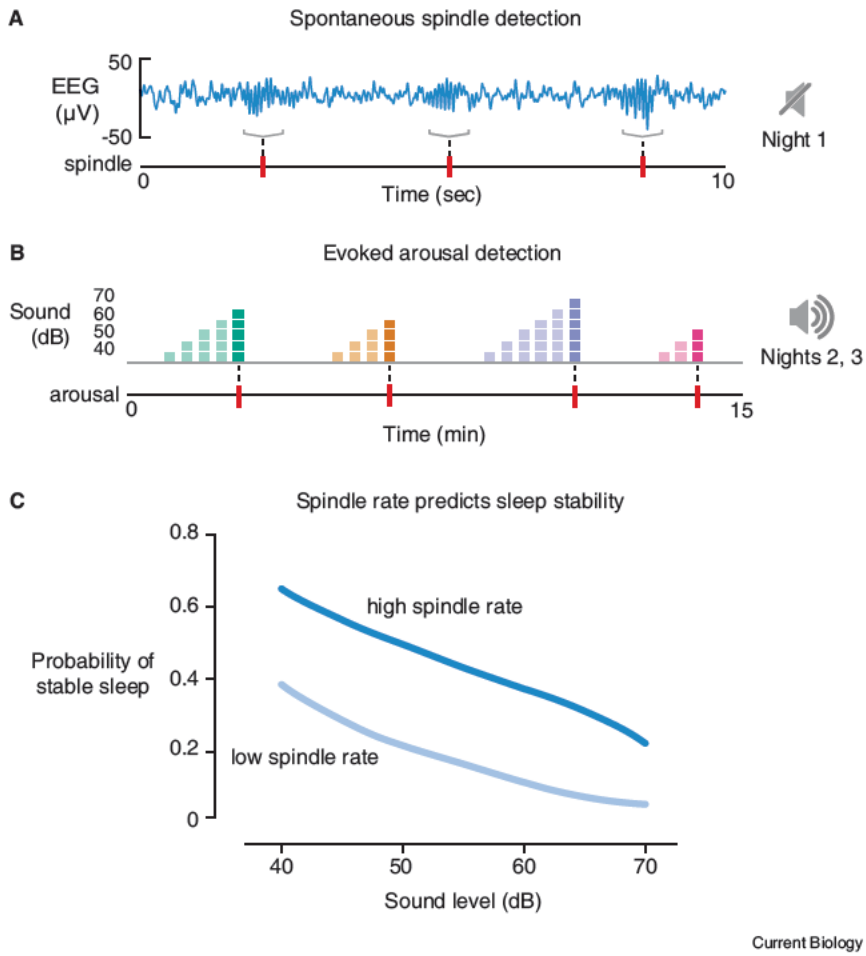

Figure 1. Spindle rate predicts sleep stability.

(A) Sleep spindles were automatically detected on central EEG channels during a quiet night of sleep. The number of detected events (vertical bars on the bottom line) per minute defined each subject's spindle rate. (B) On two subsequent nights we introduced ten-second noises, initiated at 40 decibels (dB) and presented every thirty seconds in 5 dB increments until the EEG signal was perturbed (arousal, vertical bars on the bottom line). Each colour represents a different sound type; a sample of four is shown here. (C) Observations were pooled among subjects in the lower and upper halves of the spindle rate distribution (ranges 4.57–5.44 and 5.48–6.14 spindles/min, respectively) based on EEG lead C3 during stage N2. Corresponding sleep survival curves were derived from each pool in stage N2 using the Kaplan-Meier (product-limit) method.

Current Biology Vol 20 No 15
R2

stability is defined as the maintenance of sleep without arousal.

We first considered the relationship between spindles and sleep stability during stage N2, when spindles predominate. Using Cox regression, we found that those with higher spindle rates on the quiet night exhibited greater sleep stability during the noisy nights: spindle rate carried a sleep disruption hazard ratio (HR) of 0.39 from C3 ($p = 0.001$) and 0.51 from C4 ($p = 0.002$) (see Figure 1C).

As spindles are also present in stage N3, we performed the same analysis considering stages N2 and N3 together. We again found a significant relationship between spindle rate and sleep stability (HR = 0.55, $p = 0.003$ for C3; HR = 0.64, $p = 0.018$ for C4).

This result shows that it is possible to predict an individual's ability to maintain sleep in the face of external sound: those with more abundant spindles are more resistant to sounds during sleep. It remains to be seen whether this relationship emerges from the cumulative effects of spindle and sound collision, as we suspect, or whether it is due to a yet undetermined biological process.

In line with previous reports [3], we observed consistent spindle rates from night to night (Figure S1B). We thus regard spindle rate as a stable trait, suitable for predicting sleep continuity under noisy conditions.

The extent to which the relationship between spindle rate and noise tolerance bears on different populations awaits exploration. Noise tolerance during sleep [6], like spindle rate [7], diminishes with age. On the other hand, despite reporting poor sleep, people with insomnia possess arousal thresholds similar to those of normal sleepers [8]. They likewise produce spindles at normal rates [9]. It is tempting to link these pairs of observations based on our result.

Our finding also suggests a tantalizing explanation for associations uncovered between spindle rate and learning potential (see for instance [10]): in addition to perhaps actively contributing to memory consolidation, spindles may shield sleep from disruption, allowing consolidating processes to operate unhindered.

Our data raise important questions about whether augmenting spindle rate through behaviour, drug or device might protect sleep by harnessing the spindle's ability to deflect incoming stimuli. While we await intervention-based exploration, this study provides evidence that sleep spindle rate — readily quantified from EEG — serves as a biomarker for vulnerability to sound during sleep.

Supplemental Experimental Procedures

Institutional review

Study procedures were approved by the Human Research Committees of the Brigham and Women's Hospital, Massachusetts General Hospital (MGH) and the Cambridge Health Alliance. Informed consent was obtained for all subjects.

Subjects

Twelve healthy volunteers (8 females and 4 males, age 26.3±7.5 [mean±SD]) were screened to be free from any acute or chronic medical or psychiatric conditions, established on the basis of clinical history and a physical examination obtained by a physician. History of illicit drug, alcohol, or caffeine dependency was also ruled out by clinical history and confirmed by toxicological urinalysis. Participants were taking no medications (prescription or over the counter) that affect circadian rhythms or sleep. Absence of sleep pathologies, including sleep-disordered breathing and periodic limb movements, was confirmed by standard polysomnographic sleep recording (see Sleep recordings). Volunteers with hearing impairment were excluded based on audiometric screening of each ear (hearing level threshold of 25 decibels [dB] at 500, 1000, 2000 and 4000Hz).

Study conditions

Prior to the study, subjects slept at home on a consistent schedule for at least 4 days, as assessed by wrist actigraphy (AW-64, Minimitter, Bend OR). Participants were admitted to the MGH Sleep Laboratory in the early evening and stayed for 3 days. Subjects were given the opportunity to sleep for 8.5 hours at their normal bedtime. Research staff was present 24 hours a day to monitor the subject via audio and video, as well as to check vital signs, deliver meals, and ensure that subjects did not nap. Light levels were maintained at approximately 90 lux during waking periods, and <1 lux during sleep periods in order to maintain normal circadian alignment.

Sleep recordings

Polysomnographic (PSG) recordings were collected using a Comet XL system (Grass-Telefactor West Warwick, RI, USA). On all three nights, skin surface electrodes (Beckman Instrument Company, Schiller Park, IL) captured EEG from frontal (F3 and F4), central (C3 and C4) and occipital (O1 and O2) positions, electrooculogram (EOG), submental electromyogram (EMG), and electrocardiogram (ECG). Data were captured at a sampling rate of 200 Hz and conditioned by analog filters (high pass 0.3 Hz, low pass 70 Hz).

Acoustic stimuli

Fourteen sounds were recorded in a medical unit of Somerville Hospital, Somerville, Massachusetts. Sounds were drawn from a broad range of sources: an IV alarm, a phone ringing, a toilet flush, a physician's pager sounding, a door creaking and slamming, a laundry machine, an ice machine, a towel dispenser, traffic noises, snoring, a jet engine, a helicopter, and two conversations of different emotional valence (positive and negative). All sounds were 10 seconds in duration.

Sounds were presented during sleep on the second and third nights of the study. The first night was quiet, containing merely "sham" acoustic stimulation: the audio equipment was positioned as it would be on subsequent (noisy) nights, but sleep was not disturbed for the entire 8.5 hr sleep opportunity. Subjects were not informed that they would have an initial quiet night, but were rather told that sounds would be delivered during all nights.

On the noisy nights, acoustic stimuli were presented in surround sound using an array of four studio-monitor loudspeakers (Event, model PS6) placed at the circumference of a virtual circle around the subject's head (i.e., modified ITU-R BS775-1 pattern). All sounds were veridical with respect to the soundscape. If a sound in real life had motion, such as a plane or car, then it was played as having motion in space during the study. The mean (± SE) number of presented sounds per subject was 193.1 (19.6) for the second night and 242.5 (34) for the third night. Stimuli were presented on a measured average background of 34-35 dB that was due to continuous ventilation in the room.

Sound levels were measured using dBA-$L_{eq\text{-}10sec}$, consistent with standard methods used to evaluate the clinical effects of noise: 'A' refers to the weighting of sounds in ranges audible to humans; $L_{eq\text{-}10sec}$ refers to the equivalent continuous sound level, i.e., averaging of sound pressure level across the 10 sec of sound presentation.

The sound level in the patient room was logged with an environmental sound monitor (Rion Type NL-31, with Type 1 microphone) installed on a tripod roughly 10 inches above the head of the sleeping subject, and programmed to output a DC voltage proportional to the A-weighted fast response sound level. This signal was integrated by the sleep recording software and calibrated using a 1 kHz sine wave.

Once stable sleep was achieved (at least 90 seconds of the same stage was scored in real time), sounds were initiated at 40 dB and presented every thirty seconds in 5 dB increments until an arousal was observed or until 70 dB was reached. A 70 dB limit was set in order to minimize full awakenings from sleep and thus prevent significant disruption of sleep architecture (Supplemental Results). Stimuli were presented in randomized order for each participant and night. Each time a sound elicited an arousal, no further sound was presented until stable sleep resumed.

Sleep analysis

Sleep stages, spindles and arousals were identified in adherence with the recommendations of the American Academy of Sleep Medicine [5]. According to these criteria, an arousal is defined as an abrupt increase in EEG frequency that lasts at least 3 seconds, excluding that caused by a spindle, preceded by at least 10 seconds of stable sleep. Scoring of sleep was conducted by a registered polysomnographic technician under the supervision of the medical director of the MGH sleep laboratory.

Arousal threshold

Acoustic arousal threshold was defined as the sound intensity observed to evoke an EEG arousal. The mean (± SE) number of sound-evoked arousals per subject was 42.7 (± 2.8) for the second night, and 44.6 (± 4.2) for the third night. Because our hypothesis focused on spindles, arousal thresholds were first examined in epochs of stage N2 sleep, the stage during which spindles predominate [5]. As spindles are also present during stage N3, sounds and corresponding arousal thresholds were also examined during stages N2 and N3 considered together. Sounds were delivered during two nights in order to increase the sample of presented sounds [S1].

For the computation of the linear regression (see Statistical analysis section), arousal thresholds were averaged across sound types within subject.

Spindle rate

Spindle rate was quantified on EEG channels C3 and C4 (referenced to the contralateral mastoid), since they are most pronounced in these locations [7]. To this end, an automatic spindle detection algorithm was adapted from Molle et al. and others [S2-S3] (Figure S1A). According to this method, the raw EEG signal was digitally bandpass filtered in the spindle frequency range (11-15 Hz) using a linear phase finite impulse response filters (-6 dB at 11 and 15 Hz). The average root mean square (rms) power of the filtered signal was calculated in time windows of 0.25 sec with 5 msec resolution. Sleep spindles were identified during those times in which the rms power of the filtered signal achieved a value above its 87th percentile. The presence of a spindle was validated by determining whether the spindle's peak-to-peak amplitude lay between 10 and 100 μV, and its duration was at least 0.5 sec. Spindle rate was calculated as the ratio of the number of detected spindles during stages N2 and N3 to the duration (in min.) of these stages in each subject.

Because of arguments suggesting the existence of two types of spindles (fast and slow) [S3], we also tested whether there was an effect of spindle type on sleep stability in the face of noise (Supplemental Results). Detected spindles were thus classified as either fast or slow according to the peak frequency of the filtered EEG signal during each detected spindle (slow = 11-13 Hz; fast = 13-15 Hz).

In order to test whether other properties of spindles, in addition to their rate, modulate sleep stability in the face of noise, we computed the average amplitude and duration of spindles characteristic to each subject. As described above, the beginning and end of a spindle were defined as two successive threshold-crossings of the power of the filtered signal, at least 0.5 sec apart. The amplitude was computed as the maximal peak-to-peak amplitude of the filtered EEG signal during a detected spindle. We also tested a joint measure of amplitude and duration by computing the total spectral power of the filtered signal (11-15 Hz) during detected spindles (Supplemental Results). Power spectra were estimated using the multitaper method [S4].

We confirmed that spindle rate is consistent across nights, as shown previously [S5], by measuring spindle rates during the second and third (noisy) nights in addition to the first (quiet) night. To achieve this, we applied the spindle detection algorithm to EEG collected from the second and third nights, after excluding all epochs during which sounds were presented, as well as those immediately afterward. This exclusion was performed because sounds are known to influence spindle production [S6]. (See Supplemental Results below, and Figure S1B.)

Statistical analysis

Sleep stability was defined as the maintenance of sleep in the absence of arousal. Sleep stability was interrogated using survival analysis, where maintenance of sleep constitutes survival, and arousal from sleep a failure. Each sound series defined a distinct risk period during which sleep could be disrupted by a sound-induced arousal.

Empirical descriptions of the cumulative distribution of arousal thresholds, called survivor functions, were estimated using the Kaplan-Meier product-limit method for censored data. The survivor function of loudness describes the probability of tolerating sound intensities at least that loud. Across all 565 observations, 138 were right-censored, meaning that sound presentation at the highest dB level was terminated before an arousal occurred.

The effect of spindle rates from EEG channels C3 and C4 on sleep stability (i.e., absence of arousal) was evaluated using a Cox proportional hazards regression model, accounting for shared frailty among sleep periods belonging to the same subject.

The hazard ratio (similar to a measure of relative risk) represents the proportional change in hazard due to a one-unit increase in spindle rate. In the current analysis, more spindles per minute resulted in a significantly lower hazard of sleep disruption due to noise. The same method was used to test the effects of spindle amplitude, duration and power on stage N2 sleep stability.

As an alternative presentation of these data, we also tested whether spindle rates were significantly correlated to each individual's mean arousal threshold using a linear regression. In this case, right-censored events were considered as arousal thresholds of 75 dB for the calculation of the mean. (Figure S1C and Supplemental Results, below.) This further substantiates our finding.

Supplemental Results

Sleep stages

Table S1 shows the composition of total sleep time (TST) averaged across subjects, during each of the three nights in this study. These values did not differ significantly across nights ($F = 0.00016$; $p = 0.99$), showing that, aside from very brief arousals, traditionally-defined sleep architecture was not affected by sound presentation. In agreement with previous reports [S7], amounts of stages N1, N2, N3 and REM sleep (either absolute time or % of TST) and TST were not significantly correlated with arousal thresholds during stage N2.

We also compared the same parameters from the quiet night (amounts of stages N1, N2, N3 and REM, TST) among subjects in the upper and lower halves of the spindle rate distribution, as depicted in figure 1C, and found no significant difference (two-sample t-tests). This suggests that the effects observed with spindle rate are not confounded by sleep stages and total sleep time.

Spindle rate

Spindle rates on C3 were not significantly different from spindle rates on C4 (paired t-test). Spindle rates were not significantly different between females and males, either on C3 or C4 (two-sample t-test).

In order to establish that spindle rate was consistent night to night for a given subject, we compared spindle rate on the quiet night to spindle rate on the quiet portions of the noisy nights. Thus, spindle rates on nights 2 and 3 were calculated after exclusion of 30-sec epochs with sounds, as well as the subsequent epoch after sound presentation. In order to compensate for the fewer number of quiet epochs in nights 2 and 3 compared to night 1, spindle rates in nights 2 and 3 were considered together. Spindles rates were not significantly different across nights (ANOVA), either for C3 ($p = 0.15$), or C4 ($p = 0.43$). Spindle rates on night 1 were also positively correlated with those on nights 2 and 3 ($r = 0.63$, $p = 0.028$ for C4; $r = 0.68$, $p = 0.01$ for C3) (Figure S1B). This stands in agreement with previous reports, showing a consistency of spindle rate across nights within subjects [S5]. In addition, using spindle rates from nights 2 and 3 (instead of the first, quiet, night) still predicted sleep stability in the face of noise during the same nights (Cox regression: $p < 0.001$ for C3, $p = 0.028$ for C4).

The average amplitude, duration or power of spindles during the quiet night did not have a significant effect on sleep stability during noisy nights. The spindle rate weighted by either the mean amplitude or mean spectral power of spindles likewise did not predict sleep stability. Only the spindle rate weighted by duration achieved significance with sleep stability ($p = 0.013$ and $p = 0.012$, for C3 and C4, respectively). However, we found that spindle rate weighted by the spindles' average duration was strongly correlated with spindle rate alone ($R^2 = 0.845$), demonstrating that this effect was likely driven by spindle rate alone with no effect of duration itself. This was due to the relative consistency in spindle duration across subjects (mean duration = 0.84 sec; SD = 0.035 sec). When spindles were classified into fast and slow spindles, the corresponding slow and fast spindle rates had no significant effect on sleep stability from noise. Altogether, these additional analyses suggest that the number (rate) rather than the properties (amplitude, duration, power or frequency) of spindles modulates sleep stability in the face of noise.

Figure S1C shows the correlation during stage N2 between spindle rate and mean arousal threshold as assessed by linear regression. We found that spindle rate on a quiet night was positively correlated with arousal threshold during noisy nights ($r = 0.77$; $p = 0.003$ for C3; $r = 0.71$; $p = 0.01$ for C4).

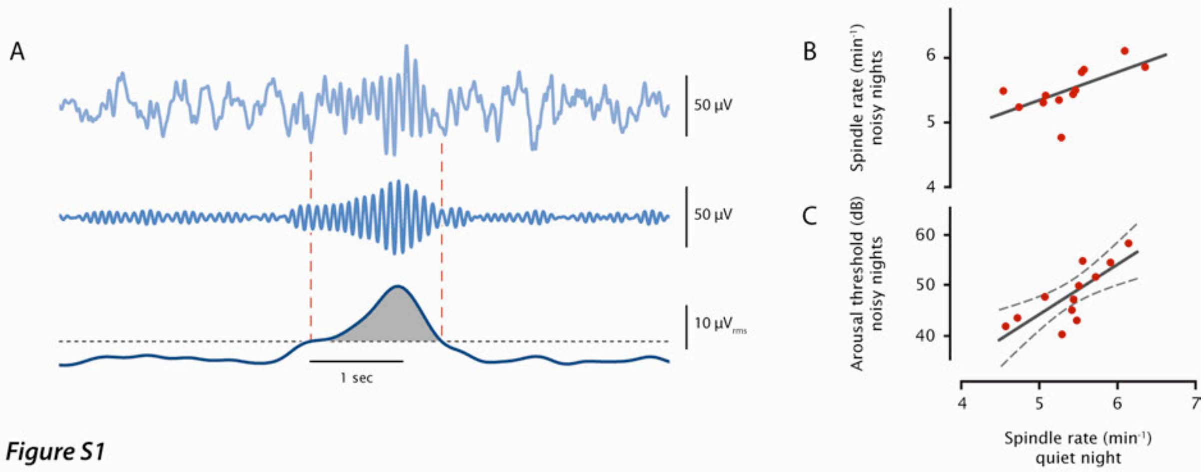

Figure S1

A. ***Spindle detection method***

(Upper trace) Electroencephalogram (EEG) depicting a typical spindle. This raw trace was derived from lead C3, referenced to the contralateral mastoid.

(Middle trace) For spindle detection, the raw signal (shown in upper trace) was first filtered in the spindle frequency band (11-15 Hz).

(Lower trace) Sleep spindles were then identified during those times when the average root mean square (rms) power of the filtered signal (shown in middle trace) achieved a value above its 87th percentile (horizontal dashed line). Additional criteria (not shown) included peak-to-peak amplitude between 10 and 100 µV, and duration longer than 0.5 sec. The vertical dashed lines delineate the detected spindle.

B. *Spindle rate is consistent across nights*

Spindle rate during the first (quiet) night positively correlated with spindle rate averaged over the second and third (noisy) nights ($r = 0.63$; $p = 0.028$), after exclusion of 30 sec-epochs during which sounds were presented as well as the epoch immediately following. Spindles rates are from EEG lead C4 and in stage N2 sleep. Each dot represents one subject. The solid line is the regression.

C. *Spindle rate predicts mean arousal threshold*

Spindle rate during the quiet night positively correlated with mean arousal threshold during noisy nights ($r = 0.77$; $p = 0.003$; the spindle rates represented here are calculated from EEG lead C3) during stage N2 sleep. Each dot represents one subject. The solid line is the regression. The dashed lines represent the 95% confidence interval.

Table S1. *Sleep composition across nights*

Sleep stage	**night 1 (quiet)**	**night 2 (noisy)**	**night 3 (noisy)**
Wake	28±4	26±6	31±5
Stage N1	52±6	53±6	54±9
Stage N2	239±9	254±10	237±9
Stage N3	92±10	68±8	89±11
REM	97±6	107±5	99±6
Latency to N2	13±2	12±2	16±3
Latency to N3	26±3	24±2	26±4
Latency to REM	94±11	79±8	74±6
Total Sleep	481±4	482±6	479±5

Mean time (± SE; min.) spent in different stages of sleep, and their corresponding latencies, across the 3 experimental nights.

Ellenbogen, J. M. et al., Wind Turbine Health Impact Study:
Report of Independent Expert Panel (2012)

February 22, 2023

Wind Turbine Health Impact Study:

Report of Independent Expert Panel

January 2012

Prepared for:

Massachusetts Department of Environmental Protection

Massachusetts Department of Public Health

Expert Independent Panel Members:

Jeffrey M. Ellenbogen, MD; MMSc
Assistant Professor of Neurology, Harvard Medical School
Division Chief, Sleep Medicine, Massachusetts General Hospital

Sheryl Grace, PhD; MS Aerospace & Mechanical Engineering
Associate Professor of Mechanical Engineering, Boston University

Wendy J Heiger-Bernays, PhD
Associate Professor of Environmental Health, Department of Environmental Health,
Boston University School of Public Health
Chair, Lexington Board of Health

James F. Manwell, PhD Mechanical Engineering;
MS Electrical & Computer Engineering; BA Biophysics
Professor and Director of the Wind Energy Center, Department of Mechanical & Industrial
Engineering University of Massachusetts, Amherst

Dora Anne Mills, MD, MPH, FAAP
State Health Officer, Maine 1996–2011
Vice President for Clinical Affairs, University of New England

Kimberly A. Sullivan, PhD
Research Assistant Professor of Environmental Health, Department of Environmental Health,
Boston University School of Public Health

Marc G. Weisskopf, ScD Epidemiology; PhD Neuroscience
Associate Professor of Environmental Health and Epidemiology
Department of Environmental Health & Epidemiology, Harvard School of Public Health

Facilitative Support provided by Susan L. Santos, PhD, FOCUS GROUP Risk
Communication and Environmental Management Consultants

The Panel Charge

The Expert Panel was given the following charge by the Massachusetts Department of Environmental Protection (MassDEP) and Massachusetts Department of Public Health (MDPH):

1. Identify and characterize attributes of concern (e.g., noise, infrasound, vibration, and light flicker) and identify any scientifically documented or potential connection between health impacts associated with wind energy turbines located on land or coastal tidelands that can impact land-based human receptors.
2. Evaluate and discuss information from peer-reviewed scientific studies, other reports, popular media, and public comments received by the MassDEP and/or in response to the *Environmental Monitor Notice* and/or by the MDPH on the nature and type of health complaints commonly reported by individuals who reside near existing wind farms.
3. Assess the magnitude and frequency of any potential impacts and risks to human health associated with the design and operation of wind energy turbines based on existing data.
4. For the attributes of concern, identify documented best practices that could reduce potential human health impacts. Include examples of such best practices (design, operation, maintenance, and management from published articles). The best practices could be used to inform public policy decisions by state, local, or regional governments concerning the siting of turbines.
5. Issue a report within 3 months of the evaluation, summarizing its findings.

To meet its charge, the Panel conducted a literature review and met as a group a total of three times. In addition, calls were also held with Panel members to further clarify points of discussion.

Executive Summary

The Massachusetts Department of Environmental Protection (MassDEP) in collaboration with the Massachusetts Department of Public Health (MDPH) convened a panel of independent experts to identify any documented or potential health impacts of risks that may be associated with exposure to wind turbines, and, specifically, to facilitate discussion of wind turbines and public health based on scientific findings.

While the Commonwealth of Massachusetts has goals for increasing the use of wind energy from the current 40 MW to 2000 MW by the year 2020, MassDEP recognizes there are questions and concerns arising from harnessing wind energy. The scope of the Panel's effort was focused on health impacts of wind turbines *per se*. The panel was *not* charged with considering any possible benefits of avoiding adverse effects of other energy sources such as coal, oil, and natural gas as a result of switching to energy from wind turbines.

Currently, "regulation" of wind turbines is done at the local level through local boards of health and zoning boards. Some members of the public have raised concerns that wind turbines may have health impacts related to noise, infrasound, vibrations, or shadow flickering generated by the turbines. The goal of the Panel's evaluation and report is to provide a review of the science that explores these concerns and provides useful information to MassDEP and MDPH and to local agencies that are often asked to respond to such concerns. The Panel consists of seven individuals with backgrounds in public health, epidemiology, toxicology, neurology and sleep medicine, neuroscience, and mechanical engineering. All of the Panel members are considered independent experts from academic institutions.

In conducting their evaluation, the Panel conducted an extensive literature review of the scientific literature as well as other reports, popular media, and the public comments received by the MassDEP.

ES 1. Panel Charge

1. Identify and characterize attributes of concern (e.g., noise, infrasound, vibration, and light flicker) and identify any scientifically documented or potential connection between health impacts associated with wind turbines located on land or coastal tidelands that can impact land-based human receptors.
2. Evaluate and discuss information from peer reviewed scientific studies, other reports, popular media, and public comments received by the MassDEP and/or in response to the *Environmental Monitor Notice* and/or by the MDPH on the nature and type of health complaints commonly reported by individuals who reside near existing wind farms.
3. Assess the magnitude and frequency of any potential impacts and risks to human health associated with the design and operation of wind energy turbines based on existing data.
4. For the attributes of concern, identify documented best practices that could reduce potential human health impacts. Include examples of such best practices (design, operation, maintenance, and management from published articles). The best practices could be used to inform public policy decisions by state, local, or regional governments concerning the siting of turbines.
5. Issue a report within 3 months of the evaluation, summarizing its findings.

ES 2. Process

To meet its charge, the Panel conducted an extensive literature review and met as a group a total of three times. In addition, calls were also held with Panel members to further clarify points of discussion. An independent facilitator supported the Panel's deliberations. Each Panel member provided written text based on the literature reviews and analyses. Draft versions of the report were reviewed by each Panel member and the Panel reached consensus for the final text and its findings.

ES 3. Report Introduction and Description

Many countries have turned to wind power as a clean energy source because it relies on the wind, which is indefinitely renewable; it is generated "locally," thereby providing a measure of energy independence; and it produces no carbon dioxide emissions when operating. There is interest in pursuing wind energy both on-land and offshore. For this report, however, the focus is on land-based installations and all comments are focused on this technology. Land-based wind turbines currently range from 100 kW to 3 MW (3000 kW). In Massachusetts, the largest turbine is currently 1.8 MW.

The development of modern wind turbines has been an evolutionary design process, applying optimization at many levels. An overview of the characteristics of wind turbines, noise, and vibration is presented in Chapter 2 of the report. Acoustic and seismic measurements of noise and vibration from wind turbines provide a context for comparing measurements from epidemiological studies and for claims purported to be due to emissions from wind turbines. Appendices provide detailed descriptions and equations that allow a more in-depth understanding of wind energy, the structure of the turbines, wind turbine aerodynamics, installation, energy production, shadow flicker, ice throws, wind turbine noise, noise propagation, infrasound, and stall vs. pitch controlled turbines.

Extensive literature searches and reviews were conducted to identify studies that specifically evaluate human population responses to turbines, as well as population and individual responses to the three primary characteristics or attributes of wind turbine operation: noise, vibration, and flicker. An emphasis of the Panel's efforts was to examine the biological plausibility or basis for health effects of turbines (noise, vibration, and flicker). Beyond traditional forms of scientific publications, the Panel also took great care to review other non-peer reviewed materials regarding the potential for health effects including information related to "Wind Turbine Syndrome" and provides a rigorous analysis as to whether there is scientific basis for it. Since the most commonly reported complaint by people living near turbines is sleep disruption, the Panel provides a robust review of the relationship between noise, vibration, and annoyance as well as sleep disturbance from noises and the potential impacts of the resulting sleep deprivation.

In assessing the state of the evidence for health effects of wind turbines, the Panel followed accepted scientific principles and relied on several different types of studies. It considered human studies of the most important or primary value. These were either human epidemiological studies specifically relating to exposure to wind turbines or, where specific exposures resulting from wind turbines could be defined, the panel also considered human experimental data. Animal studies are critical to exploring biological plausibility and understanding potential biological mechanisms of different exposures, and for providing information about possible health effects when experimental research in humans is not ethically or practically possible. As such, this literature was also reviewed with respect to wind turbine exposures. The non-peer reviewed material was considered part of the weight of evidence. In all cases, data quality was considered; at times, some studies were rejected because of lack of rigor or the interpretations were inconsistent with the scientific evidence.

ES 4. Findings

The findings in Chapter 4 are repeated here.

Based on the detailed review of the scientific literature and other available reports and consideration of the strength of scientific evidence, the Panel presents findings relative to three factors associated with the operation of wind turbines: noise and vibration, shadow flicker, and ice throw. The findings that follow address specifics in each of these three areas.

ES 4.1 Noise

ES 4.1.a Production of Noise and Vibration by Wind Turbines

1. Wind turbines can produce unwanted sound (referred to as noise) during operation. The nature of the sound depends on the design of the wind turbine. Propagation of the sound is primarily a function of distance, but it can also be affected by the placement of the turbine, surrounding terrain, and atmospheric conditions.
    a. Upwind and downwind turbines have different sound characteristics, primarily due to the interaction of the blades with the zone of reduced wind speed behind the tower in the case of downwind turbines.
    b. Stall regulated and pitch controlled turbines exhibit differences in their dependence of noise generation on the wind speed
    c. Propagation of sound is affected by refraction of sound due to temperature gradients, reflection from hillsides, and atmospheric absorption. Propagation effects have been shown to lead to different experiences of noise by neighbors.
    d. The audible, amplitude-modulated noise from wind turbines ("whooshing") is perceived to increase in intensity at night (and sometimes becomes more of a "thumping") due to multiple effects: i) a stable atmosphere will have larger wind gradients, ii) a stable atmosphere may refract the sound downwards instead of upwards, iii) the ambient noise near the ground is lower both because of the stable atmosphere and because human generated noise is often lower at night.

2. The sound power level of a typical modern utility scale wind turbine is on the order of 103 dB(A), but can be somewhat higher or lower depending on the details of the design and the rated power of the turbine. The perceived sound decreases rapidly with the distance from the wind turbines. Typically, at distances larger than 400 m, sound pressure levels for modern wind turbines are less than 40 dB(A), which is below the level associated with annoyance in the epidemiological studies reviewed.
3. Infrasound refers to vibrations with frequencies below 20 Hz. Infrasound at amplitudes over 100–110 dB can be heard and felt. Research has shown that vibrations below these amplitudes are not felt. The highest infrasound levels that have been measured near turbines and reported in the literature near turbines are under 90 dB at 5 Hz and lower at higher frequencies for locations as close as 100 m.
4. Infrasound from wind turbines is not related to nor does it cause a "continuous whooshing."
5. Pressure waves at any frequency (audible or infrasonic) can cause vibration in another structure or substance. In order for vibration to occur, the amplitude (height) of the wave has to be high enough, and only structures or substances that have the ability to receive the wave (resonant frequency) will vibrate.

ES 4.1.b Health Impacts of Noise and Vibration

1. Most epidemiologic literature on human response to wind turbines relates to self-reported "annoyance," and this response appears to be a function of some combination of the sound itself, the sight of the turbine, and attitude towards the wind turbine project.
   a. There is limited epidemiologic evidence suggesting an association between exposure to wind turbines and annoyance.
   b. There is insufficient epidemiologic evidence to determine whether there is an association between noise from wind turbines and annoyance independent from the effects of seeing a wind turbine and vice versa.

2. There is limited evidence from epidemiologic studies suggesting an association between noise from wind turbines and sleep disruption. In other words, it is possible that noise from some wind turbines can cause sleep disruption.
3. A very loud wind turbine could cause disrupted sleep, particularly in vulnerable populations, at a certain distance, while a very quiet wind turbine would not likely disrupt even the lightest of sleepers at that same distance. But there is not enough evidence to provide particular sound-pressure thresholds at which wind turbines cause sleep disruption. Further study would provide these levels.
4. Whether annoyance from wind turbines leads to sleep issues or stress has not been sufficiently quantified. While not based on evidence of wind turbines, there is evidence that sleep disruption can adversely affect mood, cognitive functioning, and overall sense of health and well-being.
5. There is insufficient evidence that the noise from wind turbines is *directly (i.e., independent from an effect on annoyance or sleep)* causing health problems or disease.
6. Claims that infrasound from wind turbines directly impacts the vestibular system have not been demonstrated scientifically. Available evidence shows that the infrasound levels near wind turbines cannot impact the vestibular system.
   a. The measured levels of infrasound produced by modern upwind wind turbines at distances as close as 68 m are well below that required for non-auditory perception (feeling of vibration in parts of the body, pressure in the chest, etc.).
   b. If infrasound couples into structures, then people inside the structure could feel a vibration. Such structural vibrations have been shown in other applications to lead to feelings of uneasiness and general annoyance. The measurements have shown no evidence of such coupling from modern upwind turbines.
   c. Seismic (ground-carried) measurements recorded near wind turbines and wind turbine farms are unlikely to couple into structures.
   d. A possible coupling mechanism between infrasound and the vestibular system (via the Outer Hair Cells (OHC) in the inner ear) has been proposed but is not yet fully understood or sufficiently explained. Levels of infrasound near wind turbines have been shown to be high enough to be sensed by the OHC. However, evidence does not

exist to demonstrate the influence of wind turbine-generated infrasound on vestibular-mediated effects in the brain.

e. Limited evidence from rodent (rat) laboratory studies identifies short-lived biochemical alterations in cardiac and brain cells in response to short exposures to emissions at 16 Hz and 130 dB. These levels exceed measured infrasound levels from modern turbines by over 35 dB.

7. There is no evidence for a set of health effects, from exposure to wind turbines that could be characterized as a "Wind Turbine Syndrome."
8. The strongest epidemiological study suggests that there is not an association between noise from wind turbines and measures of psychological distress or mental health problems. There were two smaller, weaker, studies: one did note an association, one did not. Therefore, we conclude the weight of the evidence suggests no association between noise from wind turbines and measures of psychological distress or mental health problems.
9. None of the limited epidemiological evidence reviewed suggests an association between noise from wind turbines and pain and stiffness, diabetes, high blood pressure, tinnitus, hearing impairment, cardiovascular disease, and headache/migraine.

ES 4.2 Shadow Flicker

ES 4.2.a Production of Shadow Flicker

Shadow flicker results from the passage of the blades of a rotating wind turbine between the sun and the observer.

1. The occurrence of shadow flicker depends on the location of the observer relative to the turbine and the time of day and year.
2. Frequencies of shadow flicker elicited from turbines is proportional to the rotational speed of the rotor times the number of blades and is generally between 0.5 and 1.1 Hz for typical larger turbines.
3. Shadow flicker is only present at distances of less than 1400 m from the turbine.

ES 4.2.b Health Impacts of Shadow Flicker

1. Scientific evidence suggests that shadow flicker does not pose a risk for eliciting seizures as a result of photic stimulation.

2. There is limited scientific evidence of an association between annoyance from prolonged shadow flicker (exceeding 30 minutes per day) and potential transitory cognitive and physical health effects.

ES 4.3 Ice Throw

ES 4.3.a Production of Ice Throw

Ice can fall or be thrown from a wind turbine during or after an event when ice forms or accumulates on the blades.

1. The distance that a piece of ice may travel from the turbine is a function of the wind speed, the operating conditions, and the shape of the ice.
2. In most cases, ice falls within a distance from the turbine equal to the tower height, and in any case, very seldom does the distance exceed twice the total height of the turbine (tower height plus blade length).

ES 4.3.b Health Impacts of Ice Throw

1. There is sufficient evidence that falling ice is physically harmful and measures should be taken to ensure that the public is not likely to encounter such ice.

ES 4.4 Other Considerations

In addition to the specific findings stated above for noise and vibration, shadow flicker and ice throw, the Panel concludes the following:

1. Effective public participation in and direct benefits from wind energy projects (such as receiving electricity from the neighboring wind turbines) have been shown to result in less annoyance in general and better public acceptance overall.

ES 5. Best Practices Regarding Human Health Effects of Wind Turbines

The best practices presented in Chapter 5 are repeated here.

Broadly speaking, the term “best practice” refers to policies, guidelines, or recommendations that have been developed for a specific situation. Implicit in the term is that the practice is based on the best information available at the time of its institution. A best practice may be refined as more information and studies become available. The panel recognizes that in countries which are dependent on wind energy and are protective of public health, best practices have been developed and adopted.

In some cases, the weight of evidence for a specific practice is stronger than it is in other cases. Accordingly, best practice* may be categorized in terms of the evidence available, as follows:

Descriptions of Three Best Practice Categories

Category	**Name**	**Description**
1	Research Validated Best Practice	A program, activity, or strategy that has the highest degree of proven effectiveness supported by objective and comprehensive research and evaluation.
2	Field Tested Best Practice	A program, activity, or strategy that has been shown to work effectively and produce successful outcomes and is supported to some degree by subjective and objective data sources.
3	Promising Practice	A program, activity, or strategy that has worked within one organization and shows promise during its early stages for becoming a best practice with long-term sustainable impact. A promising practice must have some objective basis for claiming effectiveness and must have the potential for replication among other organizations.

**These categories are based on those suggested in "Identifying and Promoting Promising Practices." Federal Register, Vol. 68. No 131. 131. July 2003.*
www.acf.hhs.gov/programs/ccf/about_ccf/gbk_pdf/pp_gbk.pdf

ES 5.1 Noise

Evidence regarding wind turbine noise and human health is limited. There is limited evidence of an association between wind turbine noise and both annoyance and sleep disruption, depending on the sound pressure level at the location of concern. However, there are no research-based sound pressure levels that correspond to human responses to noise. A number of countries that have more experience with wind energy and are protective of public health have developed guidelines to minimize the possible adverse effects of noise. These guidelines consider time of day, land use, and ambient wind speed. The table below summarizes the guidelines of Germany (in the categories of industrial, commercial and villages) and Denmark (in the categories of sparsely populated and residential). The sound levels shown in the table are for nighttime and are assumed to be taken immediately outside of the residence or building of concern. In addition, the World Health Organization recommends a maximum nighttime sound pressure level of 40 dB(A) in residential areas. Recommended setbacks corresponding to these values may be calculated by software such as WindPro or similar software. Such calculations are normally to be done as part of feasibility studies. The Panel considers the guidelines shown below to be Promising Practices (Category 3) but to embody some aspects of Field Tested Best Practices (Category 2) as well.

Promising Practices for Nighttime Sound Pressure Levels by Land Use Type

Land Use	**Sound Pressure Level, dB(A) Nighttime Limits**
Industrial	70
Commercial	50
Villages, mixed usage	45
Sparsely populated areas, 8 m/s wind*	44
Sparsely populated areas, 6 m/s wind*	42
Residential areas, 8 m/s wind*	39
Residential areas, 6 m/s wind*	37

**measured at 10 m above ground, outside of residence or location of concern*

The time period over which these noise limits are measured or calculated also makes a difference. For instance, the often-cited World Health Organization recommended nighttime noise cap of 40 dB(A) is averaged over one year (and does not refer specifically to wind turbine noise). Denmark's noise limits in the table above are calculated over a 10-minute period. These limits are in line with the noise levels that the epidemiological studies connect with insignificant reports of annoyance.

The Panel recommends that noise limits such as those presented in the table above be included as part of a statewide policy regarding new wind turbine installations. In addition, suitable ranges and procedures for cases when the noise levels may be greater than those values should also be considered. The considerations should take into account trade-offs between environmental and health impacts of different energy sources, national and state goals for energy independence, potential extent of impacts, etc.

The Panel also recommends that those involved in a wind turbine purchase become familiar with the noise specifications for the turbine and factors that affect noise production and noise control. Stall and pitch regulated turbines have different noise characteristics, especially in high winds. For certain turbines, it is possible to decrease noise at night through suitable control measures (e.g., reducing the rotational speed of the rotor). If noise control measures are to be considered, the wind turbine manufacturer must be able to demonstrate that such control is possible.

The Panel recommends an ongoing program of monitoring and evaluating the sound produced by wind turbines that are installed in the Commonwealth. IEC 61400-11 provides the standard for making noise measurements of wind turbines (International Electrotechnical Commission, 2002). In general, more comprehensive assessment of wind turbine noise in populated areas is recommended. These assessments should be done with reference to the broader ongoing research in wind turbine noise production and its effects, which is taking place internationally. Such assessments would be useful for refining siting guidelines and for developing best practices of a higher category. Closer investigation near homes where outdoor measurements show A and C weighting differences of greater than 15 dB is recommended.

ES 5.2 Shadow Flicker

Based on the scientific evidence and field experience related to shadow flicker, Germany has adopted guidelines that specify the following:

1. Shadow flicker should be calculated based on the astronomical maximum values (i.e., not considering the effect of cloud cover, etc.).
2. Commercial software such as WindPro or similar software may be used for these calculations. Such calculations should be done as part of feasibility studies for new wind turbines.
3. Shadow flicker should not occur more than 30 minutes per day and not more than 30 hours per year at the point of concern (e.g., residences).
4. Shadow flicker can be kept to acceptable levels either by setback or by control of the wind turbine. In the latter case, the wind turbine manufacturer must be able to demonstrate that such control is possible.

The guidelines summarized above may be considered to be a Field Tested Best Practice (Category 2). Additional studies could be performed, specifically regarding the number of hours per year that shadow flicker should be allowed, that would allow them to be placed in Research Validated (Category 1) Best Practices.

ES 5.3 Ice Throw

Ice falling from a wind turbine could pose a danger to human health. It is also clear that the danger is limited to those times when icing occurs and is limited to relatively close proximity to the wind turbine. Accordingly, the following should be considered Category 1 Best Practices.

1. In areas where icing events are possible, warnings should be posted so that no one passes underneath a wind turbine during an icing event and until the ice has been shed.
2. Activities in the vicinity of a wind turbine should be restricted during and immediately after icing events in consideration of the following two limits (in meters).

For a turbine that may not have ice control measures, it may be assumed that ice could fall within the following limit:

$$x_{\max,\, throw} = 1.5\left(2R + H\right)$$

Where: R = rotor radius (m), H = hub height (m)

For ice falling from a stationary turbine, the following limit should be used:

$$x_{\max,\, fall} = U\left(R + H\right)/15$$

Where: U = maximum likely wind speed (m/s)

The choice of maximum likely wind speed should be the expected one-year return maximum, found in accordance to the International Electrotechnical Commission's design standard for wind turbines, IEC 61400-1.

Danger from falling ice may also be limited by ice control measures. If ice control measures are to be considered, the wind turbine manufacturer must be able to demonstrate that such control is possible.

ES 5.4 Public Participation/Annoyance

There is some evidence of an association between participation, economic or otherwise, in a wind turbine project and the annoyance (or lack thereof) that affected individuals may express. Accordingly, measures taken to directly involve residents who live in close proximity to a wind turbine project may also serve to reduce the level of annoyance. Such measures may be considered to be a Promising Practice (Category 3).

ES 5.5 Regulations/Incentives/Public Education

The evidence indicates that in those parts of the world where there are a significant number of wind turbines in relatively close proximity to where people live, there is a close coupling between the development of guidelines, provision of incentives, and educating the public. The Panel suggests that the public be engaged through such strategies as education, incentives for community-owned wind developments, compensations to those experiencing documented loss of property values, comprehensive setback guidelines, and public education related to renewable energy. These multi-faceted approaches may be considered to be a Promising Practice (Category 3).

Chapter 1

Introduction to the Study

The Massachusetts Department of Environmental Protection (MassDEP), in collaboration with the Massachusetts Department of Public Health (MDPH), convened a panel of independent experts to identify any documented or potential health impacts or risks that may be associated with exposure to wind turbines, and, specifically, to facilitate discussion of wind turbines and public health based on sound science. While the Commonwealth of Massachusetts has goals for increasing the use of wind energy from the current 40 MW to 2000 MW by the year 2020, MassDEP recognizes there are questions and concerns arising from harnessing wind energy. Although fossil fuel non-renewable sources have negative environmental and health impacts, it should be noted that the scope of the Panel's effort was focused on wind turbines and is not meant to be a comparative analysis of the relative merits of wind energy vs. nonrenewable fossil fuel sources such as coal, oil, and natural gas. Currently, "regulation" of wind turbines is done at the local level through local boards of health and zoning boards. Some members of the public have raised concerns that wind turbines may have health impacts related to noise, infrasound, vibrations, or shadow flickering generated by the turbines. The goal of the Panel's evaluation and report is to provide a review of the science that explores these concerns and provides useful information to MassDEP and MDPH and to local agencies who are often asked to respond to such concerns.

The overall context for this study is that the use of wind turbines results in positive effects on public health and environmental health. For example, wind turbines operating in Massachusetts produce electricity in the amount of approximately 2,100–2,900 MWh annually per rated MW, depending on the design of the turbine and the average wind speed at the installation site. Furthermore, the use of wind turbines for electricity production in the New England electrical grid will result in a significant decrease in the consumption of conventional fuels and a corresponding decrease in the production of CO_2 and oxides of nitrogen and sulfur (see Appendix A for details). Reductions in the production of these pollutants will have demonstrable and positive benefits on human and environmental health. However, local impacts of wind turbines, whether anticipated or demonstrated, have resulted in fewer turbines being installed than might otherwise have been expected. To the extent that these impacts can be ameliorated, it should be possible to take advantage of the indigenous wind energy resource more effectively.

The Panel consists of seven individuals with backgrounds in public health, epidemiology, toxicology, neurology and sleep medicine, neuroscience, and mechanical engineering. With the exception of two individuals (Drs. Manwell and Mills), Panel members did not have any direct experience with wind turbines. The Panel did an extensive literature review of the scientific literature (see bibliography) as well as other reports, popular media, and the public comments received by the MassDEP.

Chapter 2

Introduction to Wind Turbines

This chapter provides an introduction to wind turbines so as to provide a context for the discussion that follows. More information on wind turbines may be found in the appendices, particularly in Appendix A.

2.1 Wind Turbine Anatomy and Operation

Wind turbines utilize the wind, which originates from sunlight due to the differential heating of various parts of the earth. This differential heating produces zones of high and low pressure, resulting in air movement. The motion of the air is also affected by the earth's rotation. Many countries have turned to wind power as a clean energy source because it relies on the wind, which is indefinitely renewable; it is generated "locally," thereby providing a measure of energy independence; and it produces no carbon dioxide emissions when operating. There is interest in pursuing wind energy both on-land and offshore. For this report, however, the focus is on land-based installations, and all comments will focus on this technology.

The development of modern wind turbines has been an evolutionary design process, applying optimization at many levels. This section gives a brief overview of the characteristics of wind turbines with some mention of the optimization parameters of interest. Appendix A provides a detailed explanation of wind energy.

The main features of modern wind turbines one notices are the very tall towers, which are no longer a lattice structure but a single cylindrical-like structure and the three upwind, very long, highly contoured turbine blades. The tower design has evolved partly because of biological impact factors as well as for other practical reasons. The early lattice towers were attractive nesting sites for birds. This led to an unnecessary impact of wind turbines on bird populations. The lattice structures also had to be climbed externally by turbine technicians. The tubular towers, which are now more common, are climbed internally. This reduces the health risks for maintenance crews.

The power in the wind available to a wind turbine is related to the cube of the wind speed and the square of the radius of the rotor. Not all the available power in the wind can be captured by a wind turbine, however. Betz (van Kuik, 2007) showed that the maximum power that can be extracted is 16/27 times the available power (see Appendix A). In an attempt to extract the maximum power from the wind, modern turbines have very large rotors and the towers are quite high. In this way the dependence on the radius is "optimized," and the dependence on the wind speed is "optimized." The wind speed is higher away from the ground due to boundary layer effects, and as such, the towers are made higher in order to capture the higher speed winds (more information about the wind profiles and variability is found in Appendix A). It is noted here that the rotor radius may increase again in the future, but currently the largest rotors used on land are around 100 m in diameter. This upper limit is currently a function of the radius of curvature of the roads on which the trucks that deliver the turbine blades must drive to the installation sites. Clearance under bridges is also a factor.

The efficiency with which the wind's power is captured by a particular wind turbine (i.e., how close it comes to the Betz limit) is a function of the blade design, the gearbox, the electrical generator, and the control system. The aerodynamic forces on the rotor blade play a major role. The best design maximizes lift and minimizes drag at every blade section from hub to tip. The twisted and tapered shapes of modern blades attempt to meet this optimal condition. Other factors also must be taken into consideration such as structural strength, ease of manufacturing and transport, type of materials, cost, etc.

Beyond these visual features, the number of blades and speed of the tips play a role in the optimization of the performance through what is called solidity. When setting tip speeds based on number of blades, however, trade-offs exist because of the influence of these parameters on weight, cost, and noise. For instance, higher tip speeds often results in more noise.

The dominance of the 3-bladed upwind systems is both historic and evolutionary. The European manufacturers moved to 3-bladed systems and installed numerous turbines, both in Europe and abroad. Upwind systems are preferable to downwind systems for on-land installations because they are quieter. The downwind configuration has certain useful features but it suffers from the interaction noise created when the blades pass through the wake that forms behind the tower.

The conversion of the kinetic energy of the wind into electrical energy is handled by the rotor nacelle assembly (RNA), which consists of the rotor, the drive train, and various ancillary components. The rotor grouping includes the blades, the hub, and the pitch control components. The drive train includes the shafts, bearings, gearbox (not necessary for direct drive generators), couplings, mechanical brake, and generator. A schematic of the RNA, together with more detail concerning the operation of the various parts, is in Appendix A.

The rotors are controlled so as to generate electricity most effectively and as such must withstand continuously fluctuating forces during normal operation and extreme loads during storms. Accordingly, in general a wind turbine rotor does not operate at its own maximum power coefficient at all wind speeds. Because of this, the power output of a wind turbine is generally described by a relationship, known as a power curve. A typical power curve is shown in the appendix. Below the cut-in speed no power is produced. Between cut-in and rated wind speed the power increases significantly with wind speed. Above the rated speed, the power produced is constant, regardless of the wind speed, and above the cut-out speed the turbine is shut down often with use of the mechanical brake.

Two main types of rotor control systems exist: pitch and stall. Stall controlled turbines have fixed blades and operate at a fixed speed. The aerodynamic design of the blades is such that the power is self-limiting, as long as the generator is connected to the electrical grid. Pitch regulated turbines have blades that can be rotated about their long axis. Such an arrangement allows more precise control. Pitch controlled turbines are also generally quieter than stall controlled turbines, especially at higher wind speeds. Until recently, many turbines used stall control. At present, most large turbines use pitch control. Appendices A and F provide more details on pitch and stall.

The energy production of a wind turbine is usually considered annually. Estimates are usually obtained by calculating the expected energy that will be produced every hour of a representative year (by considering the turbine's power curve and the estimated wind resource) and then summing the energy from all the hours. Sometimes a normalized term known as the capacity factor (CF) is used to characterize the performance. This is the actual energy produced (or estimated to be produced) divided by the amount of energy that would be produced if the turbine were running at its rated output for the entire year. Appendix A gives more detail on these computations.

2.2 Noise from Turbines

Because of the concerns about the noise generated from wind turbines, a short summary of the sources of noise is provided here. A thorough description of the various noise sources from a wind turbine is given in the text by Wagner et al. (1996).

A turbine produces noise mechanically and aerodynamically. Mechanical noise sources include the gearbox, generator, yaw drives, cooling fans, and auxiliary equipment such as hydraulics. Because the emitted sound is associated with the rotation of mechanical and electrical equipment, it is often tonal. For instance, it was found that noise associated with a 1500 kW turbine with a generator running at speeds between 1100 and 1800 rpm contained a tone between 20 and 30 Hz (Betke et al., 2004). The yaw system on the other hand might produce more of a grinding type of noise but only when the yaw mechanism is engaged. The transmission of mechanical noise can be either airborne or structure-borne as the associated vibrations can be transmitted into the hub and tower and then radiated into the surrounding space.

Advances in gearboxes and yaw systems have decreased these noise sources over the years. Direct drive systems will improve this even more. In addition, utility scale wind turbines are usually insulated to prevent mechanical noise from proliferating outside the nacelle or tower (Alberts, 2006)

Aerodynamic sound is generated due to complex fluid-structure interactions occurring on the blades. Wagner et al. (1996) break down the sources of aerodynamic sound as follows in Table 1.

Table 1

Sources of Aerodynamic Sound from a Wind Turbine (Wagner et al., 1996*)*.

Noise Type	**Mechanism**	**Characteristic**
Trailing-edge noise	Interaction of boundary layer turbulence with blade trailing edge	Broadband, main source of high frequency noise (770 Hz < f < 2 kHz)
Tip noise	Interaction of tip turbulence with blade tip surface	Broadband
Stall, separation noise	Interaction of turbulence with blade surface	Broadband
Laminar boundary layer noise	Non-linear boundary layer instabilities interacting with the blade surface	Tonal
Blunt trailing edge noise	Vortex shedding at blunt trailing edge	Tonal
Noise from flow over holes, slits, and intrusions	Unsteady shear flows over holes and slits, vortex shedding from intrusions	Tonal
Inflow turbulence noise	Interaction of blade with atmospheric turbulence	Broadband
Steady thickness noise, steady loading noise	Rotation of blades or rotation of lifting surface	Low frequency related to blade passing frequency (outside of audible range)
Unsteady loading noise	Passage of blades through varying velocities, due to pitch change or blade altitude change as it rotates* For downwind turbines passage through tower shadow	Whooshing or beating, amplitude modulation of audible broadband noise. For downwind turbines, impulsive noise at blade passing frequency

**van den Berg 2004.*

Of these mechanisms, the most persistent and often strongest source of aerodynamic sound from modern wind turbines is the trailing edge noise. It is also the amplitude modulation of this noise source due to the presence of atmospheric effects and directional propagation effects that result in the whooshing or beating sound often reported (van den Berg, 2004). As a turbine blade rotates through a changing wind stream, the aerodynamics change, leading to differences in the boundary layer and thus to differences in the trailing edge noise (Oerlemans, 2009). Also, the direction in which the blade is pointing changes as it rotates, leading to differences in the directivity of the noise from the trailing edge. This noise source leads to what some people call the “whooshing” sound.

Most modern turbines use pitch control for a variety of reasons. One of the reasons is that at higher wind speeds, when the control system has the greatest impact, the pitch controlled turbine is quieter than a comparable stall regulated turbine would be. Appendix E shows the difference in the noise from two such systems.

When discussing noise from turbines, it is important to also consider propagation effects and multiple turbine effects. One propagation effect of interest is due to the dependence of the speed of sound on temperature. When there is a large temperature gradient (which may occur during the day due to surface warming or due to topography such as hills and valleys) the path a sound wave travels will be refracted. Normally this means that during a typical day sound is “turned” away from the earth’s surface. However, at night the sound propagates at a constant height or even be “turned” down toward the earth’s surface, making it more noticeable than it otherwise might be.

The absorption of sound by vegetation and reflection of sound from hillsides are other propagation effects of interest. Several of these effects were shown to be influencing the sound field near a few homes in North Carolina that were impacted by a wind turbine installation (Kelley et al., 1985). A downwind 2-bladed, 2 MW turbine was installed on a mountaintop in North Carolina. It created high amplitude impulsive noise due to the interaction of the blades and the tower wakes. Some homes (10 in 1000) were adversely affected by this high amplitude impulsive noise. It is shown in the report by Kelley et al. (1985) that echoes and focusing due to refraction occurred at the location of the affected homes.

In flat terrain, noise in the audible range will propagate along a flat terrain in a manner such that its amplitude will decay exactly as distance from the source (1/distance). Appendix E provides formulae for approximating the overall sound level at a given distance from a source. In the inaudible range, it has been noted that often the sound behaves as if the propagation was governed by a $1/(\text{distance})^{1/2}$ (Shepherd & Hubbard, 1991).

When one considers the noise from a wind farm in which multiple turbines are located close to each other, an estimate for the overall noise from the farm can be obtained. Appendix E describes the method for obtaining the estimate. All these estimates rely on information regarding the sound power generated by the turbine at the hub height. The power level for several modern turbines is given in Appendix D.

2.2.a Measurement and Reporting of Noise

Turbines produce multiple types of sound as indicated previously, and the sound is characterized in several ways: tonal or broadband, constant amplitude or amplitude modulated, and audible or infrasonic. The first two characterization pairs have been mentioned previously. Audible refers to sound with frequencies from 20 Hz to 20 kHz. The waves in the infrasonic range, less than 20 Hz, may actually be audible if the amplitude of the sound is high enough. Appendix D provides a brief primer on acoustics and the hearing threshold associated with the entire frequency spectrum.

Sound is simply pressure fluctuations and as such, this is what a microphone measures. However, the amplitude of the fluctuations is reported not in units of pressure (such as Pascals) but on a decibel scale. The sound pressure level (SPL) is defined by

$$SPL = 10 \log_{10} [p^2/p^2_{ref}] = 20 \log_{10}(p/p_{ref})$$

the resulting number having the units of decibels (dB). The reference pressure p_{ref} for airborne sound is 20×10^{-6} Pa (i.e., 20 μPa or 20 micro Pascals). Some implications of the decibel scale are noted in Appendix D.

When sound is broadband (contains multiple frequencies), it is useful to use averages that measure approximately the amplitude of the sound and its frequency content. Standard averaging methods such as octave and 1/3-octave band are described in Appendix D. In essence, the entire frequency range is broken into chunks, and the amplitude of the sound at frequencies in each chunk is averaged. An overall sound pressure value can be obtained by averaging all of the bands.

When presenting the sound pressure it is common to also use a filter or weighting. The A-weighting is commonly used in wind turbine measurements. This filter takes into account the threshold of human hearing and gives the same decibel reading at different frequencies that would equate to equal loudness. This means that at low frequencies (where amplitudes have to be incredibly high for the sound to be heard by people) a large negative weight would be applied. C-weighting only filters the levels at frequencies below about 30 Hz and above 4 kHz and filters them only slightly between 0 and 30 Hz. The weight values for both the A and C weightings filters are shown in Appendix D, and an example with actual wind turbine data is presented.

There are many other weighting methods. For instance, the day-night level filter penalizes nighttime noise between the hours of 10 p.m. and 7 a.m. by adding an additional 10 dB to sound produced during these hours.

When analyzing wind turbine and other anthropogenic sound there is a question as to what averaging period should be used. The World Health Organization uses a yearly average. Others argue though that especially for wind turbines, which respond to seasonal variations as well as diurnal variations, much shorter averages should be considered.

2.2.b Infrasound and Low-frequency Noise (IFLN)

The term *infrasound* refers to pressure waves with frequencies less than 20 Hz. In the infrasonic range, the amplitude of the sound must be very high for it to be audible to humans. For instance, the hearing threshold below 20 Hz requires that the amplitude be above 80 dB for it to be heard and at 5 Hz it has to be above 103 dB (O’Neal, 2011; Watanabe & Moeller, 1990). This gives little room between the audible and the pain values for the infrasound range: 165 dB at 2 Hz and 145 dB at 20 Hz cause pain (Leventhal, 2006).

The *low frequency* range is usually characterized as 20–200 Hz (Leventhal, 2006; O’Neal, 2011). This is within the audible range but again the threshold of hearing indicates that fairly high amplitude is required in this frequency range as well. The A-weighting of sound is based upon the threshold of human hearing such that it reports the measured values adjusted by -50 dB at 20 Hz, -10 dB at 200 Hz, and + 1 dB at 1000 Hz. The A-weighting curve is shown in Appendix D.

It is known that low frequency waves propagate with less attenuation than high-frequency waves. Measurements have shown that the amplitude for the airborne infrasonic waves can be cylindrical in nature, decaying at a rate inversely proportional to the square root of the distance from the source. Normally the decay of the amplitude of an acoustic wave is inversely proportional to the distance (Shepherd & Hubbard, 1991).

It is difficult to find reliable and comparable infrasound and low frequency noise (ILFN) measurement data in the peer-reviewed literature. Table 2 provides some examples of such measurements from wind turbines. For each case, the reliability of the infrasonic data is not known (the infrasonic measurement technique is not described in each report), although it is assumed that the low frequency noise was captured accurately. The method for obtaining the sound pressure level is not described for each reported data set, and some may come from averages over many day/time/wind conditions while others may be just from a single day's measurement campaign.

Table 2
Literature-based Measurements of Wind Turbines; dB alone refers to unweighted values

Turbine Rating (kW)	Distance (m)	Frequency	Sound Pressure Level	Reference
500	200	5 20	55 dB(G)[2] 35 dB(G)[2]	Jakobsen, 2005[3]
3200	68	4 20	72 dB(G)[2] 50 dB(G)[2]	Jakobsen, 2005[3]
1500	65	5 20 100	>70 dB(A) 60 dB(A) 35 dB(A)	Leventhal, 2006
2000 (2)	100	5 20 200	95 dB 65 dB 55 dB	van den Berg, 2004[3]
1500	98	1 10 20 100 200	90 dB 70 dB 68 dB 68 dB 60 dB	Jung, 2008[3]
-	450	10 100 200	75 dB 55 dB 40 dB	Palmer, 2010
2300	305	5 20 100	73 dB(A) 55 dB(A) - 95 50 dB(A) - 70	O'Neal, 2011[3]

[1]dB alone refers to un-weighted values.
[2]G weighting reflects human response to infrasound. The curve is defined to have a gain of zero dB at 10 Hz. Between 1 Hz and 20 Hz the slope is approximately 12 dB per octave. The cut-off below 1 Hz has a slope of 24 dB per octave, and above 20 Hz the slope is -24 dB per octave. Humans can hear 95 dB(G).
[3]Indicates peer-reviewed article.

When these recorded levels are taken at face value, one might conclude that the infrasonic regime levels are well below the audible threshold. In contrast, the low frequency regime becomes audible around 30 Hz. Such data have led many researchers to conclude that the infrasound and low frequency noise from wind turbines is not an issue (Leventhal, 2009; O'Neal, 2011; Bowdler, 2009). Others who have sought explanations for complaints from those living near wind turbines have pointed to ILFN as a problem (Pierpont, 2009; Branco & Alves-

Pereira, 2004). Some have declared the low frequency range to be of greatest concern (Kamperman et al., 2008; Jung, 2008).

It is important to make the clear distinction between amplitude-modulated noise from wind turbines and the ILFN from turbines. Amplitude modulation in wind turbines noise has been discussed at length by Oerlemans (2009) and van den Berg (2004). Amplitude modulation is what causes the whooshing sound referred to as swish-swish by van den Berg (that sometimes becomes a thumping sound). The whooshing noise created by modern wind turbines occurs because of variations in the trailing edge noise produced by a rotor blade as it sweeps through its path and the directionality of the noise because of the perceived pitch of the blade at different locations along its 360° rotation. The sound is produced in the audible range, and it is modulated so that it is quiet and then loud and then quiet again at a rate related to the blade passing frequency (rate blades pass the tower) which is often around 1 Hz. Van den Berg (2004) noted that the level of amplitude modulation is often greater at night because the difference between the wind speed at the top and bottom of the rotor disc can be much larger at night when there is a stable atmosphere than during the day when the wind profile is less severe. It is further argued that in a stable atmosphere there is little wind near the ground so wind noise does not mask the turbine noise for a listener near the ground. Finally, atmospheric effects can change the propagation of the sound refracting the noise towards the ground rather than away from the ground. The whooshing that is heard is NOT infrasound and much of its content is not at low frequency. Most of the sound is at higher frequency and as such it will be subject to higher atmospheric attenuation than the low frequency sound. An anecdotal finding that the whooshing sound carries farther when the atmosphere is stable does not imply that it is infrasound or heavy in low frequency content, it simply implies that the refraction of the sound is also different when the atmosphere is stable. It is important to note then that when a complaint is tied to the thumping or whooshing that is being heard, the complaint may not be about ILFN at all even if the complaint mentions low frequency noise. Kamperman et al. (2008) state that, "It is not clear to us whether the complaints about "low frequency" noise are about the audible low frequency part of the "swoosh-boom" sound, the once-per-second amplitude modulation … of the "swoosh-boom" sound, or some combination of the two."

Chapter 3

Health Effects

3.1 Introduction

Chapter 3 reviews the evidence for human health effects of wind turbines. Extensive literature searches and reviews were conducted to identify studies that specifically evaluate population responses to turbines, as well as population and individual responses to noise, vibration, and flicker. The biological plausibility or basis for health effects of turbines (noise, vibration, and flicker) was examined. Beyond traditional forms of scientific publications, the Panel also reviewed other non-peer reviewed materials including information related to "Wind Turbine Syndrome" and provides a rigorous analysis of its scientific basis. Since the most commonly reported complaint by people living near turbines is sleep disruption, the Panel provides a robust review of the relationship between noise, vibration, annoyance as well as sleep disturbance from noises and the potential impacts of the resulting sleep deprivation.

In assessing the state of the evidence for health effects of wind turbines, the Panel relied on several different types of studies. It considered human studies of primary value. These were either human epidemiological studies specifically relating to exposure to wind turbines or, where specific exposures resulting from wind turbines could be defined, the Panel also considered human experimental data. Animal studies are critical to exploring biological plausibility and understanding potential biological mechanisms of different exposures, and for providing information about possible health effects when experimental research in humans is not ethically or practically possible (National Research Council (NRC), 1991). As such, this literature was also reviewed with respect to wind turbine exposures. In all cases, data quality is considered. At times some studies were rejected because of lack of rigor or the interpretations were inconsistent with the scientific evidence. These are identified in the discussion below.

In the specific case of the possibility of ice being thrown from wind turbine blades, the Panel discusses the physics of such ice throw in order to provide the basis of the extent of the potential for injury from thrown ice (see Chapter 2).

3.2 Human Exposures to Wind Turbines

Epidemiologic study designs differ in their ability to provide evidence of an association (Ellwood, 1998). Typical study designs include randomized trials, cohort studies, and case-control studies and can include elements of prospective follow-up, retrospective assessments, or cross-sectional analysis where exposure and outcome data are essentially concurrent. Each of these designs has strengths and weaknesses and thus can provide varying levels of strength of evidence for causal associations between exposures and outcomes, which can also be affected by analytic choices. Thus, this literature needs to be examined in detail, regardless of study type, to determine strength of evidence for causality.

Review of this literature began with a PubMed search for "wind turbine" or "wind turbines" to identify peer-reviewed literature pertaining to health effects of wind turbines. Titles and abstracts of identified papers were then read to make a first pass determination of whether the paper was a study on health effects of exposure to wind turbines or might possibly contain relevant references to such studies. Because the peer-reviewed literature so identified was relatively limited, we also examined several non-peer reviewed papers, reports, and books that discussed health effects of wind turbines. All of this literature was examined for additional relevant references, but for the purposes of determining strength of evidence, we only considered such publications if they described studies of some sort in sufficient detail to assess the validity of the findings. This process identified four studies that generated peer-reviewed papers on health effects of wind turbines. A few other non-peer reviewed documents described data of sufficient relevance to merit consideration and are discussed below as well.

3.3 Epidemiological Studies of Exposure to Wind Turbines

The four studies that generated peer-reviewed papers on health effects of wind turbines included two from Sweden (E. Pedersen et al., 2007; E. Pedersen & Waye, 2004), one from the Netherlands (E. Pedersen et al., 2009), and one from New Zealand (Shepherd at al., 2011). The primary outcome assessed in the first three of these studies is annoyance. Annoyance *per se* is not a biological disease, but has been defined in different ways. For example, as "a feeling of resentment, displeasure, discomfort, dissatisfaction, or offence which occurs when noise interferes with someone's thoughts, feelings or daily activities" (Passchier-Vermeer, 1993); or "a mental state characterized by distress and aversion, which if maintained, can lead to a deterioration of health and well-being" (Shepherd et al., 2010). Annoyance is usually assessed with questionnaires, and this is the case for the three studies mentioned above. There is consistent evidence for annoyance in populations exposed for more than one year to sound levels of 37 dB(A), and severe annoyance at about 42 dB(A) (Concha-Barrientos et al., 2004). In each of those studies annoyance was assessed by questionnaire, and the respondent was asked to indicate annoyance to a number of items (including wind turbines) on a five-point scale (do not notice, notice but not annoyed, slightly annoyed, rather annoyed, very annoyed). While annoyance as such is certainly not to be dismissed, in assessing global burden of disease the World Health Organization (WHO) has taken the approach of excluding annoyance as an outcome because it is not a formally defined health outcome *per se* (Concha-Barrientos et al., 2004). Rather, to the extent annoyance may cause other health outcomes, those other outcomes could be considered directly. Nonetheless, because of a paucity of literature on the association between wind turbines and other health outcomes, we consider here the literature on wind turbines and annoyance.

3.3.a Swedish Studies

Both Swedish studies were cross sectional and involved mailed questionnaires to potential participants. For the first Swedish study, 627 households were identified in one of five areas of Sweden chosen to have enough dwellings at varying distances from wind turbines and of comparable geographical, cultural, and topographical structure (E. Pedersen & Waye, 2004). There were 16 wind turbines in the study area and of these, 14 had a power of 600–650 kW, and the other 2 turbines had 500 kW and 150 kW. The towers were between 47 and 50 m in height. Of the turbines, 13 were WindWorld machines, 2 were Enercon, and 1 was a Vestas turbine. Questionnaires were to be filled out by one person per household who was between the ages of 18 and 75. If there was more than one such person, the one whose birthday was closest to May 20th was chosen. It is not clear how the specific 627 households were chosen, and of the 627, only 513 potential participants were identified, although it is not clear why the other households did not have potential participants. Of the 513 potential participants, 351 (68.4%) responded.

The purpose of the questionnaire was masked by querying the participant about living conditions in general, some questions on which were related to wind turbines. However, a later section of the questionnaire focused more specifically on wind turbines, and so the degree to which the respondent was unaware about the focus on wind turbines is unclear. A-weighted sound levels were determined at each respondent's dwelling, and these levels were grouped into

6 categories (in dB(A): <30, 30–32.5, 32.5–35, 35–37.5, 37.5–40, and >40). Ninety-three percent of respondents could see a wind turbine from their dwelling.

The main results of this study were that there was a significant association between noise level and annoyance. This association was attenuated when adjusted for the respondent's attitude towards the visual impact of the turbines, which itself was a strong predictor of annoyance levels, but the association with noise still persisted. Further adjustment for noise sensitivity and attitude towards wind turbines in general did not change the results. The authors indicated that the reporting of sleep disturbances went up with higher noise categories, but did not report on the significance of this association. Nor did the authors report on associations with other health-related questions that were apparently on the questionnaire (such as headache, undue tiredness, pain and stiffness in the back, neck or shoulders, or feeling tensed/stressed, or irritable).

The 68% response rate in this study is reasonably good, but it is somewhat disconcerting that the response rate appeared to be higher in the two highest noise level categories (76% and 78% vs. 60–69%). It is not implausible that those who were annoyed by the turbines were more inclined to return the questionnaire. In the lowest two sound categories (<32.5 dB(A)) nobody reported being more than slightly annoyed, whereas in the highest two categories 28% (37.5–40 dB(A)) and 44% (>40 dB(A)) reported being more than slightly annoyed (unadjusted percentages). Assuming annoyance would drive returning the questionnaires, this would suggest that the percentages in the highest categories may be somewhat inflated. The limited description of the selection process in this study is a limitation as well, as is the cross sectional nature of the study. Cross-sectional studies lack the ability to determine the temporality of cause and effect; in the case of these kinds of studies, we cannot know whether the annoyance level was present before the wind turbines were operational from a cross sectional study design. Furthermore, despite efforts to blind the respondent to the emphasis on wind turbines, it is not clear to what degree this was successful.

The second Swedish study (E. Pedersen & Persson Waye, 2007) took a similar approach to the first, but in this study the selection procedures were explained in more detail and were clearly rigorous. Specific details on the wind turbines in the area were not provided, but it was noted that areas were sought with wind turbines that had a nominal power of more than 500 kW, although some of the areas also contained turbines with lower power. A later publication by these authors (Pedersen et al., 2009) indicates that the turbines in this study were up to 1.5 MW and up to 65 m high. In the areas chosen, either all households were recruited or a random sample was used. In this study 1,309 questionnaires were sent out and 754 (57.6%) were returned. The response rate by noise category level, however, was not reported. There was a clear association between noise level and hearing turbine noise, with the percentage of those hearing turbine noise steadily increasing across the noise level categories. However, despite a significant unadjusted association between noise levels and annoyance (dichotomized as more than slightly annoyed or not), and after adjusting for attitude towards wind turbines or visual aspects of the turbines (e.g., visual angle on the horizon, an indicator of how prominent the turbines are in the field of view), each of which was strongly associated with annoyance, the association with noise level category was lost. The model from which this conclusion was drawn, however, imposed a linear relation on the association between noise level category and annoyance. But in the crude percentages of people annoyed across noise level categories, it appeared that the relation might not be linear, but rather most prevalent in the highest noise. The percentage of those in the highest noise level category (>40 dB(A)) reporting annoyance (~15%) appeared to be higher than among people in the lower noise categories (<5%).

Given the more rigorous description of the selection process in this study, it has to be considered stronger than the first Swedish study. While 58% is pretty good for a questionnaire response rate, the non-response levels still leave room for bias. The authors do not report the response rate by noise level categories, but if the pattern is similar to the first Swedish study, it could suggest that the percentage annoyed in the highest noise category could be inflated. The cross sectional nature of the study is also a limitation and complicates interpretation of the effects on the noise-annoyance association of adjustment for the other factors. Regarding the loss of the association after adjustment for attitude, if one assumes that the noise levels caused a negative attitude towards wind turbines, then the loss of association between noise and annoyance after adjusting for attitude does not argue against annoyance being caused by increasing turbine noise, but rather that that is the path by which noise causes annoyance (louder noise→negative attitude→annoyance). If, on the other hand, the attitude towards turbines was not caused by the noise, then the results would suggest that noise levels did not cause the annoyance. Visual angle, however, clearly does not cause the noise level; thus, the lack of association between noise and annoyance in analyses adjusted for visual angle more strongly suggest that the turbine noise level is not causing the annoyance, but perhaps the visual intrusion instead. This is similar to the conclusion of an earlier Danish report (T. H. Pedersen & Nielsen, 1994). Either way, however, the data still suggest that there may be an association between turbine noise and annoyance when the noise levels are >40 dB(A).

A more intricate statistical model of the association between turbine noise levels and annoyance that used the data from both Swedish studies was reported separately (Pedersen & Larsman, 2008). The authors used structural equation models (SEMs) to simultaneously account for several aspects of visual attitude towards the turbines and general attitude towards the turbines. These analyses suggested a significant association between noise levels and annoyance even after considering other factors.

3.3.b Dutch Study

The Dutch study aimed to recruit households that reflected general wind turbine exposure conditions over a range of background sound levels. All areas within the Netherlands that were characterized by one of three clearly defined land-use types—built-up area, rural area with a main road, and rural area without a main road—and that had at least two wind turbines of at least 500 kW within 500 meters of each other were selected for the study. Sites dominated by industry or business were excluded. All addresses within these areas were obtained and classified into one of five wind turbine noise categories (<30, 30–35, 35–40, 40–45, and >45 dB(A)) based on characteristics of nearby wind turbines, measurements of sound from those turbines, and the International Standards Organization (ISO) standard model of wind turbine noise propagation. Individual households were randomly selected for recruitment within noise/land type categories, except for the highest noise level for which all households were selected because of the small number exposed at the wind turbine noise levels of the highest category.

As with the Swedish studies, the Dutch study was cross sectional and involved a mailed questionnaire modeled on the one used in the Swedish studies. Of 1,948 mailed surveys, 725 (37%) were returned. There was only minor variation in response rate by turbine noise category, although unlike the Swedish studies, the response rate was slightly lower in the higher noise categories. A random sample of 200 non-responders was sent an abbreviated questionnaire asking only two questions about annoyance from wind turbine noise. There was no difference in the distribution of answers to these questions among these non-responders and those who responded to the full questionnaire.

One of the more dramatic findings of this study was that among people who benefited economically from the turbines (n=100; 14%)—who were much more commonly in the higher noise categories—there was virtually no annoyance (3%) despite the same pattern of noticing the noise as those who did not benefit economically. It is possible that this is because attitude towards turbines drives annoyance, but it was also suggested that those who benefit economically are able to turn off the turbines when they become annoying. However, it is not clear how many of those who benefited economically actually had that level of control over the turbines.

Similarly, there was very little annoyance among people who could not see a wind turbine from their residence even when those people were in higher noise categories (although none were in the highest category). In models that adjusted for visibility of wind turbines and economic benefit, sound level was still a significant predictor of annoyance. However, because of the way in which sound and visibility were modeled in this analysis, the association between higher noise levels and higher annoyance could have been driven entirely by those who could see a wind turbine, while there could still have been no association between wind turbine noise level and annoyance among those who could not see a wind turbine. Thus, this study has to be considered inconclusive with respect to an association between wind turbine sound level and annoyance *independent of* the effect of seeing a wind turbine (and vice versa).

The Dutch study has the limitation of being cross sectional as were the Swedish studies, and the non-response in the Dutch study was much larger than in the Swedish studies. The results of the limited assessment of a subset of non-responders mitigate somewhat against the concerns raised by the low response rate, but not completely.

3.3.c New Zealand Study

The New Zealand study recruited participants from what the authors refer to as two demographically matched neighborhoods (an exposed group living near wind turbines and a control group living far from turbines), although supporting data for this are not presented. The area with the turbines is described as being characterized by hilly terrain, with long ridges running 250–450 m above sea level, on which 66 125 m high wind turbines are positioned. The power of the turbines is not provided. For the exposed group, participants were drawn from those 18 years and older living in 56 houses located within 2 km of a wind turbine, and for the control group participants were drawn from those 18 years and older living in 250 houses located at least 8 km from the wind turbines. It is unclear how many participants per household were recruited, but the final study sample included 39 people in the exposed group and 158 in the control group. Response rates of 34% for the exposed group and 32% for the control group are given. The outcome assessed was response to the abbreviated version of the WHO's quality of life (QOL)-BREF (WHOQOL-BREF)—a health-related QOL questionnaire. These questions were embedded within a larger questionnaire with various facets designed to mask the focus on wind turbines. Although there were no statistically significant demographic differences between the two groups, 43.6% of those in the exposed group had a university education while only 34.2% in the control group did.

The exposed group was found to have significantly worse physical QOL (in particular the sleep and energy level items of this scale) and worse environmental QOL (in particular ratings of how healthy the environment is and satisfaction with the conditions of their living space). The groups did not differ in scores on the social or psychological scales. The mean ratings for an overall QOL item was significantly lower in the exposed group. All of these analyses were adjusted for length of residence, but for no other variables.

As with the other studies discussed, this study has the limitation of being cross sectional. As with the Dutch study, the response rate in the present study is rather low, and unfortunately, there are no data in the New Zealand study on non-participants. This raises concern that self-selection into the study could differ by important factors in some way between the two groups. The difference seen in education level between the groups exacerbates this concern. It is also unclear whether appropriate statistical analysis methods were used given that there may have been multiple respondents from the same household, which is not stated but would have needed to have been accounted for in the analysis. The lack of control for other variables that may be related to reporting of QOL is also a limitation. In this regard it is important to note that a lack of a statistically significant difference in factors between groups does not rule out the possibility of those factors potentially accounting for some of the difference in outcome scores between groups, particularly when the sample size is small like in this study. Whether participants could see wind turbines was not assessed, but it is likely that most if not all in the exposed group could and most if not all in the control group could not, given their locations. Given the findings in the

Swedish and Dutch studies, this means that even if the difference in QOL scores seen are due to wind turbines, it is possible that it is driven by seeing the turbines rather than sound from the turbines. Overall, the level of evidence from this study for a causal association between wind turbines and reported QOL is limited.

3.3.d Additional Non-Peer Reviewed Documents

Papers that appear in the peer-reviewed literature have by definition undergone a level of review external to the study team by not only the editors of the journal, but also two to three (usually) scientists familiar with the field of the study and the methodology used. These hurdles provide an opportunity to identify problems with the paper—from methodology to interpretation of the results—and either provide the opportunity to address problems or reject the paper if the problems are considered fatal to the interpretation of the results. Non-peer reviewed literature is not subject to this external review scrutiny. This does not mean that all peer-reviewed literature is of high quality nor that non-peered reviewed literature is necessarily inferior to peer-reviewed literature, but it does mean that non-peered reviewed literature does not need to undergo any review process to appear. Indeed, at times studies appear in non-peer reviewed outlets precisely because they did not meet the bar of quality necessary to appear in the peer-reviewed literature. Thus, non-peer reviewed literature needs to be scrutinized with this in mind. Four such non-peer-reviewed reports are described below. In addition to those four, a few early reports of annoyance from wind turbines generally found a weak relationship between annoyance and the equivalent A-weighted SPL, although those studies were mainly based on studies of smaller turbines of less than 500 kW (T. H. Pedersen & Nielsen, 1994; Rand & Clarke, 1990; Wolsink et al., 1993).

<u>Project WINDFARMperception: Visual and acoustic impact of wind turbine farms on residents (van den Berg et al., 2008).</u> This report describes the study upon which the Dutch paper summarized above (E. Pedersen et al., 2009) is based. The characteristics of the wind turbines are thus as described above. In addition to the data that appeared in the peer-reviewed literature, this report describes analyses of additional data that was collected. These additional data relate to health effects and turbine noise exposure. The questionnaire assessed stress levels with the General Health Questionnaire (GHQ), a validated scale that has been widely used in such studies and which assesses symptoms felt over the past several weeks. In models adjusted for age, economic benefit from the turbines, and sex, there was no association between sound

levels and stress. In contrast, there was a significant association between sound levels and interrupted sleep (at least once a month), even when further adjusting for background noise levels. This was most obvious at turbine noise levels >45 dB(A), but there appeared to be an increasing trend in occurrence of interrupted sleep with increasing noise categories even across the lower noise categories. This study also asked participants about chronic health conditions including diabetes, high blood pressure, tinnitus, hearing impairment, cardiovascular disease, and migraine. Although no associations were seen between wind turbine noise and these outcomes in adjusted analyses, the chronic nature of these outcomes and the lack of data on timing of onset with respect to when the wind turbines were introduced make interpreting these negative findings difficult.

Report to the commission related to Moturimu wind farm, New Zealand (Phipps, 2007). This report to a commission in New Zealand related to the Moturimu wind farm describes a survey conducted by Robyn Phipps to investigate the visual and acoustical effects experienced by residents living at least 2 km from existing wind farms in the Manawatu and Tararua regions of New Zealand. Most respondents were within 3 km, although a few lived further away, as far as 15 km. The characteristics and number of wind turbines was not provided. Although this work does not appear to have come out in the peer-reviewed literature, reasonable details about the methodology are provided.

Roughly 1,100 surveys were delivered to postal addresses and 614 (56%) were returned. Participants were asked to rate on a scale of 1–5 their agreement with different statements related to their perceptions of the wind turbines. When these questions dealt with visual issues, they were framed both positively and negatively (e.g., “I think the turbines spoil the view,” and “I think the turbines are quite attractive”). This apparently was not the case with other questions (e.g., “Watching the turbines can create an unpleasant physical sensation in my body”).

Overall, 9% of respondents endorsed being “affected” by the flicker of the wind turbines; 15% were sufficiently bothered by the visual and noise effects of the turbines to consider complaining, and 10% actually had complained. While 56% is a relatively good response rate for a mailed survey, the reasons for non-response of nearly half of potential participants must be considered. It is possible that non-respondents did not care enough about the effects of the wind turbines to bother responding, which presumably would lower the overall percentages that were “affected” by the turbines. On the other hand, it is not clear how long the turbines were in operation prior to the survey, and it is conceivable that some more affected people may have moved out of the area before the time of the survey.

A further drawback to the reported survey was that there was not a determination of how the percentage of "affected" respondents related to distance from the turbines, the ability to see the turbines, or noise levels experienced from the turbines. The report cites a lot of literature on noise and health effects, and while such effects have been reported in the literature, they are almost uniformly at sound levels above what is usually found for people living near turbines (and most certainly higher than those usually reported for people living more than 2 km from a turbine). A WHO report provides a good review of this literature (WHO, 2009). The lowest threshold levels for seeing any effect are about 35 dB(A) (maximum per event or L_{Amax}) for some physiological sleep responses (e.g., EEG, or duration of sleep stages), but these thresholds are for levels inside the house near the sleeper, which will be much lower than what is experienced outside the house. The lowest threshold level for complaints of well-being were estimated at 35 dB(A) as a yearly average outside the house at night ($L_{night,\ outside}$). But for health outcomes the thresholds for any effect are much higher, for example 50 dB(A) ($L_{night,\ outside}$) for hypertension or myocardial infarction.

<u>"Wind Turbine Syndrome" (Pierpont, 2009)</u>: This book describes several people who suffer health symptoms that they attribute to wind turbines. Such descriptions can be informative in describing phenomena and raising suggestions for possible follow-up with more rigorous study designs, but generally are not considered evidence for causality. In this particular case, though, there are elements that go beyond the most basic symptom descriptions and so warrant consideration as a study. But limitations to the design employed make it impossible for this work to contribute any evidence to the question of whether there is a causal association between wind turbine exposure and health effects. Given this, the very term "Wind Turbine Syndrome" is misleading as it implies a causal role for wind turbines in the described health symptoms.

The book describes health symptoms experienced among 38 people from 10 different families who lived near wind turbines and subsequently either moved away from the turbines or spent significant periods of time away. The participants ranged in age from less than 1 to 75 years old, with 13 (34%) younger than 16 years and 17 (45%) younger than 22. The participants were queried about their health symptoms before exposure to turbines (presumably before the turbines were operational), during exposure to turbines, and after moving away. There is an impressive detailed description of the extent and severity of health symptoms experienced by this group, with a core group of symptoms centered around vibratory responses and termed Visceral Vibratory Vestibular Disturbance (VVVD) by Pierpont. While these symptoms for the most part are attributed to exposure to the wind turbines by the participants—either because they appeared once the turbines were operational or because they seemed to diminish after going away from the turbines—the way in which these participants were recruited makes it impossible to draw any conclusions about attributing causality to the turbines.

The most critical problem with respect to inferring causality from Pierpont's findings lies in how the families were identified for participation. To be included in the study, among other criteria, at least one family member had to have severe symptoms *and* reside near a recently erected wind turbine. In epidemiological terms this is selecting participants based on both exposure and outcome, which guarantees a biased (non-causal) association between wind turbines and symptoms. While it could be argued that other family members may not have had severe symptoms—and so would not be selected based on outcome—it is hard to consider other family members as truly independent observations, as their reporting of symptoms, or indeed their experiencing of symptoms, could be influenced by the more severely affected family member. This is particularly so when the symptoms are in the realm of anxiety, sleep disturbance, memory, and concentration; and the severely affected family members are reporting increased irritability, anger, and shouting.

Although not always, several of the participants reported an improvement of symptoms after moving away from the wind turbines. While this is suggestive and should not be discounted as something to explore further, the highly selective nature of the interviewed group as a whole makes the evidence for causality from these data *per se* weak. There are also many factors that change when moving, making it difficult to attribute changes to any specific difference with certainty. Additional factors that contribute to the inability to infer causality from these data include the small sample size, lack of detail on the larger population that could have been considered for inclusion in the study, and lack of detail on precisely how the actual participants were recruited. In addition, while the clinical history was extensive, the symptom data were all self-reported. Another complication is that there are no precise data on distance to turbines, and noise levels or infrasound vibration levels at the participants' homes.

"Adverse health effects of industrial wind turbines: a preliminary report" (Nissenbaum et al., 2011): This report describes a study involving questionnaire assessment of mental and physical health (SF-36), sleep disturbance (Pittsburgh Sleep Quality Index), and sleepiness (Epworth Sleepiness Scale) among residents near one of two wind farms in Maine (Vinalhaven & Mars Hill). The Mars Hill site is a linear arrangement of 28 General Electric 1.5 MW turbines, sited on a ridgeline. The Vinalhaven site is a cluster of three similar turbines, sited on a flat, tree-covered island. All residents within 1.5 km of one of the turbines were identified, and all those older than 18 years and non-demented were considered eligible for the study. A set of households from an area of similar socioeconomic makeup but 3–7 km from wind turbines were also recruited. The recruitment process involved house-to-house visits up to three times to recruit participants. Among those within at most 1.5 km from the nearest turbine, 65 adults were identified and 38 (58%; 22 male, 16 female) participated from 23 unique households. Among those 3-7 km from the nearest turbine, houses were visited until a similar number of participants were recruited. This process successfully recruited 41 adults (18 male, 23 female) from 33 unique households. No information was given on the number of homes or people approached so the participation rate cannot be determined.

Analyses adjusted for age, sex, and site (the two different wind farms) found that those living within 1.5 km of a wind turbine had worse sleep quality and mental health scores and higher ratings of sleepiness than those living 3–7 km from a turbine. Physical health scores did not differ between the groups. Similar associations were found when distance to the nearest turbine was analyzed as a continuous variable.

This study is somewhat limited by its size—much smaller than the Swedish or Dutch studies described above—but nonetheless suggests relevant potential health impacts of living near wind turbines. There are, however, critical details left out of the report that make it difficult to fully assess the strength of this evidence. In particular, critical details of the group living 3–7 km from wind turbines is left out. It is stated that the area is of similar socioeconomic makeup, and while this may be the case, no data to back this up are presented—either on an area level or on an individual participant level. In addition, while the selection process for these participants is described as random, the process of recruiting these participants by going home to home until a certain number of participants are reached is not random. Given this, details of how homes were identified, how many homes/people were approached, and differences between those who did and did not participate are important to know. Without this, attributing any of the observed associations to the wind turbines (either noise from them or the sight of them) is premature.

3.3.e Summary of Epidemiological Data

There is only a limited literature of epidemiological studies on health effects of wind turbines. Furthermore, existing studies are limited by their cross sectional design, self-reported symptoms, limited ability to control for other factors, and to varying degrees of non-response rates. The study that accounted most extensively for other factors that could affect reported symptoms had a very low response rate (E. Pedersen et al., 2009; van den Berg, et al., 2008).

All four peer-reviewed papers discussed above suggested an association between increasing sound levels from wind turbines and increasing annoyance. Such an association was also suggested by two of the non-peer reviewed reports that met at least basic criteria to be considered studies. The only two papers to consider the influence of seeing a wind turbine (each one of the peer-reviewed papers) both found a strong association between seeing a turbine and annoyance. Furthermore, in the studies with available data, the influence of either sound from a turbine or seeing a turbine was reduced—if not eliminated, as was the case for sound in one study—when both of these factors were considered together. However, this precise relation cannot be disentangled from the existing literature because the published analyses do not properly account for both seeing and hearing wind turbines given the relation between these two that the data seem to suggest. Specifically, the possibility that there may be an association between either of those factors and annoyance, but possibly only for those who both see and hear sound from a turbine, and not for those who either do not hear sound from or do not see a turbine. Furthermore, in the one study to consider whether individuals benefit economically from the turbines in question, there appeared to be virtually no annoyance regardless of whether those people could see or hear a turbine. Even if one considers the data just for those who could see a wind turbine and did not benefit economically from the turbines, defining at what noise levels the percentage of those annoyed becomes more dramatic is difficult. Higher percentages of annoyance did appear to be more consistent above 40 dB(A). Roughly 27% were annoyed (at least 4 on a 1–5 point scale of annoyance; 5 being the worst), while roughly 18% were very annoyed (5 on a 1–5 scale). The equivalent levels of annoyed and very annoyed for 35–40 dB(A) were roughly 15% and 6%, respectively. These percentages, however, should be considered upper bounds for a specific relation with noise levels because, with respect to estimating direct effects of noise, they are likely inflated as a result of both selective participation in the studies and the fact that the percentages do not take into account the effect of seeing a turbine.

Thus, in considering simply exposure to wind turbines in general, while all seem to suggest an association with annoyance, because even the peer-reviewed papers have weaknesses, including the cross sectional designs and sometimes quite low response rates, **the Panel concludes that there is limited evidence suggesting an association between exposure to wind turbines and annoyance**. However, only two of the studies considered both seeing and hearing wind turbines, and even in these the possible contributions of seeing and hearing a wind turbine were not properly disentangled. Therefore, **the Panel concludes that there is insufficient evidence to determine whether there is an association between noise from wind turbines and annoyance independent from the effects of seeing a wind turbine and vice versa**. Even these conclusions must be considered in light of the possibility suggested from one of the peer-reviewed studies that there is extremely low annoyance—regardless of seeing or hearing sound from a wind turbine—among people who benefit economically from the turbines.

There was also the suggestion that poorer sleep was related to wind turbine noise levels. While it intuitively makes sense that more noise would lead to more sleep disruption, there is limited data to inform whether this is occurring at the noise levels produced from wind turbines. An association was indicated in the New Zealand study, suggested without presenting details in one of the Swedish studies, and found in two non-peer-reviewed studies. Therefore, **the Panel concludes that there is limited evidence suggesting an association between noise from wind turbines and sleep disruption and that further study would quantify precise sound levels from wind turbines that disrupt sleep**.

The strongest epidemiological study to examine the association between noise and psychological health suggests there is not an association between noise from wind turbines and measures of psychological distress or mental health problems. There were two smaller, weaker, studies: one did note an association, one did not. Therefore, **the Panel concludes the weight of the evidence suggests no association between noise from wind turbines and measures of psychological distress or mental health problems.**

One Swedish study apparently collected data on headache, undue tiredness, pain and stiffness in the back, neck, or shoulders, or feeling tensed/stressed and irritable, but did not report on analyses of these data. The Dutch study found no association between noise from wind turbines and diabetes, high blood pressure, tinnitus, hearing impairment, cardiovascular disease, and migraine, although this was not reported in the peer-reviewed literature. Therefore, **the Panel concludes that none of the limited epidemiological evidence reviewed suggests an association between noise from wind turbines and pain and stiffness, diabetes, high blood pressure, tinnitus, hearing impairment, cardiovascular disease, and headache/migraine.**

These conclusions align with those presented in the peer-reviewed article by Knopper and Ollson (2011). They write "Conclusions of the peer reviewed literature differ in some ways from those in the popular literature. In peer reviewed studies, wind turbine annoyance has been statistically associated with wind turbine noise, but found to be more strongly related to visual impact, attitude to wind turbines and sensitivity to noise. … it is acknowledged that noise from wind turbines can be annoying to some and associated with some reported health effects (e.g., sleep disturbance), especially when found at sound pressure levels greater than 40 db(A)."

3.4 Exposures from Wind Turbines: Noise, Vibration, Shadow Flicker, and Ice Throw

In addition to the human epidemiologic study literature on exposure to wind turbines and health effects described in the section above, the Panel assessed literature that could shed light on specific exposures resulting from wind turbines and possible health effects. The exposures covered here include noise and vibration, shadow flicker, and ice throw. Each of these exposures is addressed separately in light of their documented and potential health effects. When health effects are described in the popular media, these claims are discussed.

3.4.a Potential Health Effects Associated with Noise and Vibration

The epidemiologic studies discussed above point to noise from wind turbines as a source of annoyance. The studies also noted that some respondents note sleep disruption due to the turbine noise. In this section, the characteristics of audible and inaudible noise from turbines are discussed in light of our understanding of their impacts on human health.

It is clear that when sound levels get too high, the sound can cause hearing loss (Concha-Barrientos et al., 2004). These sound levels, however, are outside the range of what one would experience from a wind turbine. There is evidence that levels of audible noise below levels that cause hearing loss can have a variety of health effects or indicators. Detail about the evidence for such health effects have been well summarized in a WHO report that came to several relevant conclusions (WHO, 2009). First, there is sufficient evidence for biological effects of noise during sleep: increase in heart rate, arousals, sleep stage changes and awakening; second, there is limited evidence that noise at night causes hormone level changes and clinical conditions such as cardiovascular illness, depression, and other mental illness. What the WHO report also details is observable noise threshold levels for these potential effects. For such health effects, where data are sufficient to estimate a threshold level, that level is never below 40 dB(A)—as a yearly average—for noise outside (ambient noise) at night—and these estimates take into account sleeping with windows slightly open.

One difficulty with the WHO threshold estimate is that a yearly average can mask the particular quality of turbine noise that leads survey respondents to note annoyance or sleep disruption. For instance, the pulsatile nature of wind turbine noise has been shown to lead to respondents claiming annoyance at a lower averaged sound level than for road noise (E. Pederson, 2004). Yearly averaging of sound eliminates (or smooths) the fluctuations in the sound and ignores differences between day and night levels. Regulations may or may not take this into account.

Health conditions caused by intense vibration are documented in the literature. These are the types of exposures that result from jackhammers, vibrating hand tools, pneumatic tools, etc. In these cases, the vibration is called arm-body or whole-body vibration. Vibration can cause changes in tendons, muscles, bones and joints, and can affect the nervous system. Collectively, these effects are known as Hand-Arm Vibration Syndrome (HAVS). Guidelines and interventions are intended to protect workers from these vibration-induced effects (reviewed by European Agency for Safety and Health at Work, 2008; (NIOSH 1989). OSHA does not have standards concerning vibration exposure. The American Conference of Governmental Industrial Hygienists (ACGIH) has developed Threshold Limit Values (TLVs) for vibration exposure to hand-held tools. The exposure limits are given as frequency-weighted acceleration (NIOSH, 1989).

3.4.a.i Impact of Noise from Wind Turbines on Sleep

The epidemiological studies indicate that noise and/or vibration from wind turbines has been noted as causing sleep disruption. In this section sleep and sleep disruption are discussed. In addition, suggestions are provided for more definitively evaluating the impact of wind turbines on sleep.

All sounds have the potential to disrupt sleep. Since wind turbines produce sounds, they might cause sleep disruption. A very loud wind turbine at close distance would likely disrupt sleep, particularly in vulnerable populations (such as those with insomnia or mood disorders, aging populations, or "light sleepers"), while a relatively quiet wind turbine would not be expected to disrupt even the lightest of sleepers, particularly if it were placed at considerable distance.

There is insufficient evidence to provide very specific information about how likely particular sound-pressure thresholds of wind turbines are at disrupting sleep. Physiologic studies of noises from wind turbines introduced to sleeping people would provide these specific levels. Borrowing existing data (e.g., Basner, 2011) and guidelines (e.g., WHO) about noises at night, beyond wind turbines, might help provide reasonable judgment about noise limits at night. But it would be optimal to have specific data about the particular influence that wind turbines have on sleep.

In this section we introduce broad concepts about sleep, the interaction of sleep and noises, and the potential for wind turbines to cause that disruption.

Sleep

Sleep is a naturally occurring state of altered consciousness and reduced physical activity that interacts with all aspects of our physiology and contributes daily to our health and well-being.

Measurements of sleep in people are typically performed with recordings that include electroencephalography (EEG). This can be performed in a laboratory or home, and for clinical or experimental purposes. Other physiological parameters are also commonly measured, including muscle movements, lung, and heart function.

While the precise amount of sleep that a person requires is not known, and likely varies across different people and different ages, there are numerous consequences of reduced sleep (i.e., sleep deprivation).

Deficiencies of sleep can take numerous forms, including the inability to initiate sleep; the inability to maintain sleep; abnormal composition of sleep itself, such as too little deep sleep (sometimes called slow-wave sleep, or stage N3); or frequent brief disruptions of sleep, called arousals. Sources of sleep deprivation can be voluntary (desirable or undesirable) or involuntary. Voluntary sources include staying awake late at night or awakening early. These can be for work or school, or while engaging in some personal activities during normal sleep times. Sleep deprivation can also be caused by myriad involuntary and undesired problems (including those internal to the body such as pain, anxiety, mood disorders) and frequent need to urinate, or by numerous sleep disorders (including insomnia, sleep apnea, circadian disorders, parasomnias, sleep-related movement disorders, etc), or simply by the lightening of sleep depth in normal aging. Finally, sleep deprivation can be caused by numerous external factors, such as noises or other sensory information in the sleeper's environment.

Sleep is conventionally categorized into rapid eye movement (REM) and non-REM sleep. Within the non-REM sleep are several stages of sleep ranging from light sleep to deep sleep. Beyond these traditional sleep categories, the EEG signal can be analyzed in a more detailed and sophisticated way, including looking at the frequency composition of the signals. This is important in sleep, as we now know that certain signatures in the brain waves (i.e., EEG) disclose information about who is vulnerable to noise-induced sleep disruption, and what moments within sleep are most vulnerable (Dang-Vu et al., 2010; McKinney et al., 2011).

Insomnia can be characterized by a person having difficulty falling asleep or staying asleep that is not better explained by another condition (such as pain or another sleep disorder) (see ICSD, 2nd Edition for details of the diagnostic criteria for insomnia). Approximately 25% of the general population experience occasional sleep deprivation or insomnia. Sleep deprivation is defined by reduced quantity or quality of sleep, and it can result in excessive daytime sleepiness as well as problems including those associated with mood and cognitive function (Roth et al., 2001; Rogers, 2007; Walker, 2008). As might be expected, the severity of the sleep deprivation has an impact on the level of cognitive functioning, and real-life consequences can include driving accidents, impulsive behaviors, errors in attention, and mood problems (Rogers, 2007; Killgore, 2010). Loss of sleep appears to be cumulative, meaning it adds up night after night. This can result in subtle impairments in reaction times, decision-making ability, attentional vigilance, and integration of information that is sometimes only apparent to the sleep-deprived individual after an accident or error occurs, and sometimes not perceived by the sleep-deprived person at all (Rogers, 2007; van Dongen 2003).

Sleep and Wind Turbines

Given the effects of sleep deprivation on health and well-being, including problems with mood and cognition, it is possible that cognitive and mood complaints and other medical or psychological issues associated with sleep loss can stem from living in immediate proximity to wind turbines, if the turbines disrupt sleep. Existing data, however, on the relationship between wind turbines and sleep are inadequate. Numerous factors determine whether a sound disrupts sleep. Broadly speaking, they are derived from factors about the sleeper and factors about the sound.

Case reports of subjective complaints about sleep, particularly those not critically and objectively appraised in the normal scientific manner, are the lowest level of evidence, not simply because they lack any objective measurements, but also because they lack the level of scrutiny considered satisfactory for making even crude claims about cause and effect. For instance, consider the case of a person who sleeps poorly at home (near a wind turbine), and sleeps better when on vacation (away from a wind turbine). One might conclude from this case that wind turbines cause sleep disruption for this person, and even generalize that information to other people. But there are numerous factors that might make it more likely that a person can sleep well on vacation, having nothing to do with the wind turbine. Furthermore, given the enormous prevalence of sleep disorders, such as insomnia, and the potentially larger prevalence of disorders that impinge on sleep, such as depression, it is crucial that these factors be taken into consideration when weighing the evidence pointing to a causal effect of wind turbines on sleep disruption for the general population. It is also important to obtain objective measurements of sleep, in addition to subjective complaints.

Subjective reports of sleeping well or sleeping poorly can be misleading or even inaccurate. People can underestimate or overestimate the quality of their sleep. Future studies should examine the acoustic properties of wind turbines when assessing the elements that might disrupt sleep. There are unique properties of the noises wind turbines make, and there are some acoustic properties in common with other noises (such as trucks or trains or airplanes). It is important to make these distinctions when assessing the effects of wind turbines on noise, by using data from other noises. Without this physiologic, objective information, the effects of wind turbines on sleep might be over- or underestimated.

It should be noted that not all sounds impair the ability to fall asleep or maintain sleep. To the contrary, people commonly use sound-masking techniques by introducing sounds in the environment that hinder the perception of undesirable noises. Colloquially, this is sometimes called “white noise,” and there are certain key acoustic properties to these kinds of sounds that make them more effective than other sounds. Different noises can affect people differently. The emotional valence that is ascribed by an individual to a particular sound can have a major influence on the ability to initiate or maintain sleep. Certain aspects of sounds are particularly alerting and therefore would be more likely to disrupt sleep at lower sound pressure levels. But among those that are not, there is a wide range of responses to these sounds, depending partly on the emotional valence ascribed to them. A noise, for instance, that is associated with a distressing object, is more likely to impede sleep onset.

Finally, characteristics of sleep physiology change across a given night of sleep—and across the life cycle of a person—and are different for different people, including the effects of noise on sleep (e.g., Dang-Vu et al., 2010; McKinney et al., 2011). And some people might initially have difficulty with noises at night, but habituate to them with repeated exposure (Basner, 2011).

In summary, **sleep is a complex biological state, important for health and well-being across a wide range of physiologic functions. To date, no study has adequately examined the influence of wind turbines on sleep.**

Future directions: The precise effects of noise-induced sleep disruption from wind turbines may benefit from further study that examines sound-pressure levels near the sleeper, while simultaneously measuring sleep physiology to determine responses of sleep to a variety of levels of noise produced by wind turbines. The purpose would be to understand the precise sound-pressure levels that are least likely to disturb sleep. It would also be helpful to examine whether sleepers might habituate to these noises, making the impact of a given sound less and less over time. Finally, it would be helpful to study these effects in susceptible populations, including those with insomnia or mood disorders or in aging populations, in addition to the general population.

Summary of Sleep Data

In summary, sleep is a complex biological state, important for health and well-being across a wide range of physiologic functions. **To date, no study has adequately examined the influence of wind turbines and their effects on sleep.**

3.4.b Shadow Flicker Considerations and Potential Health Effects

Shadow flicker is caused when changes in light intensity occur from rotating wind turbine blades that cast shadows (see Appendix B for more details on the physics of the phenomenon.) These shadows move on the ground and on buildings and structures and vary in terms of frequency rate and intensity. Shadow flicker is reported to be less of a problem in the United States than in Northern Europe due to higher latitudes and lower sun angles in Europe. Nonetheless, it can still be a considerable nuisance to individuals exposed to shadow flicker for considerable amounts of time per day or year in the United States as well. Shadow flicker can vary significantly by wind speed and duration, geographic location of the sunlight, and the distance from the turbine blades to any relevant structures or buildings. In general, shadow flicker branches out from the wind turbine in a declining butterfly wing characteristic geographic area with higher amounts of flicker being closer to the turbine and less flicker in the outer parts of the geographic area (New England Wind Energy Education Project (NEWEEP), 2011; Smedley et al., 2010). Shadow flicker is present up until approximately 1400 m, but the strongest flicker is up to 400 m from the turbine when it occurs (NEWEEP, 2011). In addition, shadow flicker usually occurs in the morning and evening close to sunrise and sunset when shadows are the longest. Furthermore, shadow flicker can fluctuate in different seasons of the year depending on the geographic location of the turbine such that some sites will only report flicker during the winter months while others will report it during summer months. Other factors that determine shadow flicker rates and intensity include objects in the landscape (i.e., trees and other existing shadows) and weather patterns. For instance, there is no shadow flicker on cloudy days without sun as compared with sunny days. Also, shadow flicker speed (shadows passing per second) increases with the rotor speed (NRC, 2007). In addition, when several turbines are located relatively close to one another there can be combined flicker from the different blades of the different turbines and conversely, if situated on different geographic areas around structures, shadow flicker can occur at different times of the day at the same site from the different turbines so pre-planning of siting location is very important (Harding et al., 2008). General consensus in Germany resulted in the guidance of 30 hours per year and 30 minutes per day (based on astronomical, clear sky calculations) as acceptable limits for shadow flicker from wind turbines (NRC, 2007). This is similar to the Denmark guidance of 10 hours per year based on actual conditions.

3.4.b.i Potential Health Effects of Flicker

Because some individuals are predisposed to have seizures when exposed to certain types of flashing lights, there has been concern that wind turbines had the potential to cause seizures in these vulnerable individuals. In fact, seizures caused by visual or photic stimuli are typically observed in people with certain types of epilepsy (Guerrini & Genton, 2004), particularly generalized epilepsy. While it is not precisely known how many people have photosensitivity that causes seizures, it appears to be approximately 5% of people with epilepsy, amounting to about 100,000 people in the United States. And many of these people will already be treated with antiepileptic medications thus reducing this risk further.

Fortunately, not all flashing light will elicit a seizure, even in untreated people with known photosensitivity. There are several key factors that likely need to simultaneously occur in order for the stimulus to induce a seizure, even among the fraction of people with photosensitive seizures. The frequency of the stimulus is important as is the stimulus area and pattern (See below) (http://www.epilepsyfoundation.org/aboutepilepsy/seizures/photosensitivity/gerba.cfm).

Frequencies above 10 Hz are more likely to cause epileptic seizures in vulnerable individuals, and seizures caused by photic stimulation are generally produced at frequencies ranging from greater than 5 Hz. However, shadow flicker frequencies from wind turbines are related to the rotor frequency and this usually results in 0.3–1.0 Hz, which is outside of the range of seizure thresholds according to the National Resource Council and the Epilepsy Foundation (NRC, 2007). In fact, studies performed by Harding et al. (2008) initially concluded that because light flicker can affect the entire retina, and even if the eyes are closed that intermittent light can get in the retina, suggested that 4 km would be a safe distance to avoid seizure risk based on shadow flicker (Harding et al., 2008). However, a follow-up analysis considering different meteorological conditions and shadow flicker rates concluded that there appeared to be no risk for seizures unless a vulnerable individual was closer than 1.2 times the total turbine height on land and 2.8 times the total turbine height in the water, which could potentially result in frequencies of greater than 5 Hz (Smedley et al., 2010).

Although some individuals have complained of additional health complaints including migraines, nausea, dizziness, or disorientation from shadow flicker, only one government-sponsored study from Germany (Pohl et al., 1999) was identified for review. This German study was performed by the Institute of Psychology, Christian-Albrechts-University Kiel on behalf of the Federal Ministry of Economics and Technology (BMWi) and supported by the Office of Biology, Energy, and Environment of the Federal Ministry for Education and Research (BMBF), and on behalf of the State Environmental Agency of Schleswig. The purpose of this government-sponsored study was to determine whether periodic shadow with a duration of more than 30 minutes created significant stress-related health effects. The shadows were created by a projection system, which simulated the flicker from actual wind turbines.

Two groups of different aged individuals were studied. The first group consisted of 32 students (average age 23 years). The second group included 25 professionals (average age 47 years). Both men and women were included. The subjects were each randomly assigned to one of two experimental groups, so there was a control group and an experimental group. The experimental group was exposed to 60 minutes of simulated flicker. For the control group lighting conditions were the same as in the experimental group, but without periodic shadow. The main part of the study consisted of a series of six test and measurement phases, two before the light was turned on, three each at intervals of 20 minutes while the simulated shadow flickering was taking place, and one more after the flicker light was turned off. Among the variables measured were general performance indicators of stress (arithmetic, visual search tasks) and those of mental and physical well-being, cognitive processing, and stress in the autonomic nervous system (heart rate, blood pressure, skin conductance, and finger temperature). Systematic effects due to the simulated flicker could be detected in comparable ways in both exposure groups studied. Both physical and cognitive effects were found in this exposure scenario for shadow flicker.

It appears clear that shadow flicker can be a significant annoyance or nuisance to some individuals, particularly if they are wind project non-participants (people who do not benefit economically or receive electricity from the turbine) whose land abuts the property where the turbine is located. In addition, flashing (a phenomenon closely related to shadow flicker, but due to the reflection of sunlight – see Appendix B) can be a problem if turbines are sited too close to highways or other roadways. This could cause dangerous conditions for drivers. Accordingly, turbine siting near highways should be planned so as to reduce flashing as much as possible to protect drivers. However, use of low reflective turbine blades is commonly employed to reduce this potential flashing problem. Provisions to avoid many of these potential health and annoyance problems appear to be employed as current practice in many pre-planning sites with the use of computer programs such as WindPro. These programs can accurately determine shadow flicker rates based on input of accurate analysis area, planned turbine location, the turbine design (height, length, hub height, rotor diameter, and blade width), and residence or roadway locations. Many of these computer programs can then create maps indicating the location and incidence of shadow flicker. Such programs may also provide estimates of daily minutes and hours per year of expected shadow flicker that can then be used for wind turbine planning and siting or for mitigation efforts. Several states require these analyses to be performed before any new turbine projects can be implemented.

3.4.b.ii Summary of Impacts of Flicker

Collectively, although shadow flicker can be a considerable nuisance particularly to wind turbine project non-participants, the evidence suggests that there is no risk of seizure from shadow flicker caused by wind turbines. In addition, there is limited evidence primarily from a German government-sponsored study (Pohl et al., 1999) that prolonged shadow flicker (more than 30 minutes) can result in transient stress-related effects on cognition (concentration, attention) and autonomic nervous system functioning (heart rate, blood pressure). There was insufficient documentation to evaluate other than anecdotal reports of additional health effects including migraines or nausea, dizziness or disorientation. There are documented mitigation methods for addressing shadow flicker from wind turbines and these methods are presented in Appendix B.

3.4.c Ice Throw and its Potential Health Effects

Under certain weather conditions ice may form on the surface of wind turbine blades. Normally, wind turbines intended for use in locations where ice may form are designed to shut down when there is a significant amount of ice on the blades. The means to prevent operation when ice is present may include ice sensor and vibration sensors. Ice sensors are used on most wind turbines in cold climates. Vibration sensors are used on nearly all wind turbines. They would cause the turbine to shut down, for example, if ice buildup on the blades resulted in an imbalance of the rotor and hence detectable vibrations in the structure.

Ice built up on blades normally falls off while the turbine is stationary. If that occurs during high winds, the ice could be blown by the wind some distance from the tower. In addition, it is conceivable that ice could be thrown from a moving wind turbine blade under some circumstances, although that would most likely occur only during startup (while the rotational speed is still relatively low) or as a result of the failure of the control system. It is therefore worth considering the maximum plausible distance that a piece of ice could land from the turbine under two “worst case” circumstances: 1) ice falls from a stopped turbine during very high winds, and 2) ice is suddenly released from a blade when the rotor is rotating at its normal operating speed.

Ice is a physical hazard, that depending on the mass, velocity, and the angle of throw can result in a wide range of effects to humans: alarm and surprise to abrasions, organ damage, concussions, and perhaps death. Avoidance of ice throw is critical. More detail on ice throw and options for mitigation are presented in Appendix C.

3.5 Effects of Noise and Vibration in Animal Models

Domestic animals such as cats and dogs can serve as sentinels of problematic environmental conditions. The Panel searched for literature that might point to non-laboratory animal studies or well-documented cases of animals impacted by wind turbines. Anecdotal reports in the press of goat deaths (UK), premature births and adverse effects in cows (Japan, US) provide circumstantial evidence, but lack specifics regarding background rates of illness or extent of impact.

Laboratory-based animal models are often used to predict and to develop mechanistic explanations of the causes of disease by external factors, such as noise or chemicals in humans. In the absence of robust epidemiological data, animal models can provide clues to complex biological responses. However, the limitations of relying on animal models are well documented, particularly for endpoints that involve the brain. The benefits of using an animal model include ease of experimental manipulation such as multiple exposures, typically well-controlled experimental conditions, and genetically identical groups of animals.

Evaluation of biological plausibility for the multitude of reported health effects of wind turbines requires a suitable animal model documented with data that demonstrate cause and effect. Review of this literature began with a PubMed and ToxNet search for “wind turbine” or “wind turbines”; or “infrasound” or “low frequency noise”; and “animal” or “mammal” to identify peer-reviewed studies in which laboratory animals were exposed to noise or vibration intended to mimic that of wind turbines. Titles and abstracts of identified papers were read to make a first pass determination of whether the paper was a study on effects in mammals or might contain relevant references to other relevant studies. The searches yielded several studies, many of which were not peer-reviewed, were not whole-animal mammalian or were not experimental, but were reviews in which animal studies were mentioned or experiments conducted in dissected cochlea. The literature review yielded eight peer-reviewed studies, all relying on the laboratory rat as the model. The studies fall into two groups—those conducted in the 1970's and early 1980's and those conducted in 2007–2010. The most recent studies are conducted in China and are funded by the National Natural Science Foundation of China. Table AG.1 (in Appendix G) provides a summary of the studies.

There is no general agreement about the specific biological activity of infrasound on rodents, although at high doses it appears to negatively affect the cardiovascular, brain, and respiratory systems (Sienkiewicz, 2007). Early studies lacked the ability to document the doses of infrasound given the rats, did not report general pathologies associated with the exposures and lacked suitable controls. Since then, researchers have focused on the brain and cardiac systems as sensitive targets of infrasound. Experimental conditions in these studies lack a documented rationale for the selection and the use of infrasound of 5-15 Hz at 130 dB. While this appears to be standard practice, the relevance of these frequencies and pressures is unclear—both to the rat and more importantly to the human. The exposures are acute—short-term, high dose. Researchers do not document rat behaviors (including startle responses), pathologies, frank toxicities, and outcomes due to these exposures. Therefore, interpretation of all of the animal model data for infrasound outcomes must be with the lens of any high-dose, short-term exposure in toxicology, specifically questioning whether the observations are readily translatable to low-dose, chronic exposures.

Pei et al., (2007 and 2009) examine changes in cardiac ultrastructure and function in adult male Sprague-Dawley rats exposed to 5 Hz at 130 dB for 2 hours for 1, 7, or 14 successive days. Cardiomyocytes were enzymatically isolated from the adult left ventricular hearts after sacrifice. Whole cell patch-clamp techniques were employed to measure whole cell L-Type Ca^{2+} currents. The objective of these studies was to determine whether there was a cumulative effect of insult as measured by influx of calcium into cardiomyocytes. After infrasound exposure, rats in the 7– and 14–day exposure groups demonstrated statistically significant changes in intracellular Ca^{2+} homeostasis in cardiomyocytes as demonstrated by electrochemical stimulation of the cells, molecular identification of specific heart-protein levels, and calcium transport measurements.

Several studies examine the effects of infrasound on behavioral performance in rats. The first of these studies was conducted under primitive acoustic conditions compared with those of today (Petounis et al., 1977). In this study the researchers examined the behavior of adult female rats (undisclosed strain) exposed to increasing infrasound (2 Hz, 104 dB; 7 Hz, 122 dB; and 16

Hz, 124 dB) for increasing time (5-minute increments for up to 120 minutes). Decreased activity levels (sleeping more) and exploratory behavior were documented as dose and duration of exposure increased. The authors fail to mention that frank toxicity including pain is associated with these behaviors, raising the question of relevance of high dose exposures. In response to this and similar studies that identify increase in sleep, increase in avoidance behaviors and suppression of locomotor activity, Spyraki et al., (1977) hypothesized that these responses are mediated by norepinephrine levels in the brain and as such, exposed adult male Wistar rats to increasing doses of infrasound for one hour. Using homogenized brain tissue, norepinephrine concentrations were measured using fluorometric methods. Researchers demonstrated a dose-dependent decrease in norepinephrine levels in brain tissue from infrasound-treated rats, beginning at a dose of 7 Hz and 122 dB for one hour. No observations of frank toxicity were recorded. Liu et al., (2010) hypothesized that since infrasound could affect the brain, it potentially could increase cell proliferation (neurogenesis) in the dentate gyrus of the rat hippocampus, specifically a region that continues to generate new neurons in the adult male Sprague-Dawley rat. Using a slightly longer exposure period of 2 hours/day for 7 days at 16 Hz and 130 dB, the data suggest that infrasound exposure inhibits cell proliferation in the dentate gyrus, yet has no affect on early migration and differentiation. This study lacks suitable positive and negative controls that allow these conclusions to be drawn.

Several unpublished or non-peer reviewed studies reported behavioral responses as relevant endpoints of infrasound exposure. These data are not discussed, yet are the basis for several recent studies. In one more recent peer-reviewed behavioral rat study, adult male Wistar rats were classified as “superior endurance” and those as “inferior endurance” using the Rota-rod Treadmill (Yamamura et al., 1990). A range of frequencies and pressures were used to expose the rats for 60—150 minutes. Comparison of the pre-exposure endurance time on the Rota-Rod Treadmill with endurance after exposure to infrasound showed that the endurance time of the superior group after exposure to 16 Hz, 105 dB was not reduced. The endurance of the inferior group was reduced by exposure to 16 Hz, 105 dB after 10 minutes, to 16 Hz, 95 dB after 70 minutes, and to 16 Hz, 85 dB after 150 minutes. Of most relevance is the identification of a subset of rats that may be more responsive to infrasound due to their genetic makeup. There has been no follow-up regarding intra-strain susceptibility since this study.

More recent studies have focused on the mechanisms by which infrasound may disrupt normal brain function. As stated above, the infrasound exposures are acute—short-term, high dose. At the very least, researchers should document rat behaviors, pathologies, frank toxicities, and outcomes due to these high dose exposures in addition to measuring specific subcellular effects.

Some of the biological stress literature suggests that microglial activation can occur with heightened stress, but it appears to be short-lived and transitory affecting the autonomic nervous system and neuroendocrine system, resulting in multiple reported effects. To investigate the effect of infrasound on hippocampus-dependent learning and memory, Yuan et al. (2009) measure cognitive abilities and activation of molecular signaling pathways in order to determine the role of the neuronal signaling transduction pathway, BDNF-TRkB, in infrasound-induced impairment of memory and learning in the rat. Adult male Sprague-Dawley rats were exposed to infrasound of 16 Hz and 130 dB for 2 hours daily for 14 days. The acoustic conditions appeared to be well monitored and documented. The Morris water maze was used to determine spatial learning and retention, and molecular techniques were used to measure cell proliferation and concentrations of signaling pathway proteins. Using these semi-quantitative methods, rats exposed to infrasound demonstrated impaired hippocampal-dependent spatial learning acquisition and retention performance in the maze scheme compared with unexposed control rats, demonstrable downregulation of the BDNF-TRkB pathway, and decreased BrdU-labeled cell proliferation in the dentatel gyrus.

In another study, Du et al. (2010) hypothesize that microglial cells may be responsible for infrasound-induced stress. To test this hypothesis, 60 adult male Sprague-Dawley rats were exposed in an infrasonic chamber to 16 Hz at 130 dB for 2 hours. Brains were removed and sectioned and the hypothalamic paraventricular nucleus (PVN) examined. Primary microglial cells were isolated from whole brains of neonatal rats and grown in culture before they were exposed to infrasound under the same conditions as the whole animals. Molecular methods were used to identify the presence and levels of proteins indicative of biological stress (corticotrophin-releasing hormone (CRH) and corticotrophin-releasing hormone receptor (CRH type 1 receptor) in areas of the brain that control the stress response. Specifically, studies were done to determine whether microglial cells are involved in infrasound-response, changes in microglial activation, and CRH-R1 expression in vivo in the PVN and in vitro at time points after the two-hour infrasound exposure. The data show that the exposures resulted in microglial activation, beginning at 0.5 hours post exposure, and up-regulation of CRH-R1 expression. The magnitude of the response increased significantly from the control to 6 hours post exposure, returning to control levels, generally by 24 hours post-exposure. This study is well controlled, and while it does rely on a specific antagonist for dissecting the relative involvement of the neurons and the microglial cells, the data suggest that infrasound as administered in this study to rats can activate microglial cells, suggesting a possible mechanism for infrasound-induced ”stress” or nuisance at a physical level (i.e., proinflammatory cytokines causing sickness response behaviors).

In summary, there are no studies in which laboratory animals are subjected to exposures that mimic wind turbines. There is insufficient evidence from laboratory animal studies of effects of low frequency noise on the respiratory system. There is limited evidence that rats are a robust model for human infrasound exposure and effects. The reader is referred to Appendix G for specific study conditions. In any case, the infrasound levels and exposure conditions to which the rodents are exposed are adequate to cause pain to the rodents. When exposed to these levels of infrasound, there is some evidence of reversible molecular effects including short-lived biochemical alterations in cardiac and brain cells, suggesting a possible mechanism for high-dose, infrasound-induced effects in rats.

3.6 Health Impact Claims Associated with Noise and Vibration Exposure

The popular media contain a large number of articles that claim the noise and vibration from wind turbines adversely affect human health. In this section the Panel examines the physical and biological basis for these assertions. Additionally, the scientific articles from which these assertions are made are examined in light of the methods used and their limitations.

Pierpont (2009) has been cited as offering evidence of the physical effects of ILFN, referring to “Wind Turbine Syndrome” and its impact on the vestibular system—by disturbed sensory input to eyes, inner ears, and stretch and pressure receptors in a variety of body locations. The basis for the syndrome relies on data from research carried out for reasons (e.g., space missions) other than assessment of wind turbines on health. Such research can be valuable to understanding new conditions, however, when the presentation of data is incomplete, it can lead to inaccurate conclusions. A few such cases are mentioned here:

Pierpont (2009) notes that von Dirke and Parker (1994) show that the abdominal area resonates between 4 and 6 Hz and that wind turbines can produce infrasound within this range (due to the blade rotation rate). However, the von Dirke paper states that our bodies have evolved to be tolerant of the 4–6 Hz abdominal motion range: this range coincides with jogging and running. The paper also reveals that motion sickness (which was the focus of the study) only occurred when the vibrations to which people were subjected were between 0.01 and 0.5 Hz. The study exposed people to vibration from positive to negative 1 G forces. Subjects were also rotated around various axes to achieve the vibration levels and frequencies of interest in the study. Interpretation of these data may allow one to conclude that while the abdominal area has a resonance in a region at which there is infrasound being emitted by wind turbines, there will be no impact. Further, the infrasound emitted by wind turbines in the range of frequencies at which subjects did note motion sickness is orders of magnitude less than the level that induced motion sickness (see Table 2). So while a connection is made, the evidence at this point is not sufficient to draw a conclusion that a person's abdominal area or stretch point can be excited by turbine infrasound. If it were, this might lead to symptoms of motion sickness.

Pierpont (2009) points to a study by Todd et al. (2008) as potential proof that the inner ear may be playing a role in creating the symptoms of "Wind Turbine Syndrome." Todd et al. (2008) show that the vestibular system shows a best frequency response around 100 Hz. This is a fact, but again it is unclear how it relates to low frequency noise from wind turbines. The best frequency response was assessed by moving subjects' heads (knocking the side of the head) in a very specific direction because the portion of the inner ear that is being discussed acts as a gravitational sensor or an accelerometer; therefore, it responds to motion. A physical mechanism by which the audible sound produced by a wind turbine at 100 Hz would couple to the human body in a way to create the necessary motion to which this portion of the inner ear would respond is unknown.

More recently, Salt and Hullar (2010) have looked for something physical about the ear that could be responding to infrasonic frequencies. They describe how the outer (OHC) and inner (IHC) hair cells of the cochlea respond to different types of stimuli: the IHC responding to velocity and OHC responding to displacement. They discuss how the OHC respond to lower frequencies than the IHC, and how the OHC acts as an amplifier for the IHC. They state that it is known that low frequencies present in a sound signal can mask the higher frequencies—presumably because the OHC is not amplifying the higher frequency correctly when the OHC is responding to low frequency disturbances. However, they emphatically state that "although vestibular hair cells are maximally sensitive to low frequencies they typically do not respond to airborne infrasound. Rather, they normally respond to mechanical inputs resulting from head movements and positional changes with their output controlling muscle reflexes to maintain posture and eye position." It is completely unknown how the very few neural paths from the OHC to the brain respond, if they do at all (95% of the connections are between the IHC and the brain). So at this moment, inner ear experts have not found a method for airborne infrasound to impact the inner ear. The potential exists such that the OHC respond to infrasound, but that the functional role of the connection between the OHC and the brain remains unknown. Further, the modulation of the sound received at the IHC itself has not been shown to cause nausea, headaches, or dizziness.

In the discussion of amplitude-modulated noise, it was already noted that wind turbines produce audible sound in the low frequency regime (20–200Hz). It has been shown that the sound levels in this range from some turbines are above the levels for which subjects in a Korean study have complained of psychological effects (Jung & Cheung, 2008). O'Neal (2011) also shows that the sound pressure level for frequencies between 30 and 200 Hz from two modern wind turbines at roughly 310 m are above the threshold of hearing but below the criterion for creating window rattle or other perceptible vibrations. The issue of vibration is discussed more in the next section. It is noted that the amplitude-modulated noise is most likely at the heart of annoyance complaints. In addition, amplitude-modulated noise may be a source of sleep disturbance noted by survey respondents. However, direct health impacts have not been demonstrated.

3.6.a Vibration

Vibroacoustics disease (VAD) has been identified as a potential health impact of wind turbines in the Pierpont book. Most of the literature around VAD is attributed to Branco and Alves-Pereira. Related citations attributed to Takahashi (2001), Hedge and Rasmussen (1982) though are also provided. These studies all required very clear coupling to large vibration sources such as jackhammers and heavy equipment. The latter references focus on high levels of low frequency vibrations and noise. In particular, Rasmussen studied the response of people to vibrating floors and chairs. The vibration displacements in the study were on the order of 0.01 cm (or 1000 times larger than the motion found 100 m from a wind farm in a seismic study (Styles et al., 2005). Takahashi used loud speakers placed 2 m from subjects' bodies, only testing audible frequencies 20–50 Hz, using pressure levels on the order of 100–110 dB (roughly 30 dB higher than any sound measured from a wind turbine in this frequency range) to induce vibrations at various points on the body. The Hedge source is not a study but a bulleted list of points that seem to go along with a lecture in an ergonomics class for which no citations are provided. Branco's work is slightly different in that she considered very long-term exposures to moderately intense vibration inputs. While there may be possible connection to wind turbines, at present, the connection is not substantiated given the very low levels of vibration and airborne ILFN that have been measured from wind turbines.

While vibroacoustic disease may not be substantiated, vibration levels that lead to annoyance or feelings of uneasiness may be more plausible. Evidence for these responses is discussed below.

Pierpont refers to a paper by Findeis and Peters (2004). This reference describes a situation in Germany where complaints of disturbing sound and vibration were investigated through the measurement of the vibration and acoustics within the dwelling, noting that people complained about vibrations that were not audible. The one figure provided in the text shows that people were disturbed by what was determined to be structure-borne sound that was radiated by walls and floors at levels equivalent to 65 dB at 10 Hz and 40 dB at 100 Hz. The 10 Hz level is just below audible. The level reported at 100 Hz, however, is just above the hearing threshold. The authors concluded that the disturbances were due to a component of the HVAC system that coupled directly to the building.

The Findeis and Peters (2004), report is reminiscent of papers related to investigations of "haunted" spaces (Tandy, 1998, 1999). In these studies room frequencies around 18 Hz were found. The studies hypothesized that apparitions were the result of eye vibrations (the eye is sensitive to 18 Hz) induced by the room vibration field. In one of these studies, a ceiling fan was found to be the source of the vibration. In the other, the source was not identified.

When the source was identified in the previously mentioned studies, there appears to be an obvious physical coupling mechanism. In other situations it has been estimated that airborne disturbances have influenced structures. A NASA report from 1982 gives a figure that estimates the necessary sound pressure level at various frequencies to force vibrations in windows, walls, and floors of typical buildings (Stephens, 1982). The figure on page 14 of that report shows infrasound levels of 70–80 dB can induce wall and floor vibrations. On page 39 the report also shows some floor vibration levels that were associated with a wind turbine. On the graph these were the lowest levels of vibration when compared to vibrations from aircraft noise and sonic booms. Another figure on page 43 shows vibrations and perception across the infrasonic frequency range. Again, wind turbine data are shown, and they are below the perception line.

A second technical report (Kelley, 1985) from that timeframe describes disturbances from the MOD-1 wind turbine in Boone, North Carolina. This was a downwind turbine mounted on a truss tower. Out of 1000 homes within about 2 km, 10 homes experienced room vibrations under certain wind conditions. A careful measurement campaign showed that indeed these few homes had room vibrations related to the impulsive noise unique to downwind turbines. The report contains several findings including the following: 1) the disturbances inside the homes were linked to the impulsive sound generated by the turbine (due to tower wake/blade interaction) and not seismic waves, 2) the impulsive signal was feeding energy into the vibrational modes of the rooms, floors, and walls where the floor/wall modes were the only modes in the infrasonic range, 3) people felt the disturbance more than they heard it, 4) peak vibration values were measured in the frequency range 10–20 Hz (floor/wall resonances) and it was deduced that the wall facing the turbine was being excited, 5) the fact that only 10 homes out of 1000 (scattered in various directions around the turbine) were affected was shown to be related to complicated sound propagation paths, and 6) while the shape of the impulse itself was given much attention and was shown to be a driving force in the coupling to the structural vibrations, comments were made in the report to the effect that nonimpulsive signals with energy at the right frequency could couple into the structure. The report describes a situation in Oregon where resonances in the flow through an exhaust stack of a gas-run turbine plant had an associated slow modulation of the sound leading to annoyance near the plant. Again it was found that structural modes in nearby homes were being excited but this time by an acoustic field that was not impulsive in nature. This is an important point because modern wind turbines do not create impulsive noise with strong content around 20 Hz like the downwind turbine in North Carolina. Instead, they generate amplitude-modulated sound around 1 kHz as well as broadband infrasound (van den Berg, 2004). The broadband infrasound that also existed for the North Carolina turbine was not shown to be responsible for the disturbances. As well, the amplitude-modulated noise that existed was not shown to be responsible for the disturbances. So, while there are comparisons made to the gas turbine power plant and to the HVAC system component where the impulsiveness of the sound was not the same, direct comment on the effect of modern turbines on the vibration of homes is not possible.

A recent paper by Bolin et al. (2011), surveys much of the low frequency literature pertinent to modern wind turbines and notes that all measurements of indoor and outdoor levels of sound simultaneously do not show the same amplification and ringing of frequencies associated with structural resonances similar to what was found in North Carolina. Instead the sound inside is normally less than the sound outside the structure. Bolin et al. (2011) note that measurements indicate that the indoor ILFN from wind turbines typically comply with national guidelines (such as the Danish guideline for 44 dB(A) outside a dwelling). However, this does not preclude a situation where levels would be found to be higher than the standards. They propose that further investigations of an individual dwelling should be conducted if the measured difference between C-weighted and A-weighted sound pressure level of outdoor exposure is greater than 15 dB. A similar criterion is noted in the non-peer reviewed report by Kamperman et al. (2008).

Related to room vibration is window rattle. This topic is described in the NASA reports, discussed above (Stephens, 1982) and discussed in the articles by Jung and Cheung (2008) and O’Neal (2011). In these articles it has been noted that window rattle is often induced by vibrations between 5 and 9 Hz, and measurements from wind turbines show that there can be enough energy in this range to induce window rattle. Whether the window rattle then generates its own sound field inside a room at an amplitude great enough to disturb the human body is unknown.

Seismic transmission of vibration at the North Carolina site was considered. In that study the seismic waves were ruled out as too low of amplitude to induce the room vibrations that were generated. Related are two sets of measurements that were taken near wind farms to assess the potential impact of seismic activity on extremely sensitive seismic measurement stations (Styles, 2005, Schofield, 2010). One study considered both waves traveling in the ground and the coupling of airborne infrasound to the ground, showing that the dominant source of seismic motion is the Rayleigh waves in the ground transmitted directly by the tower, and that the airborne infrasound is not playing a role in creating measurable seismic motion. The two reports indicate that at 100 meters from a wind turbine farm (>6 turbines) the maximum motion that is induced is 120 nanometers (at about 1 Hz). A nanometer is 10^{-9} m. So this is 1.2×10^{-7} m of ground displacement. Extremely sensitive measuring devices have been used to detect this slight motion. To put the motion in perspective, the diameter of a human hair is on the order of 10^{-6} m. These findings indicate that seismic motion induced from one or two turbines is so small that it would be difficult to induce any physical or structural response.

Hessler and Hessler, (2010) reviewed various state noise limits and discussed them in connection with wind turbines. The article contains a few comments related to low frequency noise. It is stated that, “a link between health complaints and turbine noise has only been asserted based on what is essentially anecdotal evidence without any valid epidemiological studies or scientific proof of any kind.” The article states that if a metric for low frequency noise is needed, then a limit of 65 dB(C) could be used. This proposed criterion is not flexible for use in different environments such as rural vs. city. In this sense, Bolin et als’ suggestion of checking for a difference between C-weighted and A-weighted sound pressure level of outdoor exposure greater than 15 dB is more appropriate. This value of 15 dB, was based on past complaints associated with combustion turbines. The Bolin article, however, also cautions that obtaining accurate low frequency measurements for wind turbines is difficult because of the presence of wind. Even sophisticated windscreens cannot eliminate the ambient low frequency wind noise.

Leventhal (2006) notes that when hearing and deaf subjects are tested simultaneously, the subjects’ chests would resonate with sounds in the range of 50–80 Hz. However, the amplitude of the sound had to be 40–50 dB higher than the human hearing threshold for the deaf subjects to report the chest vibration. This leads one to conclude that chest resonance in isolation should not be associated with inaudible sound. If a room is vibrating due to a structural resonance, such levels may be obtained. Again, this effect has never been measured associated with a modern wind turbine.

The stimulation of house resonances and self-reported ill-effects due to a modern wind turbine appear in a report by independent consultants that describes pressure measurements taken inside and outside of a home in Falmouth Massachusetts in the spring of 2011 (Ambrose & Rand, 2011). The measurements were taken at roughly 500 meters from a single 1.65 MW stall-regulated turbine when the wind speeds were relatively high: 20-30 m/s at hub height. The authors noted feeling ill when the dB(A) levels indoors were between 18 and 24 (with a corresponding dB(G) level of 51-64). They report that they felt effects both inside and outside but preferred to be outside where the dB(A) levels ranged from 41-46 (with corresponding dB(G) levels from 54-65.) This is curious because weighted measurements account for human response and the weighted values were higher outside. However, the actual dB(L) levels were higher inside.

The authors present some data indicating that the G-weighted value of the pressure signal is often greater than 60 dB(G), the averaged threshold value proposed by Salt and Hullar (2011) for OHC activation. However, the method used to obtain the data is not presented, and the time scale over which the data are presented (< 0.015 seconds or 66 Hz) is too short to properly capture the low frequency content.

The data analysis differed from the common standard of practice in an attempt to highlight weaknesses in the standard measurement approach associated with the capture of amplitude modulation and ILFN. This departure from the standard is a useful step in defining a measurement technique such as that called for in a report by HGC Engineering (HGC, 2010), that notes policy making entities should "consider adopting or endorsing a proven measurement procedure that could be used to quantify noise at infrasonic frequencies."

The measurements by Ambrose and Rand (2011) show a difference in A and C weighted outdoor sound levels of around 15 dB at the high wind speeds (which is Bolin et. al.'s recommended value for triggering further interior investigations). The simultaneous indoor and outdoor measurements indicate that at very low frequencies (2-6 Hz) the indoor pressure levels are greater than those outdoors. It is useful to note that the structural forcing at the blade-passage-frequency, the time delay and the subsequent ringing that was present in the Boone homes (Kelley, 1985) is not demonstrated by Ambrose and Rand (2011). This indicates that the structural coupling is not forced by the amplitude modulation and is due to a much subtler process. Importantly, while there is an amplification at these lower frequencies, the indoor levels (unweighted) are still far lower than any levels that have ever been shown to cause a physical response (including the activation of the OHC) in humans.

The measurements did reveal a 22.9 Hz tone that was amplitude modulated at approximately the blade passage frequency. The source of the tone was not identified, and no indication as to whether the tone varied with wind speed was provided, a useful step to help determine whether the tone is aerodynamically generated. The level of this tone is shown to be higher than the OHC activation threshold. The 22.9 Hz tone did not couple to the structure and showed the normal attenuation from outside to inside the structure. In order to determine if the results that show potential tonal activation of the OHC are generalizable, it is necessary to identify the source of this tone which could be unique to stall-regulated turbines or even unique to this specific brand of turbine.

Finally, the measurements shown in the report are atypical within the wind turbine measurement literature and the data analysis is not fully described. Also, the report offers no plausible coupling mechanism of the sound waves to the body beyond that proposed by Salt and Hullar (2011). Because of this, the results are suggestive but require corroboration of the measurements and scientifically based mechanisms for human health impact.

3.6.b Summary of Claimed Health Impacts

In this section, the potential health impacts due to noise and vibration from wind turbines was discussed. Both the infrasonic and low frequency noise ranges were considered. Assertions that infrasound and low frequency noise from turbines affect the vestibular system either through airborne coupling to humans are not empirically supported. In the multitude of citations given in the popular media as to methods in which the vestibular system is influenced, all refer to situations in which there is direct vibration coupling to the body or when the wave amplitudes are orders of magnitudes greater than those produced by wind turbines. Recent research has found one potential path in the auditory system, the OHC, in which infrasound might be sensed. There is no evidence, however, that when the OHC sense infrasound, it then leads to any of the symptoms reported by complainants. That the infrasound and low frequency noise couple to humans through the forcing of structural vibration is plausible but has not been demonstrated for modern wind turbines. In addition, should it be shown that such a coupling occurs, research indicates that the coupling would be transient and highly dependent on wind conditions and localized to very few homes surrounding a turbine.

Seismic activity near a turbine due to vibrations transmitted down the tower has been measured, and the levels are too low to produce vibrations in humans.

The audible noise from wind turbines, in particular the amplitude modulated trailing edge noise, does exist, changes level based on atmospheric conditions, can change character from swish to thump-based on atmospheric effects, and can be perceived from home to home differently based on propagation effects. This audible sound has been noted by complainants as a source of annoyance and a cause for sleep disruption. Some authors have proposed nighttime noise regulations and regulations based on shorter time averages (vs. annual averages) as a means to reduce annoyance from this noise source. Some have conjectured that the low frequency content of the amplitude-modulated noise is responsible for the annoyance. They have proposed that the difference between the measured outdoor A- and C- weighted sound pressure levels could be used to identify situations in which the low frequency content is playing a larger role. Further, they note that this difference might be used as part of a regulation as a means to reduce annoyance.

Chapter 4

Findings

Based on the detailed review of the scientific literature and other available reports and consideration of the strength of scientific evidence, the Panel presents findings relative to three factors associated with the operation of wind turbines: noise and vibration, shadow flicker, and ice throw. The findings that follow address specifics in each of these three areas.

4.1 Noise

4.1.a Production of Noise and Vibration by Wind Turbines

1. Wind turbines can produce unwanted sound (referred to as noise) during operation. The nature of the sound depends on the design of the wind turbine. Propagation of the sound is primarily a function of distance, but it can also be affected by the placement of the turbine, surrounding terrain, and atmospheric conditions.
    a. Upwind and downwind turbines have different sound characteristics, primarily due to the interaction of the blades with the zone of reduced wind speed behind the tower in the case of downwind turbines.
    b. Stall regulated and pitch controlled turbines exhibit differences in their dependence of noise generation on the wind speed
    c. Propagation of sound is affected by refraction of sound due to temperature gradients, reflection from hillsides, and atmospheric absorption. Propagation effects have been shown to lead to different experiences of noise by neighbors.
    d. The audible, amplitude-modulated noise from wind turbines ("whooshing") is perceived to increase in intensity at night (and sometimes becomes more of a "thumping") due to multiple effects: i) a stable atmosphere will have larger wind gradients, ii) a stable atmosphere may refract the sound downwards instead of upwards, iii) the ambient noise near the ground is lower both because of the stable atmosphere and because human generated noise is often lower at night.
2. The sound power level of a typical modern utility scale wind turbine is on the order of 103 dB(A), but can be somewhat higher or lower depending on the details of the design and the rated power of the turbine. The perceived sound decreases rapidly with the distance from the wind turbines. Typically, at distances larger than 400 m, sound

pressure levels for modern wind turbines are less than 40 dB(A), which is below the level associated with annoyance in the epidemiological studies reviewed.

3. Infrasound refers to vibrations with frequencies below 20 Hz. Infrasound at amplitudes over 100–110 dB can be heard and felt. Research has shown that vibrations below these amplitudes are not felt. The highest infrasound levels that have been measured near turbines and reported in the literature near turbines are under 90 dB at 5 Hz and lower at higher frequencies for locations as close as 100 m.
4. Infrasound from wind turbines is not related to nor does it cause a "continuous whooshing."
5. Pressure waves at any frequency (audible or infrasonic) can cause vibration in another structure or substance. In order for vibration to occur, the amplitude (height) of the wave has to be high enough, and only structures or substances that have the ability to receive the wave (resonant frequency) will vibrate.

4.1.b Health Impacts of Noise and Vibration

1. Most epidemiologic literature on human response to wind turbines relates to self-reported "annoyance," and this response appears to be a function of some combination of the sound itself, the sight of the turbine, and attitude towards the wind turbine project.
   a. There is limited epidemiologic evidence suggesting an association between exposure to wind turbines and annoyance.
   b. There is insufficient epidemiologic evidence to determine whether there is an association between noise from wind turbines and annoyance independent from the effects of seeing a wind turbine and vice versa.
2. There is limited evidence from epidemiologic studies suggesting an association between noise from wind turbines and sleep disruption. In other words, it is possible that noise from some wind turbines can cause sleep disruption.
3. A very loud wind turbine could cause disrupted sleep, particularly in vulnerable populations, at a certain distance, while a very quiet wind turbine would not likely disrupt even the lightest of sleepers at that same distance. But there is not enough evidence to

provide particular sound-pressure thresholds at which wind turbines cause sleep disruption. Further study would provide these levels.

4. Whether annoyance from wind turbines leads to sleep issues or stress has not been sufficiently quantified. While not based on evidence of wind turbines, there is evidence that sleep disruption can adversely affect mood, cognitive functioning, and overall sense of health and well-being.
5. There is insufficient evidence that the noise from wind turbines is *directly (i.e., independent from an effect on annoyance or sleep)* causing health problems or disease.
6. Claims that infrasound from wind turbines directly impacts the vestibular system have not been demonstrated scientifically. Available evidence shows that the infrasound levels near wind turbines cannot impact the vestibular system.
    a. The measured levels of infrasound produced by modern upwind wind turbines at distances as close as 68 m are well below that required for non-auditory perception (feeling of vibration in parts of the body, pressure in the chest, etc.).
    b. If infrasound couples into structures, then people inside the structure could feel a vibration. Such structural vibrations have been shown in other applications to lead to feelings of uneasiness and general annoyance. The measurements have shown no evidence of such coupling from modern upwind turbines.
    c. Seismic (ground-carried) measurements recorded near wind turbines and wind turbine farms are unlikely to couple into structures.
    d. A possible coupling mechanism between infrasound and the vestibular system (via the Outer Hair Cells (OHC) in the inner ear) has been proposed but is not yet fully understood or sufficiently explained. Levels of infrasound near wind turbines have been shown to be high enough to be sensed by the OHC. However, evidence does not exist to demonstrate the influence of wind turbine-generated infrasound on vestibular-mediated effects in the brain.
    e. Limited evidence from rodent (rat) laboratory studies identifies short-lived biochemical alterations in cardiac and brain cells in response to short exposures to emissions at 16 Hz and 130 dB. These levels exceed measured infrasound levels from modern turbines by over 35 dB.

7. There is no evidence for a set of health effects, from exposure to wind turbines, that could be characterized as a "Wind Turbine Syndrome."
8. The strongest epidemiological study suggests that there is not an association between noise from wind turbines and measures of psychological distress or mental health problems. There were two smaller, weaker, studies: one did note an association, one did not. Therefore, we conclude the weight of the evidence suggests no association between noise from wind turbines and measures of psychological distress or mental health problems.
9. None of the limited epidemiological evidence reviewed suggests an association between noise from wind turbines and pain and stiffness, diabetes, high blood pressure, tinnitus, hearing impairment, cardiovascular disease, and headache/migraine.

4.2 Shadow Flicker

4.2.a Production of Shadow Flicker

Shadow flicker results from the passage of the blades of a rotating wind turbine between the sun and the observer.

1. The occurrence of shadow flicker depends on the location of the observer relative to the turbine and the time of day and year.
2. Frequencies of shadow flicker elicited from turbines is proportional to the rotational speed of the rotor times the number of blades and is generally between 0.5 and 1.1 Hz for typical larger turbines.
3. Shadow flicker is only present at distances of less than 1400 m from the turbine.

4.2.b Health Impacts of Shadow Flicker

1. Scientific evidence suggests that shadow flicker does not pose a risk for eliciting seizures as a result of photic stimulation.
2. There is limited scientific evidence of an association between annoyance from prolonged shadow flicker (exceeding 30 minutes per day) and potential transitory cognitive and physical health effects.

4.3 Ice Throw

4.3.a Production of Ice Throw

Ice can fall or be thrown from a wind turbine during or after an event when ice forms or accumulates on the blades.

1. The distance that a piece of ice may travel from the turbine is a function of the wind speed, the operating conditions, and the shape of the ice.
2. In most cases, ice falls within a distance from the turbine equal to the tower height, and in any case, very seldom does the distance exceed twice the total height of the turbine (tower height plus blade length).

4.3.b Health Impacts of Ice Throw

1. There is sufficient evidence that falling ice is physically harmful and measures should be taken to ensure that the public is not likely to encounter such ice.

4.4 Other Considerations

In addition to the specific findings stated above for noise and vibration, shadow flicker and ice throw, the Panel concludes the following:

1. Effective public participation in and direct benefits from wind energy projects (such as receiving electricity from the neighboring wind turbines) have been shown to result in less annoyance in general and better public acceptance overall.

Chapter 5

Best Practices Regarding Human Health Effects Of Wind Turbines

Broadly speaking, the term "best practice" refers to policies, guidelines, or recommendations that have been developed for a specific situation. Implicit in the term is that the practice is based on the best information available at the time of its institution. A best practice may be refined as more information and studies become available. The panel recognizes that in countries which are dependent on wind energy and are protective of public health, best practices have been developed and adopted.

In some cases, the weight of evidence for a specific practice is stronger than it is in other cases. Accordingly, best practice* may be categorized in terms of the evidence available, as shown in Table 3:

Table 3

Descriptions of Three Best Practice Categories

Category	Name	Description
1	Research Validated Best Practice	A program, activity, or strategy that has the highest degree of proven effectiveness supported by objective and comprehensive research and evaluation.
2	Field Tested Best Practice	A program, activity, or strategy that has been shown to work effectively and produce successful outcomes and is supported to some degree by subjective and objective data sources.
3	Promising Practice	A program, activity, or strategy that has worked within one organization and shows promise during its early stages for becoming a best practice with long-term sustainable impact. A promising practice must have some objective basis for claiming effectiveness and must have the potential for replication among other organizations.

**These categories are based on those suggested in "Identifying and Promoting Promising Practices." Federal Register, Vol. 68. No 131. 131. July 2003.*
www.acf.hhs.gov/programs/ccf/about_ccf/gbk_pdf/pp_gbk.pdf

5.1 Noise

Evidence regarding wind turbine noise and human health is limited. There is limited evidence of an association between wind turbine noise and both annoyance and sleep disruption, depending on the sound pressure level at the location of concern. However, there are no research-based sound pressure levels that correspond to human responses to noise. A number of countries that have more experience with wind energy and are protective of public health have developed guidelines to minimize the possible adverse effects of noise. These guidelines consider time of day, land use, and ambient wind speed. Table 4 summarizes the guidelines of Germany (in the categories of industrial, commercial and villages) and Denmark (in the categories of sparsely populated and residential). The sound levels shown in the table are for nighttime and are assumed to be taken immediately outside of the residence or building of concern. In addition, the World Health Organization recommends a maximum nighttime sound pressure level of 40 dB(A) in residential areas. Recommended setbacks corresponding to these values may be calculated by software such as WindPro or similar software. Such calculations are normally to be done as part of feasibility studies. The Panel considers the guidelines shown below to be Promising Practices (Category 3) but to embody some aspects of Field Tested Best Practices (Category 2) as well.

Table 4

Promising Practices for Nighttime Sound Pressure Levels by Land Use Type

Land Use	**Sound Pressure Level, dB(A) Nighttime Limits**
Industrial	70
Commercial	50
Villages, mixed usage	45
Sparsely populated areas, 8 m/s wind*	44
Sparsely populated areas, 6 m/s wind*	42
Residential areas, 8 m/s wind*	39
Residential areas, 6 m/s wind*	37

**measured at 10 m above ground, outside of residence or location of concern*

The time period over which these noise limits are measured or calculated also makes a difference. For instance, the often-cited World Health Organization recommended nighttime noise cap of 40 dB(A) is averaged over one year (and does not refer specifically to wind turbine noise). Denmark's noise limits in the table above are calculated over a 10-minute period. These limits are in line with the noise levels that the epidemiological studies connect with insignificant reports of annoyance.

The Panel recommends that noise limits such as those presented in the table above be included as part of a statewide policy regarding new wind turbine installations. In addition, suitable ranges and procedures for cases when the noise levels may be greater than those values should also be considered. The considerations should take into account trade-offs between environmental and health impacts of different energy sources, national and state goals for energy independence, potential extent of impacts, etc.

The Panel also recommends that those involved in a wind turbine purchase become familiar with the noise specifications for the turbine and factors that affect noise production and noise control. Stall and pitch regulated turbines have different noise characteristics, especially in high winds. For certain turbines, it is possible to decrease noise at night through suitable control measures (e.g., reducing the rotational speed of the rotor). If noise control measures are to be considered, the wind turbine manufacturer must be able to demonstrate that such control is possible.

The Panel recommends an ongoing program of monitoring and evaluating the sound produced by wind turbines that are installed in the Commonwealth. IEC 61400-11 provides the standard for making noise measurements of wind turbines (International Electrotechnical Commission, 2002). In general, more comprehensive assessment of wind turbine noise in populated areas is recommended. These assessments should be done with reference to the broader ongoing research in wind turbine noise production and its effects, which is taking place internationally. Such assessments would be useful for refining siting guidelines and for developing best practices of a higher category. Closer investigation near homes where outdoor measurements show A and C weighting differences of greater than 15 dB is recommended.

5.2 Shadow Flicker

Based on the scientific evidence and field experience related to shadow flicker, Germany has adopted guidelines that specify the following:

1. Shadow flicker should be calculated based on the astronomical maximum values (i.e., not considering the effect of cloud cover, etc.).
2. Commercial software such as WindPro or similar software may be used for these calculations. Such calculations should be done as part of feasibility studies for new wind turbines.
3. Shadow flicker should not occur more than 30 minutes per day and not more than 30 hours per year at the point of concern (e.g., residences).
4. Shadow flicker can be kept to acceptable levels either by setback or by control of the wind turbine. In the latter case, the wind turbine manufacturer must be able to demonstrate that such control is possible.

The guidelines summarized above may be considered to be a Field Tested Best Practice (Category 2). Additional studies could be performed, specifically regarding the number of hours per year that shadow flicker should be allowed, that would allow them to be placed in Research Validated (Category 1) Best Practices.

5.3 Ice Throw

Ice falling from a wind turbine could pose a danger to human health. It is also clear that the danger is limited to those times when icing occurs and is limited to relatively close proximity to the wind turbine. Accordingly, the following should be considered Category 1 Best Practices.

1. In areas where icing events are possible, warnings should be posted so that no one passes underneath a wind turbine during an icing event and until the ice has been shed.
2. Activities in the vicinity of a wind turbine should be restricted during and immediately after icing events in consideration of the following two limits (in meters).

For a turbine that may not have ice control measures, it may be assumed that ice could fall within the following limit:

$$x_{\max,\, throw} = 1.5\left(2R + H\right)$$

Where: R = rotor radius (m), H = hub height (m)

For ice falling from a stationary turbine, the following limit should be used:

$$x_{\max,\, fall} = U\left(R + H\right)/15$$

Where: U = maximum likely wind speed (m/s)

The choice of maximum likely wind speed should be the expected one-year return maximum, found in accordance to the International Electrotechnical Commission's design standard for wind turbines, IEC 61400-1.

Danger from falling ice may also be limited by ice control measures. If ice control measures are to be considered, the wind turbine manufacturer must be able to demonstrate that such control is possible.

5.4 Public Participation/Annoyance

There is some evidence of an association between participation, economic or otherwise, in a wind turbine project and the annoyance (or lack thereof) that affected individuals may express. Accordingly, measures taken to directly involve residents who live in close proximity to a wind turbine project may also serve to reduce the level of annoyance. Such measures may be considered to be a Promising Practice (Category 3).

5.5 Regulations/Incentives/Public Education

The evidence indicates that in those parts of the world where there are a significant number of wind turbines in relatively close proximity to where people live, there is a close coupling between the development of guidelines, provision of incentives, and educating the public. The Panel suggests that the public be engaged through such strategies as education, incentives for community-owned wind developments, compensations to those experiencing documented loss of property values, comprehensive setback guidelines, and public education related to renewable energy. These multi-faceted approaches may be considered to be a Promising Practice (Category 3).

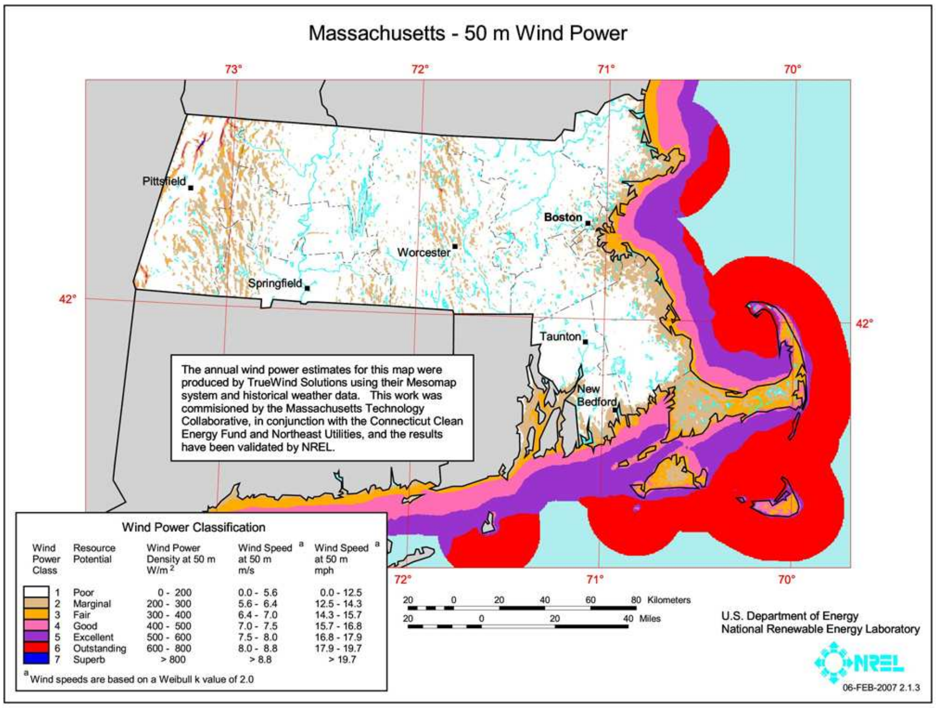
Appendix A:

Wind Turbines - Introduction to Wind Energy

Although wind energy for bulk supply of electricity is a relatively new technology, the historical precedents for it go back a long way. They are descendents of mechanical windmills that first appeared in Persia as early as the 7^{th} century (Vowles, 1932) and then re-appeared in northern Europe in the Middle Ages. They were considerably developed during the 18^{th} and 19^{th} centuries, and then formed the basis for the first electricity generating wind turbine in the late 19^{th} century. Development continued sporadically through the mid 20^{th} century, with modern turbines beginning to emerge in the 1970's. It was the introduction of other technologies, such as electronics, computers, control theory, composite materials, and computer-based simulation capability that led to the successful development of the large scale, autonomously operating wind turbines that have become so widely deployed over the past twenty years.

The wind is the most important external factor in wind energy. It can be thought of as the "fuel" of the wind turbine, even though it is not consumed in the process. The wind determines the amount of energy that is produced, and is therefore referred to as the resource. The wind resource can vary significantly, depending on the location and the nature of the surface. In the United States, the Great Plains have a relatively energetic wind resource. In Massachusetts, winds tend to be relatively low inland, except for mountaintops and ridges. The winds tend to be higher close to the coast and then increase offshore. Average offshore wind speeds generally increase with distance from shore as well. The wind resource of Massachusetts is illustrated in

Figure AA.1: Map of the Massachusetts Wind Resource (From National Renewable Energy Laboratory, http://www.windpoweringamerica.gov/images/windmaps/ma_50m_800.jpg)



This section summarizes the basic characteristics of the wind in so far as they relate to wind turbine power production. Much more detail on this topic is provided in (Manwell et al., 2009). The wind will also affect the design of the wind turbines, and for this purpose it is referred to as an "external design condition." This aspect of the wind is discussed in more detail in a later section.

AA.1 Origin of the Wind

The wind originates from sunlight due to the differential heating of various parts of the earth. This differential heating produces zones of high and low pressure, resulting in air movement. The motion of the air is also affected by earth's rotation. Considerations regarding the wind insofar as it relates to wind turbine operation include the following: (i) the winds aloft (geostrophic wind), (ii) atmospheric boundary layer meteorology, (iii) the variation of wind speed with height, (iv) surface roughness, and (v) turbulence.

The geostrophic wind is the wind in the upper atmosphere, which results from the combined effects of the pressure gradient and the earth's rotation (via the Coriolis force). The gradient wind can be thought of as an extension of the geostrophic wind, the difference in this case being that centrifugal effects are included. These result from curved isobars (lines of constant pressure) in the atmosphere. It is these upper atmosphere winds that are the source of most of the energy that eventually impinges on wind turbines. The energy in the upper atmosphere is transferred down closer to the surface via a variety of mechanisms, most notably turbulence, which is generated mechanically (via surface roughness) and thermally (via the rising of warm air and falling of cooler air).

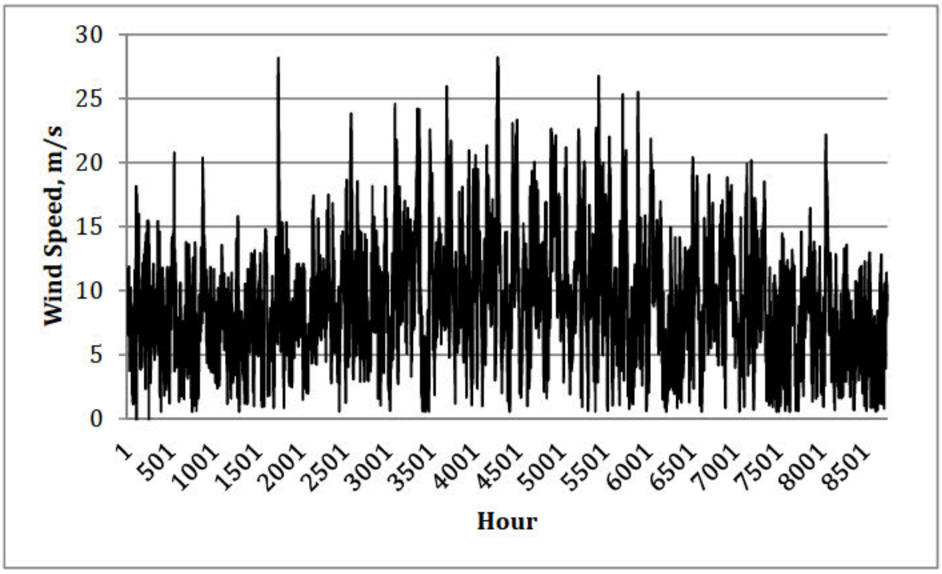
Although driven by higher altitude winds, the wind near the surface is affected by the surrounding topography (such as mountains and ridges) and surface conditions (such as tree cover or presence of buildings).

AA.2 Variability of the Wind

One of the singular characteristics of the wind is its variability, both temporal and spatial. The temporal variability includes: (i) short term (gusts and turbulence), (ii) moderately short term (e.g., hr to hr means), (iii) diurnal (variations over a day), (iv) seasonal, and (v) inter-annual (year to year). The wind may vary spatially as well, both from one location to another or with height above ground.

Figure AA.2 illustrates the variability of the hourly average wind speeds for one year at one location.

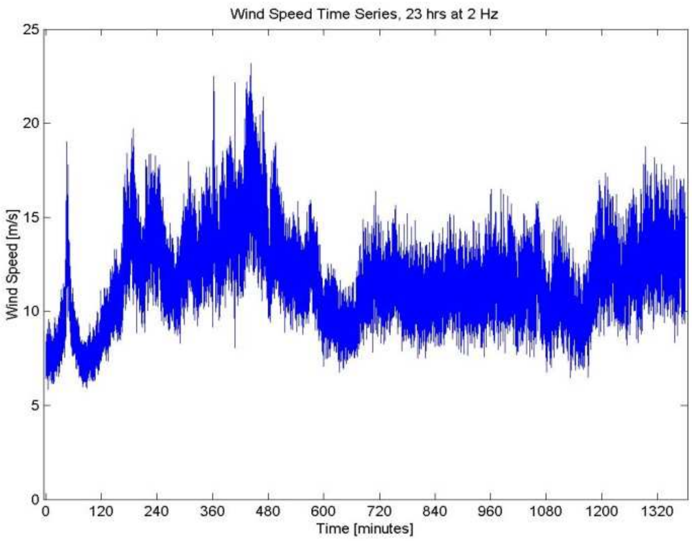
Figure AA.2: Typical hourly wind speeds over a year



As can be seen, the hourly average wind speed in this example varies significantly over the year, ranging from zero to nearly 30 m/s.

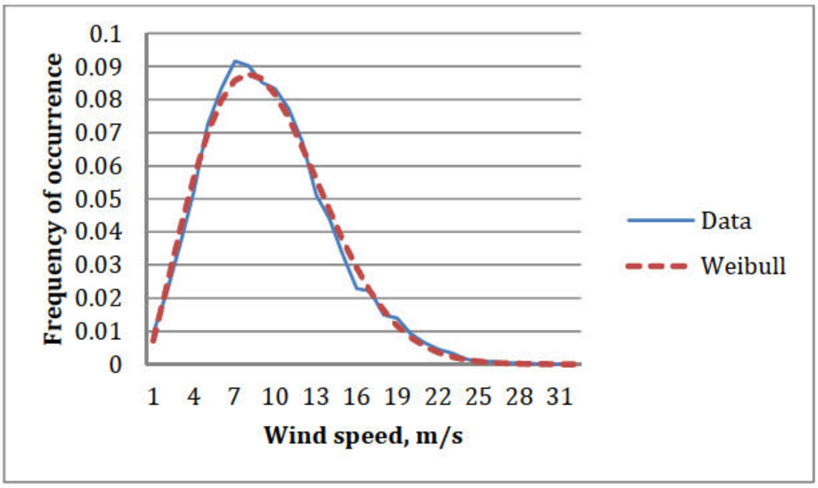
Figure AA.3 illustrates wind speed at another location recorded twice per second over a 23-hour period. There is significant variability here as well. Much of this variability in this figure is associated with short-term fluctuations, or turbulence. Turbulence has some effect on power generation, but it has a more significant effect on the design of wind turbines, due to the material fatigue that it tends to engender. Turbulence is discussed in more detail in a later section.

Figure AA.3: Typical wind data, sampled at 2 Hz for a 23-hr period



In spite of the variability in the wind time series, summary characteristics have much less variability. For example, the annual mean wind speed at a given location is generally within +/- 10% of the long-term mean at that site. Furthermore, the distribution of wind speeds, that is to say the frequency of occurrence of winds in various wind speed ranges, also tends to be similar from year. The general shape of such distributions is also similar from one location to another, even if the means are different. In fact, statistical models such as the Weibull distribution can be used to model the occurrences of various wind speeds in most locations on the earth. For example, the number of occurrences of wind speed in various ranges from the data set illustrated in Figure AA.2 are shown in Figure AA.4, together with the those occurrences as modeled by the Weibull distribution.

Figure AA.4: Typical frequency of occurrence of wind speeds, based on data and statistical model



The Weibull distribution's probability density function is given by:

$$p(U) = \left(\frac{k}{c}\right)\left(\frac{U}{c}\right)^{k-1} \exp\left[-\left(\frac{U}{c}\right)^{k}\right] \tag{1}$$

Where c = Weibull scale factor (m/s) and k = Weibull shape factor (dimensionless)

For the purposes of modeling the occurrences of wind speeds, the scale and shape factors may be approximated as follows:

$$k \approx \left(\frac{\sigma_U}{\overline{U}}\right)^{-1.086} \tag{2}$$

$$c \approx \overline{U}\left(0.568 + 0.433 / k\right)^{-(1/k)} \tag{3}$$

Where $\overline{U}$ is the long-term mean wind speed (m/s, based on 10 min or hourly averages) and σ_U is the standard deviation of the wind speed, based on the same 10 min or hourly averages.

AA.3 Power in the Wind

The power available in the wind can be predicted from the fundamental principles of fluid mechanics. First of all, the energy per unit mass of a particle of air is given simply by ½ times the square of the velocity, U (m/s). The mass flow rate of the air (kg/s) through a given area A (m^2) perpendicular to the direction of the wind is $\dot{m} = \rho AU$, where ρ is the density of the air (kg/m^3). The power in the wind per unit area, P/A, (W/m^2) is then:

$$P / A = (\dot{m} / A)\frac{1}{2}U^2 = \frac{1}{2}\rho U^3 \qquad (4)$$

AA.4 Wind Shear

Wind shear is the variation of wind speed with height. Wind shear has relevance to power generation, to turbine design, and to noise generation. The variation of wind speed with height is typically modeled with a power law as follows:

$$U_2 = U_1 [h_2 / h_1]^{\alpha} \qquad (5)$$

Where U_1 = speed at reference height h_1, U_2 is the wind speed to be estimated at height h_2 and α is the power law exponent. Values of the exponent typically range from a 0.1 for smooth surfaces to 0.4 for very rough surfaces (such as forests or built-up areas.)

Wind shear can also be affected by the stability of the atmosphere. Equations have been developed that allow the incorporation of stability parameters in the analysis, but these too are outside the scope of this overview.

AA.5 Wind and Wind Turbine Structural Issues

As discussed previously, the wind is of particular interest in wind turbine applications, since it is the source of the energy. It is also the source of significant structural loads that the turbine must be able to withstand. Some of these loads occur when the turbine is operating; others occur when it is stopped. Extreme winds, for example, are likely to affect a turbine when it is stopped. High winds with sudden directional change during operation can also induce high loads. Turbulence during normal operation results in fatigue. The following is a summary of the key aspects of the wind that affect the design of wind turbines. More details may be found in (Manwell et al., 2009).

AA.5.a Turbulence

Turbulence in the wind can have significant effect on the structure of a wind turbine as well as its operation, and so it must be considered in the design process. The term “turbulence” refers to the short-term variations in the speed and direction of the wind. It manifests itself as apparently random fluctuations superimposed upon a relatively steady mean flow. Turbulence is not actually random, however. It has some very distinct characteristics, at least in a statistical sense.

Turbulence is characterized by a number of measures. These include: (i) turbulence intensity, (ii) turbulence probability density functions (pdf), (iii) autocorrelations, (iv) integral time scales and length scales, and (v) power spectral density functions. Discussion of the physics of turbulence is outside the scope of this overview.

AA.5.b Gusts

A gust is discrete increase and then decrease in wind speed, possibly associated with a change in wind direction, which can be of significance to the design of a wind turbine. Gusts are typically associated with turbulence.

AA.5.c Extreme Winds

Extreme winds need to be considered for the design of a wind turbine. Extreme winds are normally associated with storms. They occur relatively rarely, but often enough that the possibility of their occurring cannot be ignored. Statistical models, such as the Gumbel distribution (Gumbel, 1958), are used to predict the likelihood of such winds occurring at least once every 50 or 100 years. Such intervals are called return periods.

AA.5.d Soils

Soils are also important for the design and installation of a wind turbine. In particular, the nature of the soil will affect the design of the wind turbine foundations. Discussion of soils is outside the scope of this overview.

AA.6 Wind Turbine Aerodynamics

The heart of the wind turbine is the rotor. This is a device that extracts the kinetic energy from the wind and converts it into a mechanical form. Below is a summary of wind turbine rotor aerodynamics. More details may be found in (Manwell et al., 2009).

A wind turbine rotor is comprised of blades that are attached to a hub. The hub is in turn attached to a shaft (the main shaft) which transfers the energy through the remainder of the drive train to the generator where is it converted to electricity. The maximum power that a rotor can extract from the wind is first of all limited by the power in the wind, which passes through an area defined by the passage of the rotor. At the present time, most wind turbines utilize a rotor with a horizontal axis. That is, the axis of rotation is (nominally) parallel to the earth's surface. Accordingly, the area that is swept out by the rotor is circular. Assuming a rotor radius of *R* (m), the maximum power *P* (W) available in the wind is:

$$P = \frac{1}{2}\rho\pi R^2 U^3 \tag{6}$$

Early in the 20th century, it was shown by Betz (among others, see [4]) that the maximum power that could be extracted was less than the power in the wind; in fact, it was 16/27 times that value. Betz' work led to the definition of a power coefficient, C_p, which expresses the ratio of the actual power extracted by a rotor to the power in the wind. When considering efficiencies of other components in the drive train, as expressed by the η, the total power out a wind turbine, P_{WT}, would be given by:

$$P_{WT} = C_p \eta \frac{1}{2}\rho\pi R^2 U^3 \tag{7}$$

The maximum value of the power coefficient, known as the Betz limit, is thus 16/27.

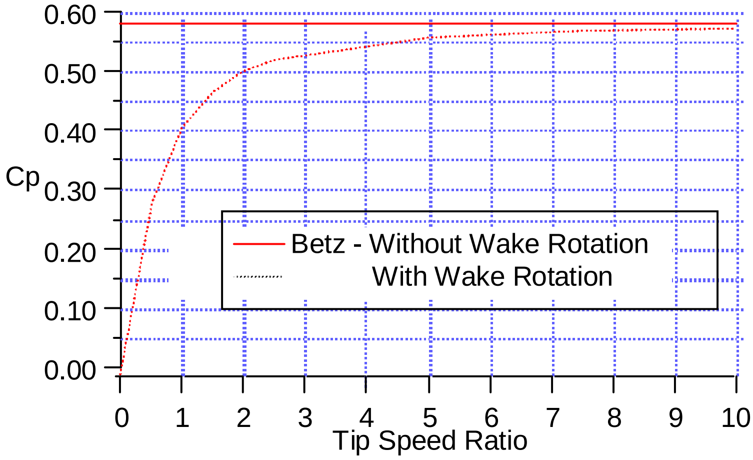
Betz' original analysis was based on the fundamental principles of fluid mechanics including linear momentum theory. It also included the following assumptions: (i) homogenous, incompressible, steady state fluid flow; (ii) no frictional drag; (iii) a rotor with an infinite number of (very small) blades; (iv) uniform thrust over the rotor area; (v) a non-rotating wake; and (vi) the static pressure far upstream and far downstream of the rotor that is equal to the undisturbed ambient static pressure.

A real rotor operating on a horizontal axis will result in a rotating wake. Some of the energy in the wind will go into that rotation and will not be available for conversion into mechanical power. The result is that the maximum power coefficient will actually be less than the Betz limit. The derivation of the maximum power coefficient for the rotating wake case use a number of terms: (i) the rotational speed of turbine rotor, Ω, in radians/sec; (ii) tip speed ratio, $\lambda = \Omega R/U$; (iii) local speed ratio, $\lambda_r = \lambda\, r/R$; (iv) rotational speed of wake, ω; (v) an axial induction factor, *a*, which relates the free stream wind speed to the wind speed at the rotor and the wind speed in the far wake ($U_{rotor} = (1-a)U_{free\ stream}$ and $U_{wake} = (1-2a)U_{free\ stream}$); and (vi) an angular induction factor, $a' = \omega/2\,\Omega$. According to this analysis, the maximum possible power coefficient is given by:

$$C_{P,\max} = \frac{8}{\lambda^2}\int_0^{\lambda} a'(1-a)\lambda_r^3\,d\lambda_r \qquad (8)$$

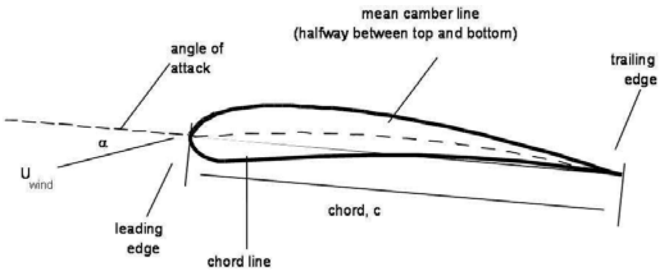
The maximum power coefficient for a rotor with a rotating wake and the Betz limit are illustrated in Figure AA.5.

Figure AA.5: Maximum theoretical power coefficients for rotating and non-rotating wakes



Neither of the analyses summarized above gives any indication as to what the blades of the rotor actually look like. For this purpose, a method called blade element momentum (BEM) theory was developed. This approach assumes that the blades incorporate an airfoil cross section. Figure AA.6 shows a typical airfoil, including some of the nomenclature.

Figure AA.6: Airfoil nomenclature



The BEM method equates the forces on the blades associated with air flowing over the airfoil with forces associated with the change in momentum of the air passing through the rotor. The starting point for this analysis is the assessment of the lift force on an airfoil. Lift is a force perpendicular to the flow. It is given by

$$\tilde{F}_L = C_L \frac{1}{2} \rho c U^2 \tag{9}$$

Where:

$\tilde{F}_L$ = force per unit length, N/m

C_L = lift coefficient, -

c = chord length (distance from leading edge to trailing edge of airfoil, m)

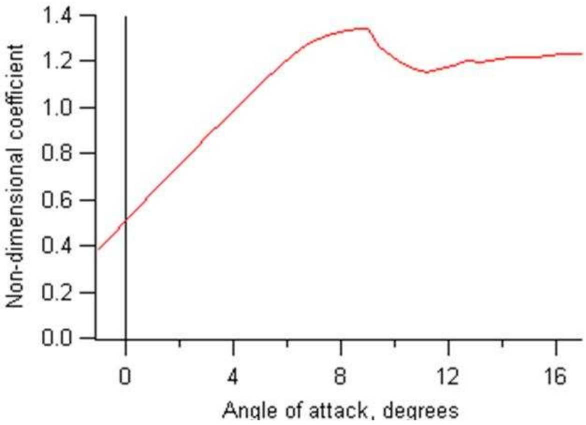
Thin airfoil theory predicts that for a very thin, ideal airfoil the lift coefficient is given by

$$C_L = 2\pi \sin\alpha \tag{11}$$

where α is the angle of attack, which is the angle between the flow and the chord line of the airfoil.

The lift coefficient for real airfoils typically includes a constant term but the slope, at least for low angles of attack, is similar to that for an ideal airfoil. For greater angles of attack (above 10–15 degrees) the lift coefficient begins to decrease, eventually approaching zero. This is known as stall. A typical lift coefficient vs. angle of attack curve is illustrated in Figure AA.7.

Figure AA.7: Typical airfoil lift vs. angle of attack



There is always some drag force associated with fluid flow. This is a force is in line with the flow. Drag force (per unit length) is given by:

$$\tilde{F}_D = C_D \frac{1}{2} \rho c U^2 \qquad (12)$$

Where C_D = drag coefficient

When designing blades for a wind turbine, it is generally desired to minimize the drag to lift ratio at the design point. This generally results in a lift coefficient in the vicinity of 1.0 and a drag coefficient of approximately 0.006, although these values can differ depending on the airfoil.

Blade element momentum theory, as noted above, relates the blade shape to its performance. The following approach is used. The blade is divided into elements and the rotor is divided into annuli. Two simultaneous equations are developed: one expresses the lift and drag coefficient (and thus forces) on the blade elements as a function of airfoil data and the wind's angle of attack. The other expresses forces on the annuli as a function of the wind through the rotor, rotor characteristics, and changes in momentum. Some of the key assumptions are: (i) the forces on blade elements are determined solely by lift/drag characteristics of the airfoil, (ii) there is no flow along the blade, (iii) lift and drag force are perpendicular and parallel respectively to a “relative wind,” and (iv) forces are resolved into components perpendicular to the rotor (“thrust”) and tangential to it (“torque”).

Using BEM theory, it may be shown for an ideal rotor that the angle of relative wind, φ, as a function of tip speed ratio and radial position on the blade is given by:

$$\varphi = \left(\tfrac{2}{3}\right)\tan^{-1}\left(1/\lambda_r\right) \qquad (13)$$

Similarly, the chord length is given by:

$$c = \frac{8\pi r}{BC_L}\left(1-\cos\varphi\right) \qquad (14)$$

Where B = the number of blades

There are some useful observations to be drawn out of the above equations. First of all, in the ideal case the blade will be twisted. In fact, the twist angle will differ from the angle of relative wind by the angle of attack and a reference pitch angle θ_p as follows:

$$\theta_T = \varphi - \alpha - \theta_p \qquad (15)$$

It may also be noted that the twist angle will at first increase slowly when moving from the tip inward and then increase more rapidly. Second, the chord of the blade will also increase upon moving from the tip inward, at first slowly and then more rapidly. In the ideal case then, a wind turbine blade is both significantly twisted and tapered. Real blades, however, are designed with a less than optimal shape for a variety of practical reasons.

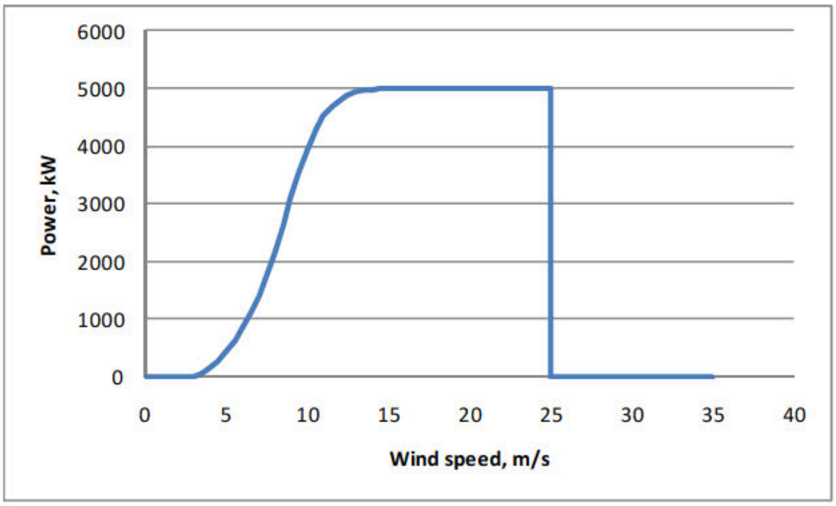
Another important observation has to do with the total area of the blades in comparison to the swept area. The ratio of the projected blade area is known as the solidity, σ. For a given angle of attack, the solidity will decrease with increasing tip speed ratio. For example, assuming a lift coefficient C_L of 1.0, the solidity of an optimum rotor designed to operate at a tip speed ratio of 2.0 is 0.43 whereas an optimum rotor designed to operate at a tip speed ratio of 6.0 would have a solidity of 0.088. It is therefore apparent that in order to keep blade material (and thus cost) to a minimum, it is desirable to design for a tip speed ratio as high as possible.

There are other considerations in selecting a design tip speed ratio for a turbine other than the solidity, however. On the one hand, higher tip speed ratios will result in gearboxes with a lower speed up ratio for a given turbine. On the other hand, the effect of drag and surface roughness of the blade surface may become more significant for a higher tip speed ratio rotor. This effect could result in decreased performance. Another concern is material strength. The total forces on the rotor are nearly the same on the rotor regardless of the solidity. Thus the stresses would be higher. A final consideration is noise. Higher tip speed ratios generally result in more noise produced by the blades.

There are numerous other considerations regarding the design of a wind turbine rotor, including tip losses, type of airfoil to be used, ease of manufacturing and transport, type of control used, selection of materials, etc. These are all outside the scope of this overview, however.

Real wind turbine rotors are designed taking into account many factors, including but not only their aerodynamic performance. In addition, the rotor must be controlled so as to generate electricity most effectively and so as to withstand continuously fluctuating forces during normal operation and extreme loads during storms. Accordingly, a wind turbine rotor does not in general operate at its own maximum power coefficient at all wind speeds. Because of this, the power output of a wind turbine is generally described by curve, known as a power curve, rather than an equation such as the one for P_{WT} which given earlier. Figure AA.8 illustrates a typical power curve. As shown there, below the cut-in speed (3 m/s in the example) no power is produced. Between cut-in and rated wind speed (14.5 m/s in this example), the power increases significantly with wind speed. Above the rated speed, the power produced is constant, regardless of the wind speed, and above the cut-out speed (25 m/s in the example), the turbine is shut down.

Figure AA.8: Typical wind turbine power curve



AA.7 Wind Turbine Mechanics and Dynamics

Earlier we discussed the aerodynamic aspects of a wind turbine, and how that related to its design, performance, and appearance. The next major consideration has to do with the turbine's survivability. This topic includes its ability to withstand the forces to which the turbine will be subjected, deflections of various components, and vibrations that may result during operations.

Issues that need to be considered include: (i) ultimate strength, (ii) relative motion of components, (iii) vibrations, (iv) loads, (v) responses, (vi) stresses, (vii) unsteady motion, resulting in fatigue, and (viii) material properties.

The types of loads that a turbine may be subjected to are as follows: static (non-rotating), steady (rotating), cyclic, transient, impulsive, stochastic, or resonance-induced. Sources of loads may include aerodynamics, gravity, dynamic interactions, or mechanical control. To understand the various loads that a wind turbine may experience, the reader may wish to review the fundamentals of statics (no motion), dynamics (motion), Newton's second law, the various rotational relations (kinematics), strength of materials (including Hooke's law and finding stresses from moments and geometry), gyroscopic forces/moments, and vibrations. Among other topics, the cantilevered beam is particularly important, since rotor blades as well as towers have similar characteristics.

Wind turbines are frequently both the source of and are subject to vibrations. Although the topic can become quite complicated, it is worthwhile to recall that the natural frequency of simple oscillating mass, *m*, and spring, with spring constant, *k*, and is given by:

$$\omega = \sqrt{k/m} \tag{16}$$

Similarly, rotational natural frequency about an axis of rotation is given by:

$$\omega = \sqrt{k_\theta / J} \tag{17}$$

Where k_θ is the rotational spring constant and J is the mass moment of inertia

A continuous body, such as a wind turbine blade, will actually have an infinite number of natural frequencies (although only the first few are important), and associated with each natural frequency will be a mode shape that characterizes it deflection. The vibration of a uniform cantilevered beam can be described relatively simply through the use of Euler's equation (see Manwell et al., 2009). Non-uniform elements require more complex methods for their analysis.

AA.7.a Rotor Motions

There is a variety of motions that occur in the rotor that can be significant to the design or operation of the turbine. These include those in the flapwise, edgewise, and torsional directions.

Flapwise motions are those that are perpendicular to plane of the rotor, and are considered positive in the direction of the thrust. Flapwise forces are the source of the highest aerodynamic bending moments, and accordingly the most significant stresses.

Lead-lag, or edgewise, motions are in plane of rotor and are considered positive when in the direction of the torque. Fluctuating motions in this direction are reflected in the power.

Torsion refers to the twisting of blade about its long axis. Torsional moments in the blades must be accounted for in the design of pitch control mechanisms.

The most important rotor load is the thrust. This is the total force on the rotor in the direction of the wind (flapwise). It is associated with the conversion of the kinetic energy of the wind to mechanical energy. The thrust, T, (N) is given by:

$$T = C_T \frac{1}{2} \rho \pi R^2 U^2 \tag{18}$$

Where C_T is the thrust coefficient. For the ideal rotor in which the axial induction factor, a, is equal to 1/3 (corresponding to the Betz limit), it is easy to show that the thrust coefficient is equal to 8/9. For the same rotor, the thrust coefficient may be as high as 1.0, but this would not occur at $C_p = C_{p,Betz}$.

This thrust gives rise to flapwise bending moments at the root of the blade. For example, for the ideal rotor when a = 1/3, and assuming a very small hub, it may be shown that the flapwise bending moment M_β at the root of the blade would be given by:

$$M_\beta = \frac{T}{B} \frac{2}{3} R \tag{19}$$

Where B = number of blades

From the bending moment, it is straightforward to find the maximum bending stress in the blade. For example, suppose that a blade is $2t$ m thick at the root, has a symmetrical airfoil, and that the thrust force is perpendicular to the chord line. Then the bending stress would be:

$$\sigma_{\beta,\max} = \frac{M_\beta t}{I_b} \tag{20}$$

(Note that for a real blade, the asymmetry and the angles would complicate the calculation, but the principle is the same.)

Another important load is torque, Q (Nm). Torque is given by:

$$Q = C_Q \frac{1}{2} \rho \pi R^2 U^2 \qquad (21)$$

Where C_Q = the torque coefficient, which also equal to C_p/λ.

Note that torque is also given by:

$$Q = P / \Omega \qquad (22)$$

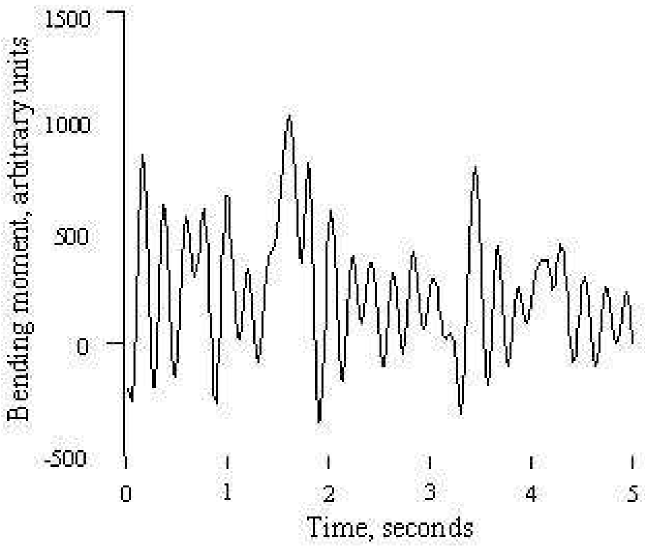
Where P = power (W)

The dynamics of a wind turbine rotor are quite complicated and do not lend themselves to simple illustrations. There is one approach, however, due to Stoddard (Eggleston and Stoddard, 1987) and summarized by (Manwell et al., 2009) which is relatively tractable, but will not be discussed here. In general, the dynamic response of wind turbine rotors must be simulated by numerical models, such as the FAST code (Jonkman, 2005) developed by the National Renewable Energy Laboratory.

AA.7.b Fatigue

Fatigue is an important phenomenon in all wind turbines. The term refers to the degradation of materials due to fluctuating stresses. Such stresses occur constantly in wind turbines due to the inherent variability of the wind, the rotation of the rotor and the yawing of the rotor nacelle assembly (RNA) to follow the wind as its direction changes. Fatigue results in shortened life of many materials and must be accounted for in the design. Figure AA.9 illustrates a typical time history of bending moment that would give rise to fluctuating stresses of similar appearance.

Figure AA.9: Typical wind turbine blade bending moment



The ability of a material to withstand stress fluctuations of various magnitudes is typically illustrated in an S-N curve. In such curves the stress level is shown on the *y* axis and is plotted against the number of cycles to failure. As is apparent from the figure above, stress fluctuations of a variety of magnitudes are likely. The effect of a number of cycles of different ranges is accounted for by the damage due to each cycle using “Miner’s Rule.” In this case, an amount of damage, *d*, due to *n* cycles, where the stress is such that *N* cycles will result in damage is found as follows:

$$d = n / N \tag{23}$$

Miner’s Rule states that the sum of all the damage, *D*, from cycles of all magnitudes must be less than 1.0, or failure is to be expected imminently:

$$D = \sum n_i / N_i \leq 1 \tag{24}$$

Miner’s Rule works best when the cycling is relatively simple. When cycles of varying amplitude follow each other, an algorithm called "rainflow" cycle counting” (Downing and Socie, 1982) is used.

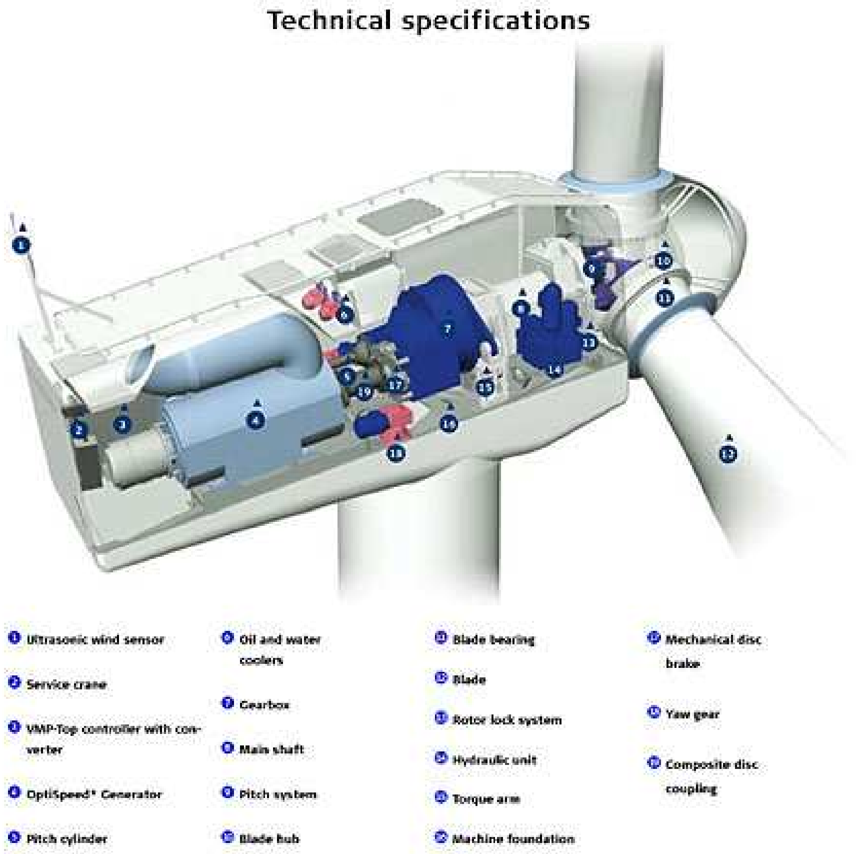
AA.8 Components of Wind Turbines

Wind turbines consist of two main subsystems, the rotor nacelle assembly and the support structure, and each of these is comprised of many components. The following provides some more description of these subsystems. More details, particularly on the rotor nacelle assembly may be found in (Manwell et al., 2009).

AA.8.a Rotor Nacelle Assembly

The rotor nacelle assembly (RNA) includes the majority of the components associated with the conversion of the kinetic energy of the wind into electrical energy. There are two major component groupings in the RNA as well as a number of ancillary components. The main groupings are the rotor and the drive train. The rotor includes the blades, the hub, and pitch control components. The drive train includes shafts, bearings, gearbox (if any), couplings, mechanical brake, and generator. Other components include the bedplate, yaw bearing and yaw drive, oil cooling system, climate control, other electrical components, and parts of the control system. An example of a typical rotor nacelle assembly is illustrated in Figure AA.10.

Figure AA.10: Typical Rotor Nacelle Assembly



(From Vestas http://re.emsd.gov.hk/english/wind/large/large_to.html)

AA.8.b Rotor

The primary components of the rotor are the blades. At the present time, most wind turbines have three blades, and they are oriented so as to operate upwind of the tower. It is to be expected that in the future some wind turbines, particularly those intended for use offshore, will have two blades and will be oriented downwind of the tower, however. For a variety of reasons (including that downwind turbines tend to be noisier) it is less likely that they will be used on land, particularly in populated areas.

The general shape of the blades is chosen in accordance with the principles discussed previously. The other major factor is the required strength of the blades. For this reason, it is often the case that thicker airfoils are used nearer the root than are used closer to the tip. Blades for most modern wind turbines are constructed of composites. The laminates are primarily fiberglass with some carbon fiber for additional strength. The binders are polyester or epoxy.

At the root of the blades the composite material is attached to a steel root, which can then be subsequently bolted to the hub. Most utility scale wind turbines at present include blade pitch control, so there is a mechanism present at the interface of the hub and the blades that will both secure the blades and facilitate their rotation about their long axis.

The hub of the wind turbine rotor is constructed from steel. It is designed so as to attach to the main shaft of the drive train as well as to connect with the blades.

AA.8.c Drive train

The drive train consists of a number of components, including shafts, couplings, a gearbox (usually), a generator, and a brake.

AA.8.d Shafts

The main shaft of the drive train is designed to transmit the torque from the rotor to the gearbox (if there is one) or directly to the generator if there is no gearbox. This shaft may also be required to carry some or all of the weight of the rotor. The applied torque will vary with the amount of power being produced, but in general it is given by the power divided by the rotational speed. As discussed previously, a primary consideration in the aerodynamic design of a wind turbine rotor is the tip speed ratio. A typical design tip speed ratio is 7. Consider a wind turbine with a diameter of 80 m, designed for most efficient operation at a wind speed 12 m/s. The rotational speed of the rotor and thus the main shaft under these conditions would be 20 rpm.

AA.8.e Gearbox

Wind turbines are intended to generate electricity, but most conventional generators are designed to turn at higher speeds than do wind turbine rotors (see below). Therefore, a gearbox is commonly used to increase the speed of the shaft that drives the generator relative to that of the main shaft. Gearboxes consist of a housing, gears, bearings, multiple shafts, seals, and lubricants. Gearboxes for wind turbines are typically either of the parallel shaft or planetary type. Frequently a gearbox incorporates multiple stages, since the maximum allowed ratio per stage is usually well under 10:1. There are trade-offs in the selection of gearbox. Parallel shaft gearboxes are generally less expensive than planetary ones but they are also heavier. Gearboxes are generally quite efficient. Thus the power out is very nearly equal to the power in. The torque in the shafts is then equal to the power divided by the speed of the shaft.

AA.8.f Brake

Nearly all wind turbines incorporate a mechanical brake somewhere on the drive train. This brake is normally designed to stop the rotor under all foreseeable conditions, although in some cases it might only serve as a parking brake for the rotor. Mechanical brakes on utility scale wind turbines are mostly of the caliper/disc type although other types are possible. Brakes may be placed on either the low speed or the high speed side of the gearbox. The advantage of placing it on the high speed side is that less braking torque is required to stop the rotor. On the other hand, the braking torque must then pass through the gearbox, possibly leading to premature failure of the gearbox. In either case, the brake must be designed to absorb all of the rotational energy in the rotor, which is converted into heat as the rotor stops.

AA.8.g Generator

Electrical generators operate via the rotation of a coil of wire in a magnetic field. The magnetic field is created by one or more pairs of magnetic poles situated opposite each other across the axis of rotation. The magnetic field may be created either by electromagnets (as in conventional synchronous generators), by induction in the rotor (as in induction generators,) or with permanent magnets. In alternating current systems the number of pairs of poles and the grid frequency determine the nominal operating speed of the generator. For example, in a 60 Hz AC system, such as the United States, a generator with two pairs of poles would have a nominal operating speed of 1800 rpm. In most AC generators, the field rotates and while the current is generated in a stationary armature (the stator).

The majority of utility scale wind turbines today use wound rotor induction generators (WRIG). This type of generator can function over a relatively wide range of speeds (on the order of 2:1). Wound rotor induction generators are employed together with a power electronic converter in the rotor circuit. In such an arrangement approximately 2/3 of the power is produced on the stator in the usual way. The other third of the power is produced on the rotor and converted to AC of the correct frequency by the power electronic converter. In this configuration the WRIG is often referred to as a doubly fed induction generator (DFIG).

A number of wind turbines use permanent magnet generators. Such generators often have multiple pole pairs as well. This can allow the generator to have the same nominal speed as the wind turbine rotor so the main shaft can be connected directly to the generator without the use of a gearbox. Most permanent magnet generators are designed to operate together with power electronic converters. These converters facilitate variable speed operation of the turbine, while ensuring that the electricity that is produced is of constant frequency and compatible with the electrical grid to which the turbine is connected.

AA.8.h Bedplate

The bedplate is a steel frame to which components of the drive train and other components of the RNA are attached. It ensures that all the components are properly aligned.

AA.8.i Yaw System

Most wind turbines today include a yaw system. This system facilitates orienting the RNA into the wind as the wind direction changes. First of all, there is a slewing bearing that connects the top of the tower to the RNA, allowing the latter to rotate with respect to the former. Also attached to the top of the tower, and often to the outside perimeter of the slewing bearing, is a large diameter bull gear. A yaw motor connected to a smaller gear is attached to the bedplate. When the yaw motor is energized, the small gear engages the bull gear, causing the RNA to move relative to the tower. A yaw controller ensures that the motion is in the proper direction and that it continues until the RNA is aligned with the wind. A yaw brake holds the RNA fixed in position until the yaw controller commands a new orientation.

AA.8.j Control System

A wind turbine will have a control system that ensures the proper operation of the turbine at all times. The control system has two main functions: supervisory control and dynamic control. The supervisory control continuously monitors the external conditions and the operating parameters of the turbine, and starts it up or shuts it down as necessary. The dynamic control system ensures smooth operation of various controllable components, such the pitch of the blades or the electrical torque of the generator. The control system may also be integrated with or at least be in communication with a condition monitoring system that watches over the condition of various key components.

AA.8.k Support Structure

The support structure of a wind turbine is any part of the turbine that is below the main bearing. The support structure for land-based wind turbines may be conceptually divided into two main parts: the tower and the foundation. The tower of a wind turbine is normally constructed of tapered steel tubes. The tubes are bolted together on site to form a single structure of the desired height. The foundation of a wind turbine is the part of the support structure, which is in contact with the ground. Foundations are typically constructed of reinforced concrete. When turbines are installed on rock, the foundations may be attached to the rock with rods, which are grouted into predrilled holes.

AA.8.l Materials for Wind Turbines

The primary types of materials used in the various components of wind turbines are steel, copper, composites, and concrete.

AA.9 Installation

Installation of wind turbines may be a significant undertaking. It involves the following:

- Complete assessment of site conditions
- Detailed preparing for the installation
- Constructing the foundation
- Delivering the components to the site
- Assembling the components into sub-assemblies
- Lifting the sub-assemblies into place with a crane
- Installing the electrical equipment
- Final testing

More details may be found in (Manwell et al., 2009).

AA.10 Energy Production

The purpose of wind turbines is to produce energy. Energy production is usually considered annually. The amount of energy that a wind turbine will produce in a year, E_y, is a function of the wind resource at the site where it is installed and the power curve of the wind turbine. Estimates are usually done by calculating the expected energy that will be produced every hour of a representative year and then summing the energy from all of those hours as shown below:

$$E_y = \sum_{i=1}^{8760} P_{WT}(U_i)\Delta t \qquad (25)$$

Where U_i is the wind speed in the i^{th} hour of the year, $P_{WT}(U_i)$ is the average power (based on the power curve) during the i^{th} hour and Δt is the length of the time period of interest (here, one hr). The units of energy are Wh, but the amount of energy production is frequently expressed in either kWh or MWh for the sake of convenience.

It is sometimes cumbersome to characterize the performance of a wind turbine by its actual energy production. Accordingly, a normalized term known as the capacity factor, *CF*, is used. This is the given by the actual energy that is produced (or estimated to be produced) divided by the amount of energy that would be produced if the turbine were running at is rated output, P_R, for the entire year. It is found from the following equation:

$$CF = \frac{E_y}{8760 P_R} \qquad (26)$$

AA.11 Unsteady Aspects of Wind Turbine Operation

There are a number of unsteady aspects of wind turbine operation that are significant to the discussion of public reaction to wind turbines. These in particular include the variations in the wind field that can change the nature of the sound emitted from the rotor during operation. These unsteady effects include the following:

1. Wind shear – Wind shear refers to the variation of wind speed across some spatial dimension. Wind shear is most commonly thought of as a vertical phenomenon, that is to say, the increase of wind speed with height. Wind shear can also occur laterally across the rotor under some circumstances. Vertical wind shear is often modeled by a power law as discussed earlier. There are some situations, however, in which such a model is not applicable. One example has to with highly stable atmosphere, such that the wind near the ground is relatively light, but at the height of the rotor the wind is high enough that turbine may be operating. Under such conditions there may be sound emanating from the rotor, but relatively little wind induced sound near the ground to mask that from the rotor. Wind shear may also result in a cyclically varying aspect to the sound produced by the blades as they rotate. This occurs due to the changing magnitude and direction of the relative wind as the blades pass through zones of different wind speed.
2. Tower shadow or blockage – The wind flow near the tower is inevitably somewhat different from where there is no tower. The effect is much more pronounced on wind turbines with downwind rotors, but it still occurs with up-wind rotors. This tower effect can result in a distinct change in sound once per revolution of each blade.

3. Turbulence – Turbulence refers to changes in magnitude and direction of the wind at varying time scales and length scales. The presence of turbulence can affect the nature of the sound.
4. Changes in wind direction – Wind turbines are designed to yaw in response to changes in wind direction. The yawing process takes a finite amount of time and during that time the wind impinging on the rotor will do so at a different direction than it will when the yawing process is complete. Sound produced during the yawing process may have a somewhat different character than after it is complete.
5. Stall – Under some conditions part or all of the airfoils on the blades may be in stall. That is, the angle of relative wind is high enough that the airfoil begins to lose lift. Additional turbulence may also be generated. Again, the nature of the sound produced by the rotor may be different than during an unstalled state. It may also be noted that some turbines intentionally take advantage of stall to limit power in high winds. Under such conditions there may also be a change in sound in comparison to normal operation.

AA.11.a Periodicity of Unsteady Aspects of Wind Turbine Operation

Due to the rotation of the rotor and the nature of the wind, there tend to be certain features of the turbine's operation that are periodic in nature. The most dominant of these have frequencies associated with the rotational speed of the rotor and the blade passage frequency, which is simply the rotational speed times the number of blades. For example, the dominant frequencies in a 3-blade wind turbine rotating at 20 rpm would be 0.33 Hz and 1 Hz. Other significant frequencies may be the first few harmonics of the rotational frequency and blade passage frequency.

AA.12 Wind Turbines and Avoided Pollutants

Wind turbines have a positive impact on human health via avoiding emission of pollutants that would result if the electricity that they generate were produced instead by other generators. While the average emissions of various pollutants per MWh produced from conventional generators is relatively easy to estimate, it is harder to estimate the actual impact of wind turbine generation. This is because the electricity distributed by the electrical grid is produced by different types of generators, and the operation of these generators will be affected differently as a result of the supply of part of the total electrical demand by the wind turbines.

In general, electricity in any large utility network comes from three types of generators: base load, intermediate load, and peaking plants. The fuel or energy source supplying these generators is likely to be coal, fuel oil, natural gas, uranium (nuclear plants), or water (hydroelectric plants). Base load plants are typically coal fired or nuclear plants. Intermediate load plants often use fuel oil or natural gas. Peaking plants are normally natural gas or hydroelectric. There are a considerable number of plants that may be operating at any given time. Which plants are actually operating is determined by the system operator in accordance with what the near term forecasted load is expected to be and the estimated (bid) cost per MWh from all the plant operators in the system. For thermal plants the bid cost is close to that projected fuel cost/MWh. This in turn is found from heat rate of the fuel (kg/MWh) for the plant in question times the unit cost of the fuel ($/kg). Less efficient plants or those with higher unit fuel costs tend to have relatively high bid costs. (Note on the other hand, that wind turbines would have bid costs of zero, since they do not use fuel.)

If a large number of wind turbines are operating such that they are contributing a significant amount of electricity to the total load, the mix of generators may well be different than it would be if the turbines were not present. If only a small number of wind turbines are present, then the mix of generators may not change. However, certain of the plants would be curtailed so as to produce less energy and thus consume less fuel. The emissions of pollutants from all the operating plants could be calculated and so could the projected emissions that would have resulted if the wind turbines were not present. The difference in amount of pollutants produced could then be assigned to the wind turbine as the avoided emissions.

To do such an analysis properly involves estimating the actual impact of wind turbine generation on the mix of generators and the operating level of those generators for every hour of the year. This is a non-trivial exercise, but it has been done for an offshore wind farm that was proposed for the town of Hull, MA. That project was to have included four 3.6 MW turbines, for a total capacity of 14.4 MW. The pollutants considered in the study were CO_2, $NO_{X,}$ and SO_X. The results of that study are described in detail in (Rached, 2008). The results of that study are summarized in Table AA.1. The results in the table are normalized for a 1 MW (rated) wind turbine and use the medium estimated wind speed for the site. (Note under the assumptions of Rached's study, a one MW (rated) wind turbine in the medium wind speed scenario at the site would generate 2,580 MWh/yr).

Table AA.1:

Avoided emissions of pollutants for 14.4 MW wind project (based on Rached, 2008)

CO_2 (kg/MWyr)	SO_X (kg/MWyr)	NO_X (kg/MWyr)
1,970,000	3,480	1,490

A simpler but less accurate way to estimate the avoided emissions is to use the marginal rates for pollutants as specified by the Massachusetts Greenhouse Gas policy (MEPA, 2007). Applying this method Rached calculated avoided emissions per MW (rated) for the three pollutants for one year of 1,320,000 kg CO_2, 2,080 kg of SO_2, and 701 kg of NO_x.

In the analysis summarized above the majority of the avoidance of pollutant production would be due to reduced consumption of natural gas. If a larger fraction of Massachusetts' energy were to be produced by wind energy, there could be significant reductions of the consumption of fuel oil and coal as well. This should result in larger amounts of avoided pollution per unit of wind turbine production

Appendix B

Wind Turbines – Shadow Flicker

AB.1 Shadow Flicker and Flashing

Shadow flicker occurs when the moving blades of a wind turbine rotor cast moving shadows that cause a flickering effect. This flicker could annoy people living close to the turbine. Similarly, it is possible for sunlight to be reflected from gloss-surfaced turbine blades and cause a "flashing" effect. This phenomenon will occur during a limited amount of time in a year, depending on the altitude of the sun, α_s; the height of the turbine, H, the radius of the rotor, R, and the height, direction and distance to the viewing point. At any given time the maximum distance from a turbine that a flickering shadow will extend is given by:

$$x_{shadow,\max} = \left(H + R - h_{view}\right) / \tan\left(\alpha_s\right) \qquad (27)$$

Where h_{view} is the height of the viewing point.

The solar altitude depends on the latitude, the day of the year, and the time as given in the following equations (Duffie and Beckman, 2006)

$$\alpha_s = 90° - \cos^{-1}\left[\cos(\delta)\cos(\phi)\cos(\omega) + \sin(\delta)\sin(\phi)\right] \qquad (28)$$

Where δ = declination of the earth's axis, ø = latitude and ω = the hour angle

The declination is found from the following equation:

$$\delta = 23.45\sin(360(284 + n)/365) \qquad (29)$$

Where n = day of the year

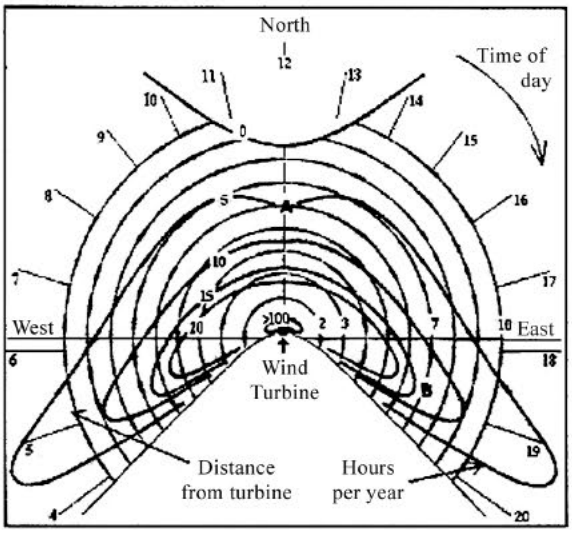
The hour angle is found from the hours from noon (solar time, negative before noon, positive after noon), divided by 15 to convert to degrees.

Another relevant angle is the solar azimuth. This indicates the angle of the sun with respect to certain reference direction (usually north) at a particular time. For example, the sun is always in the south at solar noon, so its azimuth is 180° at that time. The solar azimuth is important since it determines the angle of the wind turbine's shadow with respect to the tower. See Duffie and Beckman (2006) for details on calculating the solar azimuth.

F r examp e consider a location that as a atitude of 4 °. Assum that the day is March 1 (day 60) and the time s 3:0 in the afternoon Also as me that h turbine has a tower height of 80 m an ra i s of 0 m and that the viewing height s 2 m. T e de lination is -8.3°, the solar altitude is 24.4°, and the solar zimuth is 5 .2° W of S. h ma imum extent of the shadow is 38 m from t e turbine. The angle of the shadow is 50.2° E of N.

S tes are typically characterized by charts such t e on ill st t i Figure AB.1 for a location in Den ark (WEA, 2004). T e chart gives the number of ho rs per year of flicker shadow as a function o direction a d distanc (me sured in un ts of hub height). In the example shown, two viewing points re consider d. One o them (A) s directly t the north of turbine at a distance of 6 times the hub height. The other (B) is l cated to the sou h east at a distance of 7 times the hub height. The figure shows th t the fir t viewing point ill e perience shadow flicker from the turbine for 5 ho rs per year. The second p i t will experien flicker for about 12 hours per year.

Figure AB 1: Diagram f shadow flic er ca cu ation WEA, 2004)



A, B are viewing points
Note tha t e equations above assume a cl r sk an the absence of rain, c ouds, etc.

AB.2 itigation Possibilit es

M st modern wind turbines allow for real-t me contr l f turb n peration by computer in order to shut down uring high shadow flicker times, if necessary. In addition, computer programs can allow for pre-plan ing of sitin lo ati n ahe d of ime to know what a project specific impac will be in t r s of shado fli ker when pla ning a wind turbine project (as discussed in the previous paragraph). This planning can be site-specific in order to avoid potential problems with specific sites based on geographical location or weather patterns.

In terms of safe distances to reduce shadow flicker, these are often project-specific because it depends on whether there are residences or roadways present and what the geographic layout is. This could be particularly important in areas with more forestry and existing shadow, which could reduce nuisance from turbine produced shadow flicker or whether it is an otherwise open land area such as farmland that would be more susceptible to the annoyance of shadow flicker. A general estimate for modeling a shadow flicker risk zone includes 10 times the rotor diameter such that a 90-meter diameter would be equivalent to a 900-meter impact area. However, only certain portions of this zone are actually likely to experience shadow flicker for a significant amount of time. Other modeling considerations include when at least 20% of the sun is covered by the blade and whether to include the blade width in estimates as well. In terms of distance, 2,000 meters is the WindPro computer program default distance (NEWEEP, 2011) for calculations of wind turbine produced shadow flicker. Finally, due to atmospheric effects, 1400 m is the maximum distance from a turbine within which shadow flicker is likely to be significant.

In terms of existing regulations regarding shadow flicker rates, there are no current shadow flicker regulations in Massachusetts (or many other New England states, but there are statewide and local guidelines that have been implemented. These guidelines were provided by the Department of Energy Resources in March 2009 and state that, “wind turbines shall be sited in a manner that minimizes shadowing or flicker impacts” and, “the applicant has the burden of proving that this effect does not have significant adverse impact on neighboring or adjacent uses.” Local Massachusetts regulations include the Worcester, MA zoning ordinance, which requires, “The facility owner and operator shall make reasonable efforts to minimize shadow flicker to any occupied building on a non-participating landowner’s property.” Also, a shadow flicker assessment report is required as is a plan showing the “area of estimated wind turbine shadow flicker.” Similarly, the Newburyport, MA regulations require that wind turbines do not result in significant shadow or flicker impacts and an analysis is required for planned projects (NEWEEP, 2011).

The Maine model wind energy facility ordinance states that wind turbines should, “avoid unreasonable adverse shadow flicker effect at any occupied building located on a non-participating landowner's property." They do not state any specific limit to shadow flicker other than these guidelines. However, the New Hampshire Model Small Wind Energy Systems Ordinance states that wind turbines, "shall be sited in a manner that does not result in significant shadow flicker impacts…significant shadow flicker is defined as more than 30 hours per year on abutting occupied buildings." Similar to Maine, several states in the US have adopted the German model of 30 hours per year of allowed shadow flicker that was primarily based on the government-sponsored study summarized above. However, other states or localities including Hutchinson, Minnesota have enacted stricter guidelines including no shadow flicker to be allowed at an existing residential structure, and up to 30 hours per year of shadow flicker allowed on roadways or residentially zoned properties and a computer analysis is required for project approval (NEWEEP, 2011).

In addition, computer programs such as WindPro are also recommended by most states and localities for use in all new planned installations to reduce this potential nuisance of shadow flicker on residential properties or potential health hazards to drivers on busy highways or roadways.

Appendix C

Wind Turbines – Ice Throw

AC.1 Ice Falling or Thrown from Wind Turbines

Under certain weather conditions ice may form on the surface of wind turbine blades. Normally, wind turbines intended for use in locations where ice may form are designed to shut down when there is a significant amount of ice on the blades. The means to prevent operation when ice is present may include ice sensor and vibration sensors. Ice sensors are used on most wind turbines in cold climates. Vibration sensors are used on nearly all wind turbines. They would cause the turbine to shut down, for example, if ice buildup on the blades resulted in an imbalance of the rotor and hence detectable vibrations in the structure.

Ice built up on blades normally falls off while the turbine is stationary. If that occurs during high winds, the ice could be blown by the wind some distance from the tower. In addition, it is conceivable that ice could be thrown from a moving wind turbine blade under some circumstances, although that would most likely occur only during startup (while the rotational speed is still relatively low) or as a result of the failure of the control system. It is therefore worth considering what the maximum plausible distance that a piece of ice could land from the turbine under two "worst case" circumstances: 1) ice falls from a stopped turbine during very high winds, and 2) ice is suddenly released from a blade when the rotor is rotating at its normal operating speed.

In both cases, the distance that the ice may travel is governed by Newton's laws and the principles of fluid mechanics. Calculations are quite simple when the effect of the air (and the wind) is ignored. For example, in that case if a piece of ice falls from a turbine, it will land directly below where it is released. The situation is a little more complex, but still readily solvable if the piece of ice is moving when it is released. For example, suppose that the ice is initially on the tip of a blade, and the blade is pointing vertically upward. Once the ice is released it will continue moving horizontally at the speed it had when it was still attached to the blade. But it will also begin to fall towards the ground, so the piece of ice will have two components of velocity until the ice hits the ground. The time t_g (s) it takes for the ice to reach the ground (assuming a horizontal surface) is $t_g = \sqrt{2h/g}$ where h = height (m) at which the ice is released and g = acceleration of gravity (9.81 m/s^2). The distance x (m) that the ice would travel is $x = t_g \Omega R$ where Ω is the rotational speed of the rotor (rad/s) and R is the length of the blade (m).

Such an analysis is overly simplified, however. It would underestimate the distance that the ice would travel if it fell from a stationary turbine in a high wind, and it would overestimate the distance that the ice would travel if it were suddenly released from a moving blade. It is necessary to consider the effect of the air and the force that it will impart upon the falling ice. For motion in the vertical (z) direction the equation of motion is the following:

$$F_z = ma_z \tag{30}$$

where F_z is the net force (N), m is the mass (kg), and a_z is the acceleration (m/s^2). The force includes two main components. One is the weight, W (N). It is due to gravity and acts in the negative z direction. The other one is due to the drag of the air and it acts opposite to the direction of the velocity. It is found from:

$$F_D = \frac{1}{2} C_D \rho A V_z^2 \tag{31}$$

where ρ is the density of air (1.225 kg/m^2 under standard conditions), A is the projected area (m^2) of the piece of ice, C_D is the drag coefficient of the ice and V_z is the velocity of the ice (m/s) in the z direction.

Acceleration is the derivative of the velocity, so we can rewrite the equation of motion for the vertical direction as follows:

$$\frac{dV_z}{dt} = \left(-W - sign(V_z) \frac{1}{2} C_D \rho A V_z^2 \right) / m \tag{32}$$

Where *sign* (…) indicates the direction of motion along the z axis. For the general case, the piece of ice may leave the blade with initial speed ΩR at an arbitrary angle θ with respect to the horizontal. Accordingly, there will be two components of the velocity, one in the z direction (as before) V_z, the other in the x direction, V_x. This assumes that the x axis is horizontal, is also in the plane of the rotor, and is positive in the direction of the tip of the blade at its apogee.

These velocities are initially:

$$V_{z,0} = \Omega R \sin(\theta) \tag{33}$$

$$V_{x,0} = \Omega R \cos(\theta) \tag{34}$$

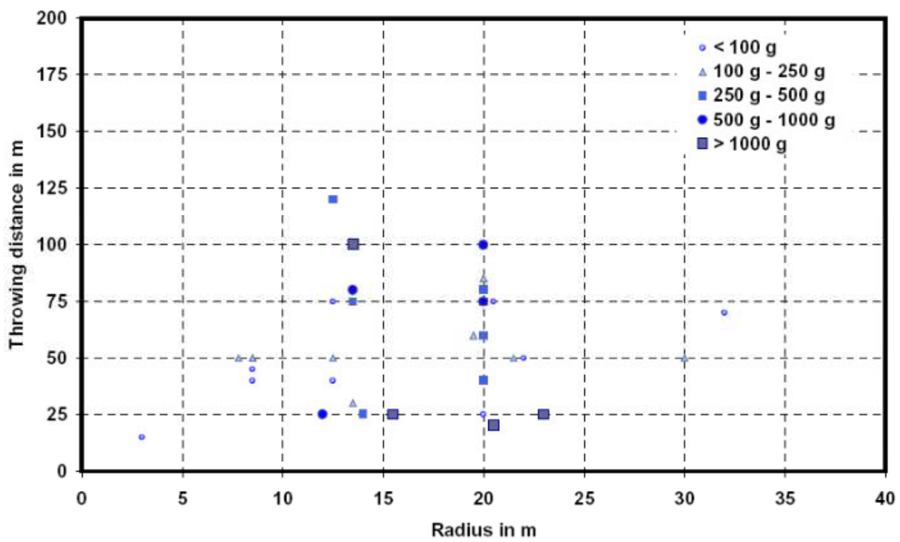
The equation of motion for the *x* direction is:

$$\frac{dV_x}{dt} = \left(-sign(V_z)\frac{1}{2} C_D \rho A V_x^2 \right) / m \tag{35}$$

The above equations are a bit difficult to solve analytically, but they can be solved numerically fairly easily. Similar equations may also be developed for the case of a particle of ice falling from a stationary turbine.

Some data from actual ice throw has been compiled by Seifert et al. (2003). Figure AC.1, taken from that report is shown below.

Figure AC.1: Observed throwing distance of ice (from Seifert et al., 2003)



As may be seen in the figure, the maximum distance that ice was observed to fall from a turbine with a diameter of 20 m during operation was approximately 100 m. Based on the observed data, Seifert et al. suggest the following simplified formula for the maximum throwing distance:

$$x_{\max,throw} = 1.5\left(2R + H\right) \tag{36}$$

Where $x_{max,throw}$ = maximum throwing distance (m), R = rotor diameter (m) and H = hub height (m).

By way of illustration, Equation 36 was used to predict the maximum throwing distance of a piece of ice from a turbine with a rotor radius of 20 m installed on a tower 50 m high. That distance was 135 m. The theoretical equations given previously were also used to calculate throwing distance. The following assumptions were made: spherically shaped piece of ice, drag coefficient of 1.2, air density of 1.225 kg/m^3, ice density of 700 kg/m^3, rotor speed of 40 rpm (corresponding to a tip speed ratio of 7 at a wind speed of 12 m/s), angle of release of 45°, and instantaneous release of the ice. The equations predict a maximum throwing distance of 226 m or somewhat less than twice that predicted from the empirical equation. The difference is deemed to be reasonable, especially considering the idealized shape of the particle. Real pieces of ice would actually be highly non-spherical in shape and experience considerably more drag. It may also be noted that it was reported in Cattin et al. (2007) that ice did not fall as far from a wind turbine in the Swiss Alps as would be predicted from Equation 36. In that case the maximum observed distance from a turbine with radius of 20 m and a tower height of 50 m was 92 m. As noted above, Equation 36 predicts 135 m.

Seifert et al. also considered data regarding ice thrown from stationary turbines. Based on the available data they proposed a simple equation for predicted ice fall. That equation is

$$x_{\max,\,fall} = U\left(R + H\right)/15 \tag{37}$$

Where U = wind speed at hub height in m/s, $x_{max,fall}$ = maximum falling distance (m), R = rotor radius (m), H = hub height (m).

Using Equation 37, the predicted maximum distance for a turbine with a radius of 20 m, a tower height of 50 m, and a wind speed of 20 m/s is 120 m. By way of comparison, the fall distance was predicted from the theoretical equations given above for the same situation. The results are highly dependent on the size of the piece of ice and hence the surface to volume ratio. To take one example, a piece of ice that was assumed to be spherical and to have a weight of 10 g would land 110 m from the tower. In the examples discussed by Seifert et al., all the pieces of ice landed less than 100 m from the tower.

AC.2 Summary of Ice Throw Discussion

As noted above, there are two plausible scenarios in which ice may fall from a wind turbine and may land at some distance from the tower. In the first scenario, ice that falls from a stationary turbine is blown some distance from the tower. In the second scenario, ice is thrown from the blade of an operating turbine during a failure of the control system. In the first case, ice may land 100 m or more from the tower in high winds, depending on the wind speed, the height from which the ice falls, and the dimensions of the ice. In the second case, the ice could land even further from the turbine. Just how far would depend on the actual speed of the rotor when the ice was shed, the height of the tower, the length of the blade, the angular position of the blade when the ice was released, and the size and shape of the ice. In general, it appears that ice is unlikely to land farther from the turbine than its maximum vertical extent (tower height plus the radius.)

Appendix D

Wind Turbine – Noise Introduction

Noise is defined simply as unwanted sound. Sound is defined as the sensation produced by stimulation of the organs of hearing by vibrations transmitted through the air or other medium. In air, the transmission is due to a repeating cycle of compressed and expanded air. The frequency of the sound is the number of times per second, Hertz (Hz), that the cycle repeats. Sound at a single frequency is called a tone while sound that is a combination of many frequencies is called broadband.

The human ear is capable of responding over a frequency range from approximately 20 Hz to 20 kHz (Hz: Hertz = 1 cycle/second; Middle C on a piano is a frequency of 262 Hz).

AD.1 Sound Pressure Level

Sound is characterized by both its frequency and its amplitude. Sound pressure is measured in micro Pascals (μPa). Because sound pressure can vary over a wide range of magnitudes a logarithmic scale is used to convert micro Pascals to decibels. Thus sound pressure level (SPL) is defined by SPL = $10 \log_{10} [p^2/p^2_{ref}] = 20 \log_{10}(p/p_{ref})$ with the resulting number having the units of decibels (dB). The reference pressure p_{ref} for airborne sound is 20×10^{-6} Pa (i.e., 20μPa or 20 micro Pascals). This means that SPL of 0 dB corresponds to a sound wave with amplitude 20μPa. 140 dB is considered the threshold of pain and corresponds to 20,000,000 μPa. Doubling the amplitude of the sound wave increases the SPL by 6 dB.

Therefore, a 40μPa amplitude sound wave would have an SPL of about 6 dB.

When it is stated that there is a large frequency range over which humans can hear, it is also noted that the ear does not hear each frequency similarly. In fact, there is a frequency-dependent threshold of hearing (lower limit) and threshold of pain (higher limit). Experiments have been performed to determine these thresholds. The threshold of hearing curves show that one can hear a tone at 3 kHz (3000 Hz) with an SPL < 0 dB while at 100 Hz one does not hear the tone until its SPL is about 30 dB. Curves showing the thresholds can be easily found in textbooks and online (one online example is at

http://www.santafevisions.com/csf/html/lectures/007_hearing_II.htm). Experiments have also been conducted to determine equal loudness level contours. These contours indicate when two tones of dissimilar frequencies appear to be equally loud.

Some characteristics of human response to sound include:

- Changes in sound level <1 dB cannot be perceived
- Doubling the magnitude of the acoustic pressure leads to a 6 dB increase in SPL
- A 5 dB SPL change will result in a noticeable community response
- A 10 dB SPL change is subjectively heard as an approximate doubling in loudness

AD.2 Frequency Bands

Most sounds in our environment contain multiple frequencies and are variable in that successive identical experiments cannot result in the exact same plot or tabulation of pressure vs. time. Therefore, it is common to use averages that measure approximately the amplitude of the sound and its frequency content. Common averaging methods rely on the principle of octaves, such as 1/10, 1/3, and single octave bands. This means that the entire frequency range is broken into chunks such that the relation between the starting and ending frequencies of each chunk, f_1 and f_2 respectfully, are related by $f_2 = 2^{1/N}f_1$ where N = 1 for a single octave band and 3 for a 1/3 octave band. Because the bands can be constructed based on any starting frequency, a standardized set of bands have been specified. They are usually described by the center frequency of each band. The standard octave-bands are given in Table AD.1 (measured in Hz):

Table AD.1:

Octave bands. Values given in Hz.

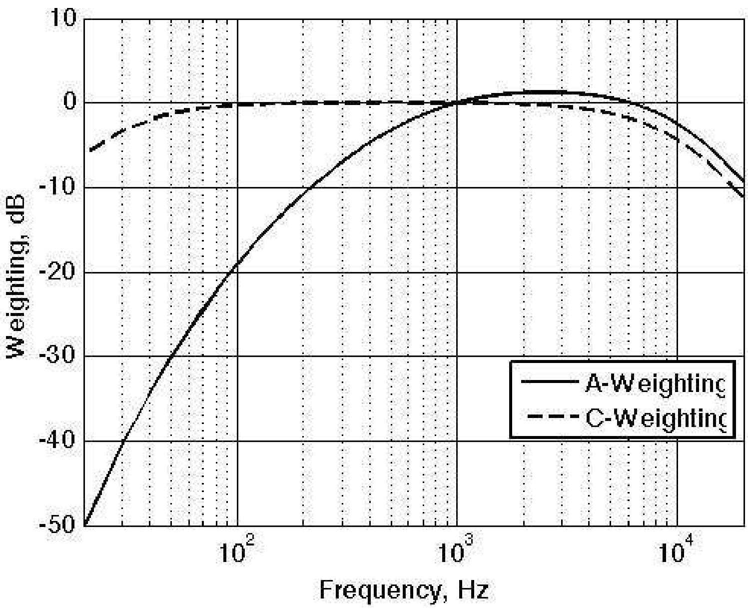
Center Frequency	Lower Band limit	Upper Band Limit
16	11	22
31.5	22	44
63	44	88
125	88	177
250	177	355
500	355	710
1000	710	1420
2000	1420	2840
4000	2840	5680
8000	5680	11360
16000	11360	22720

A similar set of bands can be written for the 1/3 octaves. For each octave band there are 3-1/3 octave bands. Many text and online resources specify the 1/3 octave bands such as (http://www.engineeringtoolbox.com/octave-bands-frequency-limits-d_1602.html). The 1/10 octave band is a narrow-band filter and is used when the sound contains important tones.

AD.3 Weightings

Noise data are often presented as 1/3 octave band measurements. Again, this means that the sound in each frequency band has been averaged over that frequency range. Noise levels are also often reported as weighted values. The most common weighting is A weighting. It was originally intended to be such that sounds of different frequencies giving the same decibel reading with A weighting would be equally loud. The weighting of the octave band centered at 31.5 Hz requires one to subtract 39.4 dB from the actual SPL. The octave bands with centers from 1000 to 8000 where human hearing is most sensitive are corrected by only about +/- 1 dB. When considered together with the threshold of hearing, it is clear that the A-weighting is most applicable for sounds of small amplitude. C-weighting on the other hand subtracts only a few dB from the very highest and very lowest frequency bands. It is therefore more applicable for higher levels of sound. The figure below shows these two weightings. When weighted, the sound pressure level is reported as dBA or dBC respectively.

Figure AD.1: Weighting values for reporting sound pressure levels



.

Noise levels change several times per day. To account for these differences other environmental noise measures are often used as shown in Table AD1.

Table AD 2:

A set of visual examples for these measures can be found at (*http://www.epd.gov.hk/epd/noise_education/web/ENG_EPD_HTML/m2/types_3.html*)

Indicator	**Meaning**
L_{max}	The maximum A-weighted sound level measured
L_{10}, L_{50}, L_{90}	The A-weighted sound level that is exceeded n%, of the time, where n is 10, 50, and 90 respectively. During the measurement period L_{90} is generally taken as the background sound level.
L_{eq}	Equivalent sound level. The average A-weighted sound pressure level, which gives the same total energy as the varying sound level during the measurement period of time.
Ldn	Day-night level. The average A-weighted sound level during a 24-hour day after addition of 10 dB to levels measured in the night between 10 p.m. and 7 a.m.

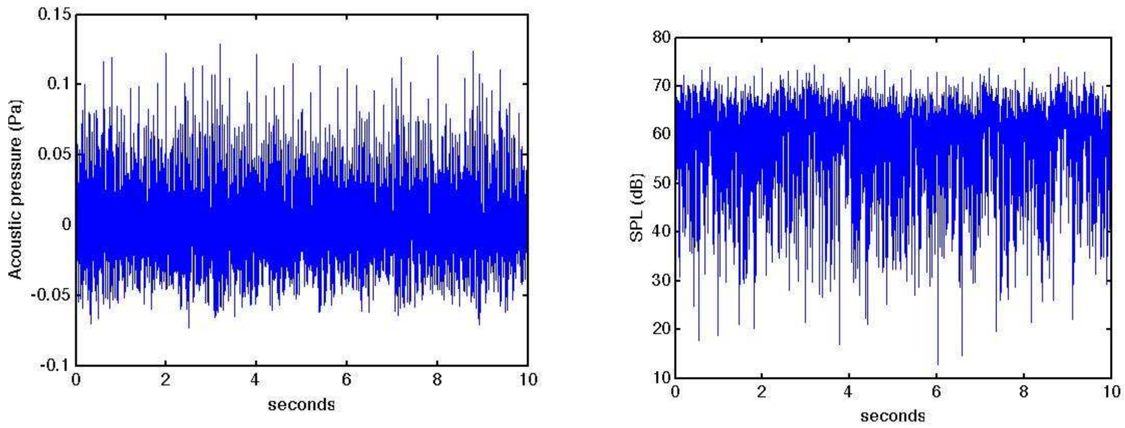
AD.4 Sound Power

Sound intensity and sound power are also often reported. Sound intensity is a measure of the energy transported per unit area and time in a certain direction. It can be shown that the intensity (I) perpendicular to the direction of sound propagation is related to the amplitude of the pressure wave squared, the density of the air (ρ), and the speed of sound (c), $I \sim p^2/\rho c$. The sound power, P, is the total intensity passing through a surface around a sound source. Intensity has units of Watts per square meter (W/m^2) and Power is measured in Watts (W). Both of these quantities are normally reported in dB where the intensity level is calculated as $L_I = 10 \log_{10}(|I|/I_{ref})$ and the power level is calculated as $L_W = 10 \log_{10}(P/P_{ref})$. The reference intensity level is related to the threshold of hearing at 1000 Hz such that $I_{ref} = 10^{-12}$ W/m^2. The reference power value is $P_{ref} = 10^{-12}$ W (1 picowatt). Here a doubling of the power leads to a 3 dB increase in the sound power level (PWL).

AD.5 Example Data Analysis

This is an example of the type of analysis done on sound measurements from a wind turbine. First, the actual signal might look something like what is shown in Figure AD.2.

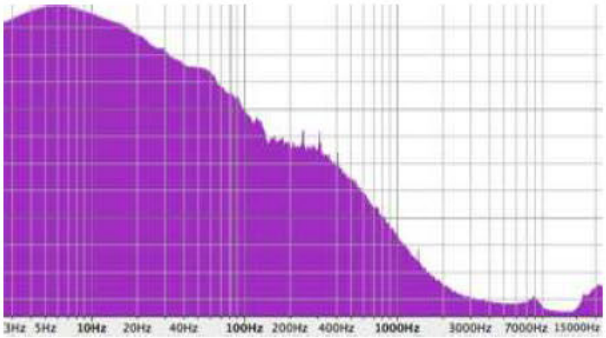
Figure AD.2: Pressure signal from a wind turbine



. *(From(van den Berg, 2011), related to Rheine wind turbine farm). Left in Pascals, right as SPL in dB.*

In Figure AD.2, just the acoustic pressure is shown, which means that atmospheric pressure, which is about 103,000 Pa, has been subtracted and the fluctuations then appear around 0 Pa. These data can easily be presented as SPL by transforming the pressure from Pa to dB. In order to analyze the pressure signal for low frequency content, a much longer time signal must be obtained. The frequency content of a long time signal is analyzed by performing a Fourier Transform. A typical transform of data from a wind turbine is shown in Figure AD.3.

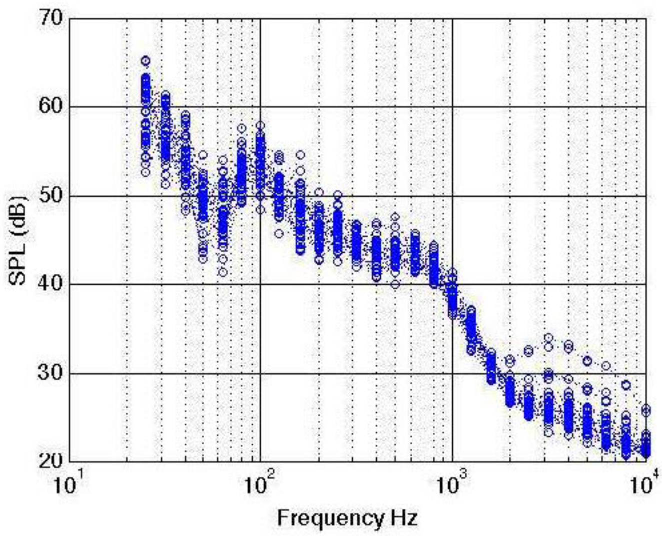
Figu e AD.3: Frequency cont nt of typical wind tu b ne measu e e t. (fr m lmer ASA paper.)



(This figure does n t corresp nd to the Rheine data for w i h the w iter is not ble to produce the full frequency domain plot.)

In ord r to better assess the bro dba d natu e of wind turbin und, the results are presented in 1/3-oc ave ban form. The averages that a e tak n i e ch 1 3-octave band can be done on fast or slow time i tervals. F r in ta ce, the ata i i ure 3 co ld be averaged on 1/3-oc ave bands to come up wit the overall SPL in the ban s. Or, as a measurement is being taken, the instrumentation can provide 1/3-oc ave ban verages on shor time s ales. For the Rheine data a fast average n 0.05 seconds was recorded. A few of the 1/3-oc a e band results are shown in Figure AD.4.

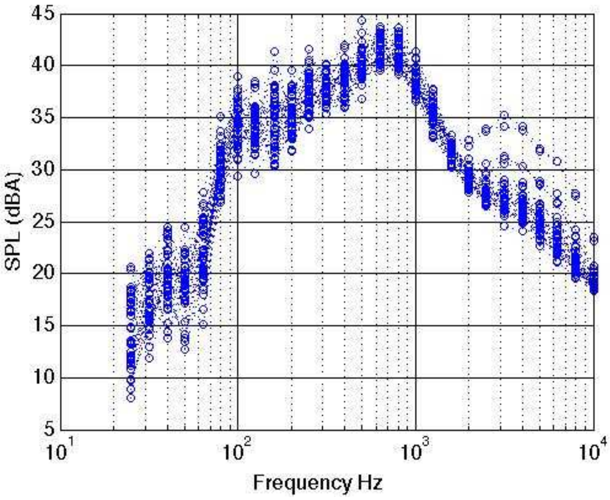
Figure AD.4: Fast averages for 1/3-octave band an ly is.



Shown results for 0–0.05, 5–0.05, 10–10.05, ..., 200– 00.05 seconds.

From hese a in l overall spectrum emerges. If t ese were presented as A-weighted spectrum, then Figure AD.5 is what is presented.

Figure AD.5: Fast averages for 1/3-octave band A-weighted analysis.



Shown results for 0–0.05, 5–0.05, 10–10.05, …, 200–200.05 seconds.

AD.6 Wind Turbine Noise from Some Turbines

What is known about aerodynamically generated noise from wind turbines is that it nominally increases with increasing wind speed until the max power is obtained, and it increases with increasing rotor tip speed. A report out of the Netherlands by (van den Berg et al., 2008) reports a vast amount of noise data related to wind turbines. The tables in Appendices B and C from the report clearly show these trends. Some of the data are reproduced here. Only measurements that were made by third parties (not specified by the wind turbine company) are reproduced here.

Table AD.3:

Sound power level in dB(A) from various wind turbines. (van den Berg et al., 2008).

Manufacturer Make and model	**Power kW**	**Hub Height m**	**Diameter m**	**rpm**	**4 m/s**	**5m/s**	**7m/s**	**8m/s**	**10m/s**
Enron TW1.5s	1500	80	70	11	100	100	100	100	
Enron TW1.5s	1500	81	70	22		102	102	103	104
NegMicon NM52	900	70	52	15	93	93			
NegMicon NM52	900	70	52	22		98	100	101	103
NegMicon NM54	950	46	54	15		95.6			
NegMicon NM54	950	46	54	22		101.6			
Vesta V66	1650	70	66	15	97	97	98	98	
Vesta V66	1650	70	66	19		101	101	102	102

It must be noted here that what has been reported are the sound power levels, which represents the total sound energy that propagates away from the wind turbine (i.e., the sound energy at the center of the blades, which propagates outward at the height of the hub). The sound level measured at a single position at the base of the turbine can easily be 50 dB lower (Lawrence rep.).

AD.7 Definition of Infrasound

Discussion of the aerodynamic source of sound known as thickness noise or self-noise requires one to define low frequency sound and infrasound. By definition, infrasound is a pressure wave that is not audible. Nominally this means waves with frequency less than 20 Hz. It is noted though that waves with high enough amplitude below 20 Hz may still be audible. Low frequency sound is characterized as having a frequency between 20 and 200 Hz. As mentioned earlier, some mechanical noise sources contribute to the low frequency range, and clearly some of the aerodynamic sources of broadband sound will contribute to noise in the low frequency range. Thickness noise, if present, would have an associated frequency equal to the blade passing frequency. Hence, a turbine with 3-bladed rotor turning at 20 rpm might generate thickness noise at a frequency of 1 Hz, which is clearly in the infrasonic range. Downwind rotors produce slightly stronger infrasound at the blade passing frequency because the blades interact directly with the wake behind the tower. The levels of the thickness noise generated by modern upwind turbines are not perceptible by the human auditory system. Any impulsive noise that is audible, which seems to have a frequency equivalent to the blade passing frequency, is actually the broadband noise generated by the other mechanisms being modified by differences in the flow that occur on a once-per-rev basis as discussed above. The frequencies of this pulsating sound are all in the audible range, and thus this sound is not infrasound.

Appendix E

Wind Turbine – Sound Power Level Estimates and Noise Propagation

AE.1 Approximate Wind Turbine Sound Power Level Prediction Models

The following are some approximate equations that are sometimes used to estimate the A-weighted sound power level, L_{WA}, from a typical wind turbine. The first equation gives the estimate in terms of the rated power of the turbine, P_{WT} (W). The second gives the estimate in terms of the diameter, D (m). The third gives it in terms of both the tip speed, V_{Tip} (m/s), and diameter. These equations should only be used when test data is not available.

$$L_{WA} = 10(\log_{10} P_{WT}) + 50 \quad (38)$$

$$L_{WA} = 22(\log_{10} D) + 72 \quad (39)$$

$$L_{WA} = 50(\log_{10} V_{Tip}) + 10(\log_{10} D) - 4 \quad (40)$$

AE.2 Sound Power Levels due to Multiple Wind Turbines

When multiple wind turbines are located close to each other, the total sound power can be estimated by applying logarithmic relations. For example, for two turbines with sound power levels L_{W1} and L_{W2}, the total sound power is:

$$L_{total} = 10 \log_{10} (10^{L_1/10} + 10^{L_2/10}) \quad (41)$$

For N turbines, the corresponding relation is:

$$L_{total} = 10 \log_{10} \sum_{i=1}^{N} 10^{L_i/10} \quad (42)$$

where L_{wi} is the sound power level of the i^{th} turbine. For turbines that are some distance away from each other the mathematics is more complicated, and the relations of interest (actually the sound pressure level) take into account the relative position of the turbines and the location of the observer as described below.

AE.3 Noise Propagation from Wind Turbines

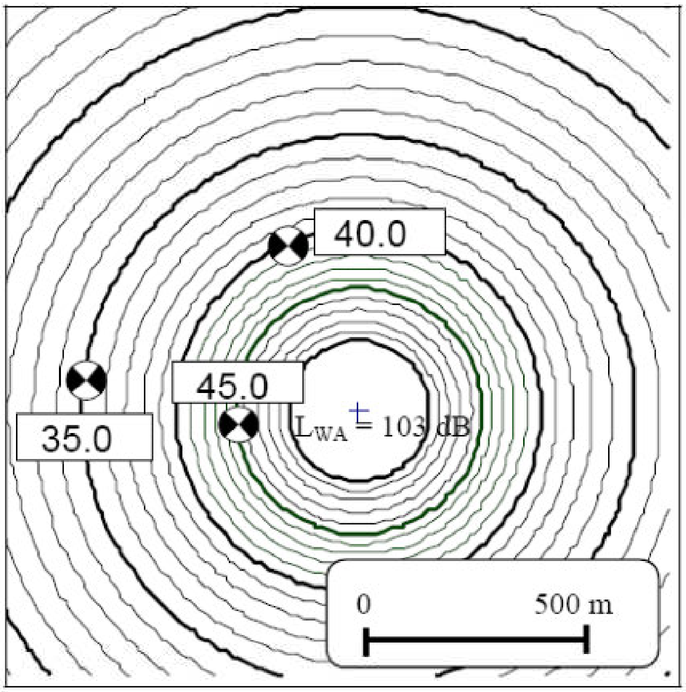
The sound pressure level will decrease with distance from a turbine. For estimation purposes, a simple model based on hemispherical noise propagation over a reflective surface, including air absorption, is given as:

$$L_p = L_W - 10 \log_{10}(2\pi R^2) - \alpha R \tag{43}$$

where L_p is the sound pressure level (dB) a distance R from a noise source radiating at a power level L_W (dB) and α is the frequency-dependent sound absorption coefficient. For broadband estimates the absorption coefficient is often approximated by a constant value of 0.005 dB(A)/m.

Figure AE.1 (from Materialien 63) indicates the sound pressure level as a function of distance from a single wind turbine with a sound power level of 103 dB(A).

Figure AE.1: Typical sound pressure level vs. distance from a single wind turbine (From Materialien 63)



The results are summarized in Table AE-1.

Table AE-1

Sound pressure level vs. distance

Sound Pressure, dB(A)	**Distance, m**
45	280
40	410
35	620

It may be seen that Equation 43, using the broadband absorption coefficient, predicts results close to those in the table (270 m, 435 m, and 675 m respectively).

AE.4 Noise Propagation from Multiple Wind Turbines

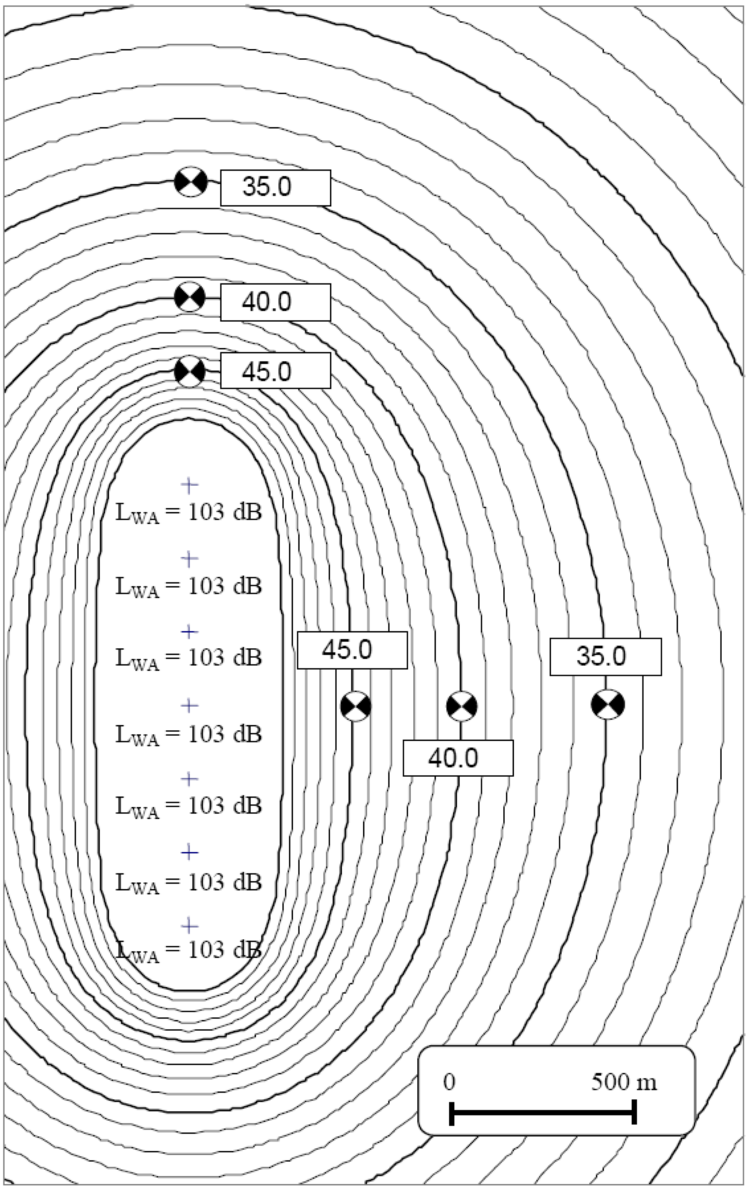
The sound perceived at a distance from multiple wind turbines is a function of the sound power level from each wind turbine and the distance to that turbine. The perceived value can be approximated by the following equation:

$$L_p = 10\log_{10}\left[\sum_{i=1}^{N} \frac{10^{\left(L_{W,i}/10 - \alpha R_i/10\right)}}{2\pi R_i^2}\right] \qquad (44)$$

Where R_i is the distance to the ith turbine.

Figure AE-2 illustrates the sound pressure level at various distances and directions from a line of seven wind turbines, each of which is operating at a sound power level of 103 dB(A).

Figure AE.2: Sound pressure level due to a line of seven wind turbines, each operating at a sound power level of 103 dB(A) (from Materialien 63



The results are summarized in the Table AE-2.

Table AE 2:

The distances shown are in the direction perpendicular to the line of the turbines

Sound Pressure, dB(A)	**Distance**
45	440
40	740
35	1100

.

Appendix F

Wind Turbine – Stall vs. Pitch Control Noise Issues

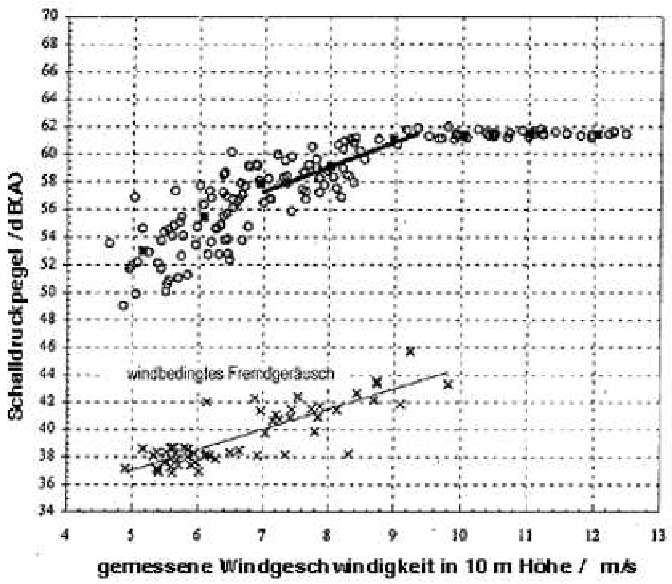
As noted in Appendix A, pitch regulated turbines are quieter than those with stall control. This is particularly the case at higher wind speeds. This appendix illustrates the difference, based on one source.

AF.1 Typical Noise from Pitch Regulated Wind Turbine

The figure below illustrates sound pressure level as a function of wind speed from a pitch regulated wind turbine (The data was taken at an unspecified distance from the turbine).

As can be seen, the noise level increases with wind speed up to a certain wind speed, here 9 m/s. After that wind speed is reached the blade pitch regulates the power and the noise level remains constant.

Figure AF.1: Sound pressure vs. wind speed from a pitch regulated wind turbine (from Materialien 63)



y-axis: sound pressure level, dB(A)

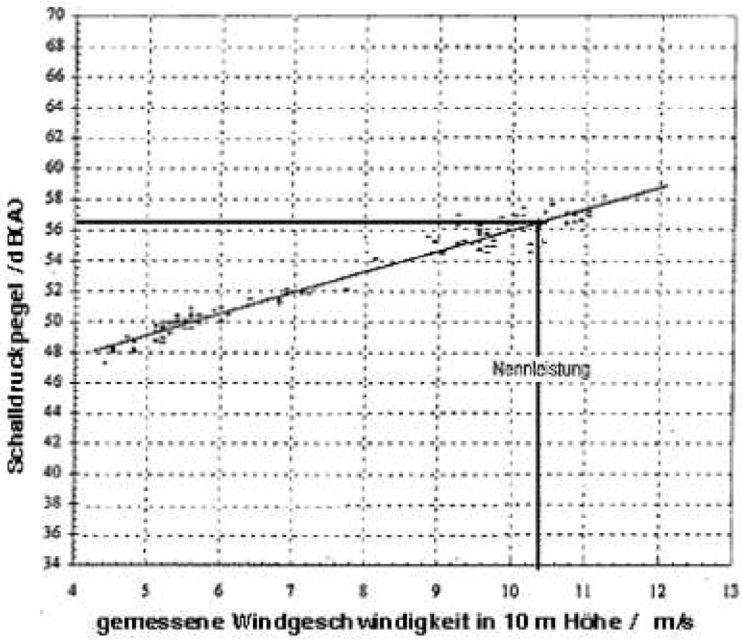
x- axis measured wind speed at 10 m height, m/s

lower line: wind-induced background noise

AF.2 Noise from a Stall Regulated Wind Turbine

The figure below illustrates sound pressure level as a function of wind speed from a stall controlled wind turbine (The data was taken at an unspecified distance from the turbine).

Figure AF.2: from Materialien 63



y-axis: sound pressure level, dB(A)

x- axis measured wind speed at 10 m height, m/s

The rated wind speed of this turbine is 10.4 m/s

As can be seen, the noise level increases approximately linearly with wind speed and does not level off.

Appendix G

Summary of Lab Animal Infrasound and Low Frequency Noise (IFLN) Studies

Table AG.1

Summary of Lab Animal Infrasound and Low Frequency Noise (IFLN) Studies

Study #	Animal Model	Endpoint	"Dose"	Timing	Measured Effects	Notes	Citation
1	Male Sprague-Dawley rats; 32 rat, 10 wks	Cardiac: ultrastructure observations, Ca2+, SERCA2 expression	5 Hz at 130 dB	2 hrs - 1 day	inc in [Ca2+]*l*; sig inc. SERCA2	No noted observation of frank toxicity. Responses increased across groups; heart rates increased in 1 day group, not in others; left ventricular pressures increased with dose chamber; Animal dose is at or slightly below 5 Hz/130 dB; Pentobarb anesthesia	Pei et al., 2007
			5 Hz at 130 dB	2 hrs - 7 days	inc in [Ca2+]*l*; Sig decr. In SERCA2 compared with control & 1 day		
			5 Hz at 130 dB	2 hrs - 14 days	inc in [Ca2+]*l*; Sig decin SERCA2 compared with control and 7 day group		
2	Male Adult Sprague-Dawley rats	Cardiac: whole-cell L-type Ca2+ currents (WLCC) in rat ventricular myocytes	5 Hz at 130 dB	2 hrs - 1 day; examined 1, 7 or 14 days post-exposure	Inc in [Ca2+](I) levels, LCC & SERCA2	No noted observation of frank toxicity. [Ca2+](I) levels as well as expression of LCC and SERCA2 may contribute to the infrasound exposure-elicited cardiac response; cannot concur with micrograph data	Pei et al., 2009
3	Male Sprague-Dawley rats	Neuronal release of stress-induced hormones	16 Hz at 130 dB	2 hrs - single exposure	activation of microglial cells and upregulation of Corticotrophin releasing hormone receptor (CRH R1); also upregulation expression is blocked by antalarmin	No noted observation of frank toxicity. .Measured in the hypothalamic paraventricular neurons. Antalarmin is a non-peptide drug that blocks the CRF-1 receptor, and, as a consequence, reduces the release of ACTH in response to chronic stress	Du et al., 2010
4	Male Sprague-Dawley rats	Neurogenesis	16 Hz at 130 dB	2 hrs/day - 7 days (sacrificed at 3, 6, 10, 14 & 18 days post-exposure)	Measured early migration and differentiation in newly generated progenitor cells by examining BUdR uptake in cells in the hippocampus (dentate gyrus)	No noted observation of frank toxicity. Authors conclude infrasound inhibits cell proliferation and that effects on proliferation appear to be reversible in the 18 days post exposure groupbackground - 40 dB; authors report reversibility, but the data don't support this - also, comparisons are with the "normal" group (in chamber, but no infrasound) but no comparison with control.	Liu et al., 2010
5	Male Albino Wistar Rats	Neural: Behavioral Performance - vestibular function	16 Hz at 72-105 dB		Rota-rod Treadmill evaluation	No noted observation of frank toxicity. Rats selected for superior performance were unaffected, but inferior rats were less able to perform for as long at same exposures.	Yamamura & Kishi, 1980
6	Male Wistar rats	Neurological - biochemical	2 Hz at 105 dB	1 hr & then sac'd	Measured brain neurepinephrine levels	No noted observation of frank toxicity. No control to determine whether Norepi levels were due to experimental design - not well controlled.	Spyraki et al., 1978
			7 Hz at 122 dB	1 hr & then sac'd	Measured brain neurepinephrine levels		
			26 Hz at 124 dB	1 hr & then sac'd	Measured brain neurepinephrine levels		
7	Female rats - no strain given	Neural	2 Hz at 105 dB 7 Hz at 122 dB 16 Hz at 124 dB		Observations made about rats' activity	Decreased time to sleep and decreased activity. Chamber and set-up is somewhat archaic and confirmatory measures are not made.	Spyraki et al., 1978
8	adult male Sprague-Dawley rats	Neural: hippocampus - dependent spatial learning and memory	16 Hz at 130 dB	14 days	Observations made using Morris water maze, measured expression and protein levels of brain-derived neurotrophic factor-tyrosine kinase receptor B.	No noted observation of frank toxicity. Calibration of sound chamber not discussed.	Yuan et al., 2009

CONTENTS

PREFACE

The aim of this edition continues to be the presentation of the latest information on the most frequently encountered noise and vibration problems. We have endeavored to introduce new chapters and to update those chapters where the field has advanced. New or fully rewritten chapters are Sound Generation, Noise Control in Heating, Ventilating, and Air Conditioning Systems, Active Control of Noise and Vibration, Sound-Absorbing Materials and Sound Absorbers, Outdoor Sound Propagation, Criteria for Noise in Buildings and Communities, and Acoustical Standards for Noise and Vibration Control. Substantial new information has been added to Passive Silencers. All other chapters have been reviewed for timeliness.

Worldwide, there has been increased interest in noise and vibration control. Much of this interest has been generated by the expanding activities in the countries of the European Union and the Far East. Workshops on the latest developments in global noise policy are being held annually—the latest in Prague (Czech Republic) in 2004 and in Rio de Janeiro (Brazil) in 2005. There are signs of expanded interest in noise policy in the United States. Consumers are demanding quiet to a greater degree, the best example being the improved quiet interiors of automobiles. Other consumer products with greater noise control are already following or are likely to follow. Manufacturers must be alert to the increased competitiveness of imported products.

We are particularly indebted to John Bradley, Richard D. Godfrey, Colin H. Hanson, William W. Lang, George C. Mailing, Jr., Howie Noble, Robert Preuss, and Paul Schomer, who rendered help and criticism during the preparation of this book, and to the many individuals and organizations who gave us permission to use copyrighted technical information. We are also indebted to Acentech, Inc., BBN Technologies, Inc., Mueller-BBM Corporation and Harris Miller, Miller & Hanson, Inc., for encouraging members of their senior technical staff to contribute chapters and for assistance in many ways. It gives us special pleasure to acknowledge the help of Kathy Coleman and Jane Schultz, who assisted in the preparation of many chapters, and to Robert L. Argentieri, Fred Bernardi, and Robert H. Hilbert our editors at John Wiley & Sons, for their effective help and guidance in the production of this book.

CHAPTER 1

Basic Acoustical Quantities: Levels and Decibels

LEO L. BERANEK

Consultant
Cambridge, Massachusetts

1.1 BASIC QUANTITIES OF SOUND WAVES

Sound Waves and Noise

In the broadest sense, a *sound wave* is any disturbance that is propagated in an elastic medium, which may be a gas, a liquid, or a solid. Ultrasonic, sonic, and infrasonic waves are included in this definition. Most of this text deals with sonic waves, those sound waves that can be perceived by the hearing sense of a human being. *Noise* is defined as any perceived sound that is objectionable to a human being. The concepts basic to this chapter can be found in references 1–7. Portions are further expanded in Chapter 2.

Sound Pressure

A person who is not deaf perceives as sound any vibration of the eardrum in the audible frequency range that results from an incremental variation in air pressure at the ear. A variation in pressure above and below atmospheric pressure is called *sound pressure*, in units of pascals (Pa).* A young person with normal hearing can perceive sound in the frequency range of roughly 15 Hz (hertz) to 16,000 Hz, defined as the normal audible frequency range.

Because the hearing mechanism responds to sound pressure, it is one of two quantities that is usually measured in engineering acoustics. The normal ear is most sensitive at frequencies between 3000 and 6000 Hz, and a young person can detect pressures as low as about 20 μPa, which, when compared to the normal atmospheric pressure (101.3×10^3 Pa) around which it varies, is a fractional variation of 2×10^{-10}.

*One pascal (Pa) = 1 newton/meter squared (N/m^2) = 10 dynes/cm^2

Pure Tone

A pure tone is a sound wave that can be represented by the equation,

$$p(t) = p_0 \sin(2\pi f)t \tag{1.1}$$

where $p(t)$ is the instantaneous, incremental, sound pressure (above and below atmospheric pressure), p_0 is the maximum amplitude of the instantaneous sound pressure, and f is the frequency, that is, the number of cycles per second, expressed in hertz. The time t is in seconds.

Period

A full cycle occurs when t varies from zero to $1/f$. The $1/f$ quantity is known as the period T. For example, the period T of a 500-Hz wave is 0.002 sec.

Root-Mean-Square Amplitude

If we wish to determine the mean value of a full cycle of the sine wave of Eq. (1.1.) (or any number of full cycles), it will be zero because the positive part equals the negative part. Thus, the mean value is not a useful measure. We must look for a measure that permits the effects of the rarefactions to be added to (rather than subtracted from) the effects of the compressions.

One such measure is the root-mean-square (rms) sound pressure p_{rms}. It is obtained, first, by squaring the value of the sound pressure disturbance $p(t)$ at each instant of time. Next the squared values are added and averaged over one or more periods. The rms sound pressure is the square root of this time average. The rms value is also called the *effective value*. Thus

$$p_{\text{rms}}^2 = \tfrac{1}{2} p_0^2 \tag{1.2}$$

or

$$p_{\text{rms}} = 0.707 p_0 \tag{1.3}$$

In the case of nonperiodic sound pressures, the integration interval should be long enough to make the rms value obtained essentially independent of small changes in the length of the interval.

Sound Spectra

A sound wave may be comprised of a pure tone (single frequency, e.g., 1000 Hz), a combination of single frequencies harmonically related, or a combination of single frequencies not harmonically related, either finite or infinite in number. A combination of a finite number of tones is said to have a *line spectrum.* A combination of an infinite (large) number of tones has a *continuous spectrum.* A continuous-spectrum noise for which the amplitudes versus time occur with a

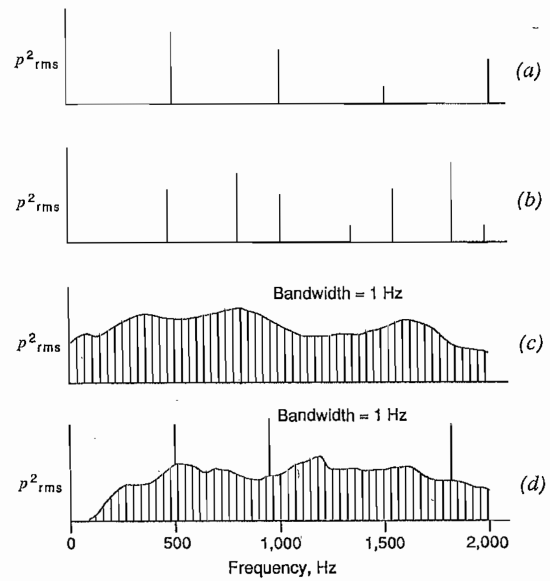

FIGURE 1.1 Mean-square sound pressure spectra: (*a*) harmonically related line spectrum; (*b*) inharmonically related line spectrum; (*c*) continuous power spectral density spectrum; (*d*) combination line and continuous power spectral density spectrum (complex spectrum).

normal (Gaussian) distribution is called *random noise*. Three of these types of noise are shown by the frequency spectra in Figs. 1.1*a–c*. A combination of a line and a continuous spectrum, called a complex spectrum, is shown in Fig. 1.1*d*.

Regardless of which type of sound wave is considered, when propagating at normal sound pressure amplitudes (to avoid nonlinearity) in air over reasonably short distances (so that sound attenuation in the air itself, which becomes significant at frequencies above 1000 Hz, can be neglected), the waveform is unchanged. Thus, a violin heard at a distance of 30 m sounds the same as at 5 m, although it is less loud.

Sound Intensity

The second quantity commonly measured in engineering acoustics is *sound intensity*, defined as the continuous flow of power carried by a sound wave through an incrementally small area at a point in space. The units are watts per square meter (W/m^2). This quantity is important for two reasons. First, at a point in free space, it is related to the total power radiated into the air by a sound source and, second, it bears at that point a fixed relation to the sound pressure.

Sound intensity at a point is directional (a vector) in the sense that the position of the plane of the incrementally small area can vary from being perpendicular to the direction in which the wave is traveling to being parallel to that direction. It has its maximum value, I_{max}, when its plane is perpendicular to the direction of travel. When parallel, the sound intensity is zero. In between, the component of I_{max} varies as the cosine of the angle formed by the direction of travel and a line perpendicular to the incremental area.

Another equation, which we shall develop in the next chapter, relates sound pressure to sound intensity. In an environment in which there are no reflecting surfaces, the sound pressure *at any point in any type of freely traveling* (plane, cylindrical, spherical, etc.) wave is related to the maximum intensity I_{max} by

$$p_{rms}^2 = I_{max} \cdot \rho c \quad \text{Pa}^2 \tag{1.4}$$

where p_{rms} = rms sound pressure, Pa (N/m^2)
ρ = density of air, kg/m^3
c = speed of sound in air, m/s [see Eq. (1.7)]
N = force, N

Sound Power

A sound source radiates a measurable amount of power into the surrounding air, called *sound power*, in watts. If the source is nondirectional, it is said to be a *spherical sound source* (see Fig. 1.2). For such a sound source the measured (maximum) sound intensities at all points on an imaginary spherical surface centered on the acoustic center of the source are equal. Mathematically,

$$W_s = (4\pi r^2) I_s(r) \quad \text{W} \tag{1.5}$$

where $I_s(r)$ = maximum sound intensity at radius r at surface of an imaginary sphere surrounding source, W/m^2
W_s = total sound power radiated by source in watts, W (N · m/s)
r = distance from acoustical center of source to surface of imaginary sphere, m

A similar statement can be made about a line source; that is, the maximum sound intensities at all points on an imaginary cylindrical surface around a *cylindrical sound source*, $I_c(r)$, are equal:

$$W_c = (2\pi r l) I_c(r) \quad \text{W} \tag{1.6}$$

where W_c = total sound power radiated by cylinder of length l, W
r = distance from acoustical centerline of cylindrical source to imaginary cylindrical surface surrounding source

Inverse Square Law

With a spherical source, the radiated sound wave is spherical and the total power radiated in all directions is W. The sound intensity $I(r)$ must decrease with

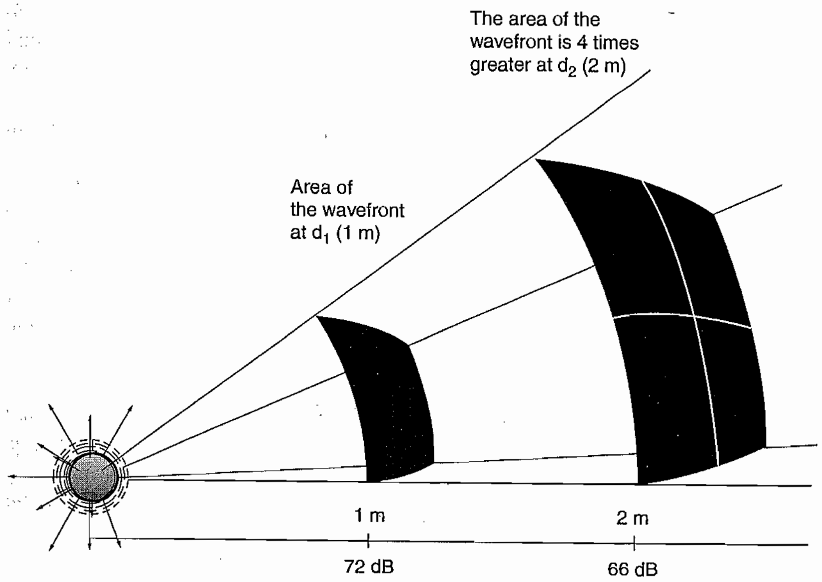

FIGURE 1.2 Generation of a one-dimensional spherical wave. A balloonlike surface pulsates uniformly about some equilibrium position and produces a sound wave that propagates radially away from the balloon at the speed of sound. (Courtesy of Ref. 8.)

distance in proportion to the sound pressure squared, that is $W/4\pi r^2$ [Eq. (1.5)]. Hence the name inverse square law. This is illustrated by the diagram in Fig. 1.2, where at a distance of 1 m the area of the wave front shown is a square meters and at 2 m it becomes $4a$ square meters. To preserve sound energy, the same amount of power flows through the larger area; thus Fig. 1.2 diagrammatically shows the intensity decreasing by a factor of 4, or, as shown later, 6 dB, from 72 to 66 dB.

Particle Velocity

Consider that the surface of the spherical source of Fig. 1.2 is expanding and contracting sinusoidally. During the first half of its sinusoidal motion, it pushes the air particles near its surface outward. Because air is elastic and compresses, the pressure near the surface will increase. This increased pressure overcomes the inertia of the air particles a short distance away and they move outward. That outward movement causes the pressure to build up at this new distance and, in turn, pushes more removed particles outward. This outward movement of the disturbance takes place at the speed of sound.

In the next half of the sinusoid, the sinusoidally vibrating spherical source reverses direction, creating a drop of pressure near its surface that pulls nearby air particles toward it. This reverse disturbance also propagates outward with the speed of sound. Thus, at any one point in space, there will be sinusoidal to-and-fro movement of the particles, called the *particle velocity*. Also at any point, there will be sinusoidal rise and fall of sound pressure.

From the basic equations governing the propagation of sound, as is shown in the next chapter, we can say the following:

1. In a *plane wave* (approximated at a large distance from a point source) propagated in free space (no reflecting surfaces) the sound pressure and the particle velocity reach their maximum and minimum values at the same instant and are said to be in phase.
2. In such a wave the particles move back and forth along the line in which the wave is traveling. In reference to the spherical radiation discussed above, this means that the particle velocity is always perpendicular to the imaginary spherical surface (the wave front) in space. This type of wave is called a longitudinal, or compressional, wave. By contrast, a transverse wave is illustrated by a surface wave in water where the particle velocity is perpendicular to the water surface while the wave propagates in a direction parallel to the surface.

Speed of Sound

A sound wave travels outward at a rate dependent on the elasticity and density of the air. Mathematically, the *speed of sound* in air is calculated as

$$c = \sqrt{\frac{1.4P_s}{\rho}} \quad \text{m/s} \tag{1.7}$$

where P_s = atmospheric (ambient) pressure, Pa
ρ = density of air, kg/m^3

For all practical purposes, the speed of sound is dependent only on the absolute temperature of the air. The equations for the speed of sound are

$$c = 20.05\sqrt{T} \quad \text{m/s} \tag{1.8}$$

$$c = 49.03\sqrt{R} \quad \text{ft/s} \tag{1.9}$$

where T = absolute temperature of air in degrees Kelvin, equal to 273.2 plus the temperature in degrees Celsius
R = absolute temperature in degrees Rankine, equal to 459.7 plus the temperature in degrees Fahrenheit

For temperatures near 20°C (68°F), the speed of sound is

$$c = 331.5 + 0.58^\circ\text{C} \quad \text{m/s} \tag{1.10}$$

$$c = 1054 + 1.07^\circ\text{F} \quad \text{ft/s} \tag{1.11}$$

Wavelength

Wavelength is defined as the distance the pure-tone wave travels during a full period. It is denoted by the Greek letter λ and is equal to the speed of sound divided by the frequency of the pure tone:

$$\lambda = cT = \frac{c}{f} \quad \text{m} \tag{1.12}$$

Sound Energy Density

In standing-wave situations, such as sound waves in closed, rigid-wall tubes, rooms containing little sound-absorbing material, or reverberation chambers, the quantity desired is not sound intensity, but rather the *sound energy density*, namely, the energy (kinetic and potential) stored in a small volume of air in the room owing to the presence of the standing-wave field. The relation between the *space-averaged sound energy density D* and the *space-averaged squared sound pressure* is

$$D = \frac{p_{\text{av}}^2}{\rho c^2} = \frac{p_{\text{av}}^2}{1.4P_s} \quad \text{W} \cdot \text{s/m}^3 \text{ (J/m}^3 \text{ or simply N/m}^2) \tag{1.13}$$

where p_{av}^2 = space average of mean-square sound pressure in a space, determined from data obtained by moving a microphone along a tube or around a room or from samples at various points, Pa^2
P_s = atmospheric pressure, Pa; under normal atmospheric conditions, at sea level, $P_s = 1.013 \times 10^5$ Pa

1.2 SOUND SPECTRA

In the previous section we described sound waves with line and continuous spectra. Here we shall discuss how to quantify such spectra.

Continuous Spectra

As stated before, a continuous spectrum can be represented by a large number of pure tones between two frequency limits, whether those limits are apart 1 Hz or thousands of hertz (see Fig. 1.3). Because the hearing system extends over a large frequency range and is not equally sensitive to all frequencies, it is customary to measure a continuous-spectrum sound in a series of contiguous frequency bands using a sound analyzer.

Customary bandwidths are one-third octave and one octave (see Fig. 1.4 and Table 1.1). The rms value of such a filtered sound pressure is called the one-third-octave-band or the octave-band sound pressure, respectively. If the filter bandwidth is 1 Hz, a plot of the filtered *mean-square* pressure of a *continuous-spectrum*

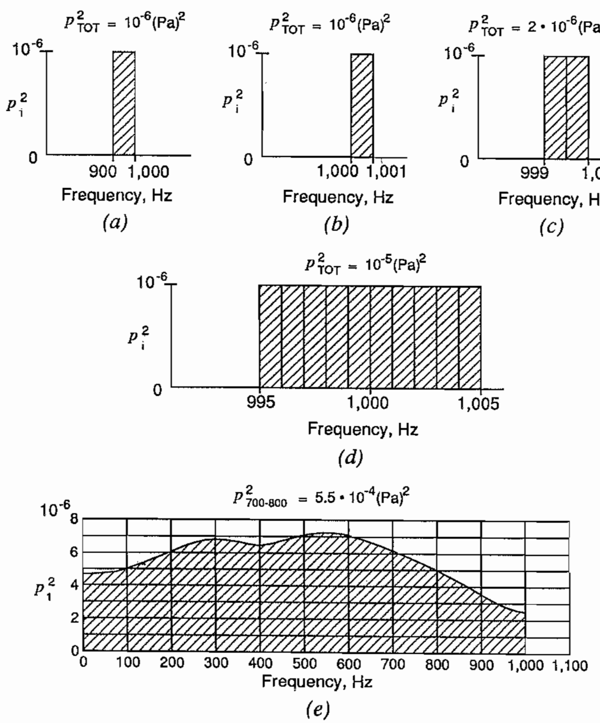

FIGURE 1.3 Power spectral density spectra showing the linear growth of total mean-square sound pressure when the bandwidth of noise is increased. In each case, p_1^2 is the mean-square sound pressure in a band 1 Hz wide.

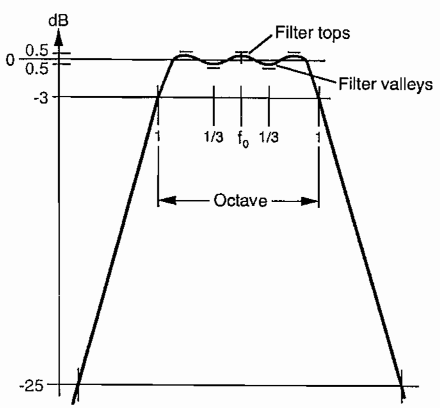

FIGURE 1.4 Frequency response of one manufacturer's octave-band filter. The 3-dB down points for the octave band and for a one-third-octave-band filter are indicated.

TABLE 1.1 Center and Approximate Cutoff Frequencies (Hz) for Standard Set of Contiguous-Octave and One-Third-Octave Bands Covering Audio Frequency Range[a]

[a]From Ref. 6.

sound versus frequency is called the *power spectral (or spectrum) density spectrum.* Narrow bandwidths are commonly used in analyses of machinery noise and vibration, but the term "spectral density" has no meaning in cases where pure tones are being measured.

The mean-square (or rms) sound pressure can be determined for each of the contiguous frequency bands and the result plotted as a function of frequency (Fig. 1.3*e*).

Bandwidth Conversion. It is frequently necessary to convert sounds measured with one set of bandwidths to a different set of bandwidths or to reduce both sets of measurements to a third set of bandwidths. Let us imagine that we have a machine that at a point in space produces a mean-square sound pressure of $p_1^2 = 10^{-6}$ Pa^2 in a 1-Hz bandwidth between 999 and 1000 Hz (Fig. 1.3*a*). Now imagine that we have a second machine the same distance away that radiates the same power but is confined to a bandwidth between 1000 and 1001 Hz (Fig. 1.3*b*). The total spectrum now becomes that shown in Fig. 1.3*c* and the total mean-square pressure is twice that in either band. Similarly, 10 machines would produce 10 times the mean-square sound pressure of any one (Fig. 1.3*d*).

In other words, if the power spectral density spectrum in a frequency band of width Δf is flat (the mean-square sound pressures in all the 1-Hz-wide bands, p_1^2, within the band are equal), the total mean-square sound pressure for the band is given by

$$p_{\text{tot}}^2 = p_1^2 \frac{\Delta f}{\Delta f_0} \quad \text{Pa}^2 \tag{1.14}$$

where $\Delta f_0 = 1$ Hz.

As an example, assume that we wish to convert the power spectral density spectrum of Fig. 1.3*e*, which is a plot of $p_1^2(f)$, the mean-square sound pressure in 1-Hz bands, to a spectrum for which the mean-square sound pressure in 100-Hz bands, p_{tot}^2, is plotted versus frequency. Let us consider only the 700–800-Hz band. Because $p_1^2(f)$ is not equal throughout this band, we could painstakingly determine and add together the actual p_1^2's or, as is more usual, simply take the average value for the p_1^2's in that band and multiply by the bandwidth. Thus, for each 100-Hz band, the total mean-square sound pressure is given by Eq. (1.14), where p_1^2 is the average 1-Hz band quantity throughout the band. For the 700–800-Hz band, the average p_1^2 is 5.5×10^{-6} and the total is $5.5 \times 10^{-6} \times 100$ Hz $= 5.5 \times 10^{-4}$ Pa^2.

If mean-square sound pressure levels have been measured in a specific set of bandwidths such as one-third-octave bands, it is possible to present accurately the data in a set of wider bandwidths such as octave bands by simply adding together the mean-square sound pressures for the component bands. Obviously, it is not possible to reconstruct a narrower bandwidth spectrum accurately (e.g., one-third-octave bands) from a wider bandwidth spectrum (e.g., octave bands.) However, it is sometimes necessary to make such a conversion in order to compare sets of data measured differently. Then the implicit assumption has to be made that the narrower band spectrum is continuous and monotonic within the larger band. In either direction, the conversion factor for each band is

$$p_B^2 = p_A^2 \frac{\Delta f_B}{\Delta f_A} \tag{1.15}$$

where p_A^2 is the measured mean-square sound pressure in a bandwidth Δf_A and p_B^2 is the desired mean-square sound pressure in the desired bandwidth Δf_B.

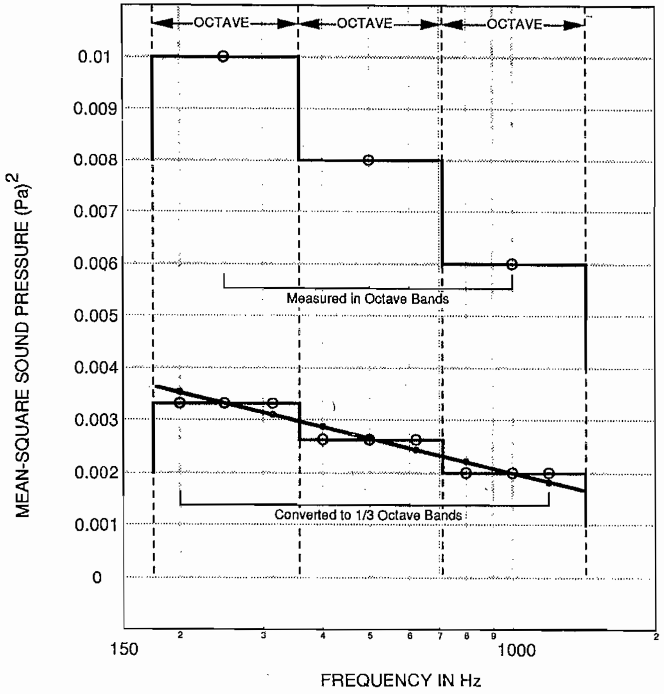

FIGURE 1.5 Conversion of octave-band mean-square sound pressures into third-octave-band mean-square sound pressures. Such conversion should be made only where necessary under the assumption that the third-octave-band mean-square pressure levels decrease monotonically with band midfrequency. The sloping solid curve is the assumed-correct converted spectrum.

As an example, assume that we have measured a sound with a continuous spectrum using a one-octave-band filterset and have plotted the intensity for the contiguous bands versus the midfrequency of each band (see the upper three circles in Fig. 1.5). Assume that we wish to convert to an approximate one-third-octave-band spectrum to make comparisons with other data possible. Not knowing how the mean-square sound pressure varies throughout each octave band, we assume it to be continuous and monotonic and apply Eq. (1.15). In this example, approximately, $\Delta f_B = \frac{1}{3}\Delta f_A$ for all the bands (see Table 1.1), and the mean-square sound pressure in each one-third-octave band with the same midfrequency will be one-third that in the corresponding one-octave band. The data would be plotted versus the midfrequency of each one-third-octave band (see Table 1.1 and Fig. 1.5). Then the straight, sloping line is added under the assumption that the true one-third-octave spectrum is monotonic.

Complex Spectra

The mean-square sound pressure resulting from the combination of two or more pure tones of different amplitudes p_1, p_2, p_3 and *different frequencies* f_1, f_2, f_3 is given by

$$p_{\mathrm{rms}}^2(\text{total}) = p_1^2 + p_2^2 + p_3^2 + \cdots \tag{1.16}$$

The mean-square sound pressure of two pure tones of the *same frequency* but different amplitudes and phases is found from

$$p_{\mathrm{rms}}^2(\text{total}) = p_1^2 + p_2^2 + 2p_1p_2 \cos(\theta_1 - \theta_2) \tag{1.17}$$

where the phase angle of each wave is represented by θ_1 or θ_2.

Comparison of Eqs. (1.16) and (1.17) reveals the importance of phase when combining two sine waves of the same frequency. If the phase difference $\theta_1 - \theta_2$ is zero, the two waves are in phase and the combination is at its maximum value. If $\theta_1 - \theta_2 = 180°$, the third term becomes $-2p_1p_2$ and the sum is at its minimum value. If the two waves are equal in amplitude, the minimum value is zero.

If one wishes to find the mean-square sound pressure of a number of waves all of which have different frequencies except, say, two, these two are added together according to Eq. (1.17) to obtain a mean-square pressure for them. Then this mean-square pressure and the mean-square pressures of the remainder of the components are summed according to Eq. (1.16).

1.3 LEVELS[6]

Because of the wide range of sound pressures to which the ear responds (a ratio of 10^5 or more for a normal person), sound pressure is an inconvenient quantity to use in graphs and tables. This is also true for the other acoustical quantities listed above. Early in the history of the telephone it was decided to adopt logarithmic scales for representing acoustical quantities and the voltages encountered in associated electrical equipment.

As a result of that decision, sound powers, intensities, pressures, velocities, energy densities, and voltages from electroacoustic transducers are commonly stated in terms of the logarithm of the ratio of the measured quantity to an appropriate reference quantity: Because the sound pressure at the threshold of hearing at 1000 Hz is about 20 μPa, this was chosen as the fundamental reference quantity around which the other acoustical references have been chosen.

Whenever the magnitude of an acoustical quantity is given in this logarithmic form, it is said to be a *level* in *decibels* (dB) *above* or *below* a zero *reference level* that is determined by a *reference quantity*. The argument of the logarithm is always a ratio and, hence, is dimensionless. The level for a very large ratio, for example the power produced by a very powerful sound source, might be given with the unit *bel*, which equals 10 dB.

Power and Intensity Levels

Sound Power Level. Sound power level is defined as

$$L_W = 10 \log_{10} \frac{W}{W_0} \quad \text{dB re } W_0 \tag{1.18}$$

and conversely

$$W = W_0 \operatorname{antilog}_{10} \frac{L_W}{10} = W_0 \times 10^{L_W/10} \quad \mathrm{W} \tag{1.19}$$

where W = sound power, W (watts)
W_0 = reference sound power, standardized at 10^{-12} W

As seen in Table 1.2, a *ratio* of 10 in the power W corresponds to a *level difference* of 10 dB regardless of the reference power W_0. Similarly, a ratio of 100 corresponds to a level difference of 20 dB. Power ratios of less than 1 are allowable: They simply lead to negative levels. For example (see Table 1.2), a power ratio of 0.1 corresponds to a level difference of −10 dB.

Column 4 of Table 1.2 gives sound power levels relative to the standard reference power level $W_0 = 10^{-12}$ W in watts.

Some sound power ratios and the corresponding sound-power-level differences are given in Table 1.3. We note from the last line that the sound power level for the *product of two ratios* is equal to the *sum of the levels* for the two ratios. For example, determine L_W for the quantity 2 × 4. From Table 1.3,

TABLE 1.2 Sound Powers and Sound Power Levels

0.01	−20
0.001	−30
$R_1 \times R_2$	$L_{W_1} + L_{W_2}$

[a]To the nearest 0.1 dB.

$L_W = 3.0 + 6.0 = 9.0$ dB, which is the sound power level for the ratio 8. Similarly, L_W for a ratio of 8000 equals the sum of the levels for 8 and 1000, that is, $L_W = 9 + 30 = 39$ dB.

Sound Intensity Level. Sound intensity level, in decibels, is defined as

$$\text{Intensity level} = L_I = 10 \log \frac{I}{I_{\text{ref}}} \quad \text{dB re } I_{\text{ref}} \tag{1.20}$$

where I = sound intensity whose level is being specified, W/m^2
I_{ref} = reference intensity standardized as 10^{-12} W/m^2

Sound power levels should not be confused with intensity levels (or with sound pressure levels, which are defined next), which also are expressed in decibels. Sound power is a measure of the *total* acoustical power radiated by a source in watts. Sound intensity and sound pressure specify the acoustical "disturbance"

produced at a point removed from the source. For example, their levels depend on the distance from the source, losses in the intervening air path, and room effects (if indoors). A helpful analogy is to imagine that sound power level is related to the total rate of heat production of a furnace, while either of the other two levels is analogous to the temperature produced at a given point in a dwelling.

Sound Pressure Level

Almost all microphones used today respond to sound pressure, and in the public mind, the word *decibel* is commonly associated with sound pressure level or A-weighted sound pressure level (see Table 1.4). Strictly speaking, sound pressure level is analogous to intensity level, because, in calculating it, pressure is first squared, which makes it proportional to intensity (power per unit area):

$$\begin{aligned}\text{Sound pressure level} = L_p &= 10 \log \left[\frac{p(t)}{p_{\text{ref}}}\right]^2 \\ &= 20 \log \frac{p(t)}{p_{\text{ref}}} \quad \text{dB re } p_{\text{ref}}\end{aligned} \tag{1.21}$$

where p_{ref} = reference sound pressure, standardized at 2×10^{-5} N/m^2 (20 μPa) for airborne sound; for other media, references may be 0.1 N/m^2 (1 dyn/cm^2) or 1 μN/m^2 (1 μPa)
$p(t)$ = instantaneous sound pressure, Pa

Note that L_p re 20 μPa is 94 dB greater than L_p re 1 Pa.

As we shall show shortly, $p(t)^2$ is only proportional to sound intensity if its mean-square value is taken. Thus, in Eq. (1.21), $p(t)$ would be replaced by p_{rms}.

The relations among sound pressure levels (re 20 μPa) for pressures in the meter-kilogram-second (mks), centimeter-gram-second (cgs), and English systems of units are shown by the four nomograms of Fig. 1.6.

1.4 DEFINITIONS OF OTHER COMMONLY USED LEVELS AND QUANTITIES IN ACOUSTICS

Analogous to sound pressure level given in Eq. (1.21), *A-weighted sound pressure level* L_A is given by

$$L_A = 10 \log \left[\frac{p_A(t)}{p_{\text{ref}}}\right]^2 \quad \text{dB} \tag{1.22}$$

where $p_A(t)$ is the instantaneous sound pressure measured using the standard frequency-weighting A (see Table 1.4).

TABLE 1.4 A and C Electrical Weighting Networks for Sound-Level Meter[a]

Frequency, Hz	A-Weighting Relative Response, dB	C-Weighting Relative Response, dB
10	−70.4	−14.3

20,000	−9.3	−11.2

[a]These numbers assume a flat, diffuse-field (random-incidence) response for the sound-level meter and microphone.

Average sound level $L_{\mathrm{av},T}$ is given by

$$L_{\mathrm{av},T} = 10 \log \frac{(1/T)\int_0^T p^2(t)\,dt}{p_{\mathrm{ref}}^2} \quad \mathrm{dB} \tag{1.23}$$

where T is the (long) time over which the averaging takes place.

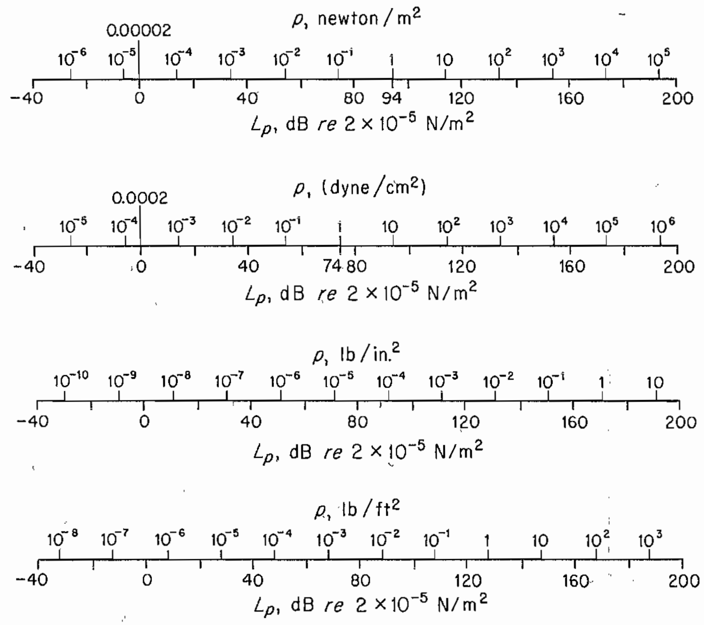

FIGURE 1.6 Charts relating L_p (dB re 20 μPa) to p in N/m²(Pa), dyn/cm², lb/in.², and lb/ft². For example, 1.0 Pa = 94 dB re 20 μPa.

Average A-weighted sound level $L_{A,T}$ (also called L_{eq}, *equivalent continuous A-weighted noise level*) is given by

$$L_{A,T} = L_{\mathrm{eq}} = 10 \log \frac{(1/T)\int_0^T p_A^2(t)\,dt}{p_{\mathrm{ref}}^2} \quad \mathrm{dB} \tag{1.24}$$

The time T must be specified. In noise evaluations, its length is usually one to several hours, or 8 h (working day), or 24 h (full day).

Day–night sound (noise) level L_{dn} is given by

$$L_{\mathrm{dn}} = 10 \log \frac{1}{24}\left[\frac{\int_{07:00}^{22:00} p_A^2(t)\,dt}{p_{\mathrm{ref}}^2} + \frac{\int_{22:00}^{07:00} 10\, p_A^2(t)\,dt}{p_{\mathrm{ref}}^2}\right] \quad \mathrm{dB} \tag{1.25}$$

where the first term covers the "daytime" hours from 07:00 to 22:00 and the second term covers the nighttime hours from 22:00 to 07:00. Here, the nighttime noise levels are considered to be 10 dB greater than they actually measure. The A-weighted sound pressure p_A is sampled frequently during measurement.

A-weighted sound exposure $E_{A,T}$ is given by

$$E_{A,T} = \int_{t_1}^{t_2} p_A^2(t)\,dt \quad \mathrm{Pa}^2 \cdot \mathrm{s} \tag{1.26}$$

This equation is not a level. The term $E_{A,T}$ is proportional to the energy flow (intensity times time) in a sound wave in the time period T. The period T starts and stops at t_1 and t_2, respectively.

A-weighted noise exposure level $L_{EA,T}$ is given by

$$L_{EA,T} = 10 \log \left(\frac{E_{A,T}}{E_0}\right) \quad \mathrm{dB} \tag{1.27}$$

where E_0 is a reference quantity, standardized at $(20\ \mu\mathrm{Pa})^2 \cdot \mathrm{s} = (4 \times 10^{-10}\ \mathrm{Pa})^2 \cdot \mathrm{s}$. However, the International Organization for Standardization standard ISO 1999: 1990-01-5, on occupational noise level, uses $E_0 = (1.15 \times 10^{-5}\ \mathrm{Pa})^2 \cdot \mathrm{s}$, because, for an 8-h day, $L_{EA,T}$, with that reference, equals the average A-weighted sound pressure level $L_{A,T}$. The two reference quantities yield levels that differ by 44.6 dB. For a single impulse, the time period T is of no consequence provided T is longer than the impulse length and the background noise is low.

Hearing threshold for setting "zero" at each frequency on a pure-tone audiometer is the standardized, average, pure-tone threshold of hearing for a population of young persons with no otological irregularities. The standardized threshold sound pressure levels at the frequencies 250, 500, 1000, 2000, 3000, 4000, 6000, and 8000 Hz are, respectively, 24.5, 11.0, 6.5, 8.5, 7.5, 9.0, 8.0, and 9.5 dB measured under an earphone. An audiometer is used to determine the difference at these frequencies between the threshold values of a person (the lowest sound pressure level of a pure tone the person can detect consistently) and the standardized threshold values. Measurements are sometimes also made at 125 and 1500 Hz.[7]

Hearing impairment (hearing loss) is the number of decibels that the permanent hearing threshold of an individual at each measured frequency is above the zero setting on an audiometer, in other words, a change for the worse of the person's threshold of hearing compared to the normal for young persons.

Hearing threshold levels associated with age are the standardized pure-tone thresholds of hearing associated solely with age. They were determined from tests made on the hearing of persons in a certain age group in a population with no otological irregularities and no appreciable exposure to noise during their lives.

Hearing threshold levels associated with age and noise are the standardized pure-tone thresholds determined from tests made on the hearing of individuals who had histories of higher than normal noise exposure during their lives. The average noise levels and years of exposure were determined by questioning and measurement of the exposure levels.

Noise-induced permanent threshold shift (NIPTS) is the shift in the hearing threshold level caused solely by exposure to noise.

1.5 REFERENCE QUANTITIES USED IN NOISE AND VIBRATION

American National Standard

The American National Standards Institute has issued a standard (ANSI S1.8-1989, Reaffirmed 2001) on "Reference Quantities for Acoustical Levels." This standard is a revision of ANSI S1.8-1969. The authors of this book have been surveyed for their opinions on preferred reference quantities. Table 1.5 is a combination of the standard references and of references preferred by the authors. The two references are clearly distinguished. All quantities are stated in terms of the International System of units (SI) and in British units.

Relations among Sound Power Levels, Intensity Levels, and Sound Pressure Levels

As a practical matter, the reference quantities for sound power, intensity, and sound pressure (in air) have been chosen so that their corresponding levels are interrelated in a convenient way under certain circumstances.

The threshold of hearing at 1000 Hz for a young listener with acute hearing, measured under laboratory conditions, was determined some years ago as a sound pressure of 2×10^{-5} Pa. This value was then selected as the reference pressure for sound pressure level.

Intensity at a point is related to sound pressure at that point in a free field by Eq. (1.14). A combination of Eqs. (1.4), (1.20), and (1.21) yields the sound intensity level

$$\begin{aligned} L_I &= 10 \log \frac{I}{I_{\mathrm{ref}}} = 10 \log \frac{p^2}{\rho c I_{\mathrm{ref}}} \\ &= 10 \log \frac{p^2}{p_{\mathrm{ref}}^2} + 10 \log \frac{p_{\mathrm{ref}}^2}{\rho c I_{\mathrm{ref}}} \\ L_I &= L_p - 10 \log K \quad \mathrm{dB\ re\ } 10^{-12}\ \mathrm{W/m^2} \end{aligned} \tag{1.28}$$

where K = const = $I_{\mathrm{ref}} \rho c / p_{\mathrm{ref}}^2$, which is dependent upon ambient pressure and temperature; quantity $10 \log K$ may be found from Fig. 1.7, or, $K = \rho c/400$

The quantity $10 \log K$ will equal zero, that is, $K = 1$, when

$$\rho c = \frac{p_{\mathrm{ref}}^2}{I_{\mathrm{ref}}} = \frac{4 \times 10^{-10}}{10^{-12}} = 400 \text{ mks rayls} \tag{1.29}$$

We may also rearrange Eq. (1.28) to give the sound pressure level

$$L_p = L_I + 10 \log K \quad \mathrm{dB\ re\ } 2 \times 10^{-5}\ \mathrm{Pa} \tag{1.30}$$

TABLE 1.5 Reference Quantities for Acoustical Levels from American National Standard ANSI S1.8-1989 (Reaffirmed 2001) and As Preferred by Authors

Name	Definition	Preferred Reference Quantities: SI	Preferred Reference Quantities: British
Sound pressure level (gases)	$L_p = 20 \log_{10}(p/p_0)$ dB	$p_0 = 20\ \mu\text{Pa} = 2 \times 10^{-5}\ \text{N/m}^2$	2.90×10^{-9} lb/in.^{2}
Sound pressure level (other than gases)	$L_p = 20 \log_{10}(p/p_0)$ dB	$p_0 = 1\ \mu\text{Pa} = 10^{-6}\ \text{N/m}^2$	1.45×10^{-10} lb/in.^{2}
Sound power level	$L_W = 10 \log_{10}(W/W_0)$ dB	$W_0 = 1\ \text{pW} = 10^{-12}\ \text{N}\cdot\text{m/s}$	8.85×10^{-12} in. · lb/s
	$L_W = \log_{10}(W/W_0)$ bel	$W_0 = 1\ \text{pW} = 10^{-12}\ \text{N}\cdot\text{m/s}$	8.85×10^{-12} in. · lb/s
Sound intensity level	$L_I = 10 \log_{10}(I/I_0)$ dB	$I_0 = 1\ \text{pW/m}^2 = 10^{-12}\ \text{N/m}\cdot\text{s}$	5.71×10^{-15} lb/in. · s
Vibratory force level	$L_{F0} = 20 \log_{10}(F/F_0)$ dB	$F_0 = 1\ \mu\text{N} = 10^{-6}\ \text{N}$	2.25×10^{-7} lb
Frequency level	$N = \log_{10}(f/f_0)$ dB	$f_0 = 1$ Hz	1.00 Hz
Sound exposure level	$L_E = 10 \log_{10}(E/E_0)$ dB	$E_0 = (20\ \mu\text{Pa})^2 \cdot \text{s} = (2 \times 10^{-5}\ \text{Pa})^2 \cdot \text{s}$	8.41×10^{-18} lb^2/in.^{4}
The quantities listed below are not officially part of ANSI S1.8. They either are listed there for information or are included here as the authors' choice.			
Sound energy level given in ISO 1683:1983	$L_e = 10 \log_{10}(e/e_0)$ dB	$e_0 = 1\ \text{pJ} = 10^{-12}\ \text{N}\cdot\text{m}$	8.85×10^{-12} lb · in.
Sound energy density level given in ISO 1683:1983	$L_D = 10 \log_{10}(D/D_0)$ dB	$D_0 = 1\ \text{pJ/m}^3 = 10^{-12}\ \text{N/m}^2$	1.45×10^{-16} lb/in.^{2}
Vibration acceleration level	$L_a = 20 \log_{10}(a/a_0)$ dB	$a_0 = 10\ \mu\text{m/s}^2 = 10^{-5}\ \text{m/s}^2$	3.94×10^{-4} in./s^2
Vibration acceleration level in ISO 16831983	$L_a = 20 \log_{10}(a/a_0)$ dB	$a_0 = 1\ \mu\text{m/s}^2 = 10^{-6}\ \text{m/s}^2$	3.94×10^{-5} in./s^2
Vibration velocity level	$L_v = 20 \log_{10}(v/v_0)$ dB	$v_0 = 10\ \text{nm/s} = 10^{-8}\ \text{m/s}$	3.94×10^{-7} in./s
Vibration velocity level in ISO 1683:1983	$L_v = 20 \log_{10}(v/v_0)$ dB	$v_0 = 1\ \text{nm/s} = 10^{-9}\ \text{m/s}$	3.94×10^{-8} in./s
Vibration displacement level	$L_d = 20 \log_{10}(d/d_0)$ dB	$d_0 = 10\ \text{pm} = 10^{-11}\ \text{m}$	3.94×10^{-10} in.

Notes: Decimal multiples and submultiples of SI units are formed as follows: 10^{-1} = deci (d), 10^{-2} = centi (c), 10^{-3} = milli (m), 10^{-6} = micro (μ), 10^{-9} = nano (n), and 10^{-12} = pico (p). Also J = joule = W · s(N · m), N = newton, and Pa = pascal = 1 N/m^2. Note that 1 lb = 4.448 N.
Although some international standards differ, in this text, to avoid confusion between power and pressure, we have chosen to use W instead of P for power; and to avoid confusion between energy density and voltage, we have chosen D instead of E for energy density. The symbol lb means pound force.
In recent international standardization $\log_{10}$ is written lg and $20 \log_{10}(a/b) = 10 \lg (a^2/b^2)$, i.e., "20" is never used.

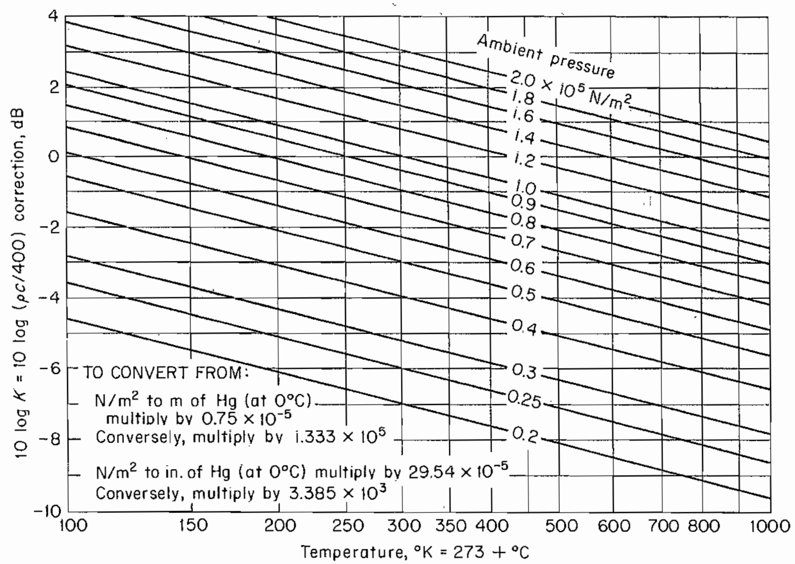

FIGURE 1.7 Chart determining the value of $10 \log(\rho c/400) = 10 \log K$ as a function of ambient temperature and ambient pressure. Values for which $\rho c = 400$ are also given in Table 1.6.

In Table 1.6, we show a range of ambient pressures and temperatures for which $\rho c = 400$ mks rayls. We see that for average atmospheric pressure, namely, 1.013×10^5 Pa, the temperature must equal 38.9°C (102°F) for $\rho c = 400$ mks rayls. However, if $T = 22$°C and $p_s = 1.013 \times 10^5$ Pa^2, $\rho c \approx 412$. This yields a value of $10 \log(\rho c/400) = 10 \log 1.03 = 0.13$ dB, an amount that is usually not significant in acoustics.

Thus, for most noise measurements, we neglect $10 \log K$ and in a free progressive wave let

$$L_p \approx L_I \tag{1.31}$$

Otherwise, the value of $10 \log K$ is determined from Fig. 1.7 and used in Eq. (1.28) or (1.30).

Under the condition that the *intensity is uniform over an area S*, the sound power and the intensity are related by $W = IS$. Hence, the sound power level is related to the intensity level as follows:

$$10 \log \frac{W}{10^{-12}} = 10 \log \frac{I}{10^{-12}} + 10 \log \frac{S}{S_0}$$

$$L_W = L_I + 10 \log S \quad \text{dB re } 10^{-12} \text{ W} \tag{1.32}$$

where S = area of surface, m^2
$S_0 = 1$ m^2

Obviously, only if the area $S = 1.0$ m^2 will $L_W = L_I$. Also, observe that the relation of Eq. (1.32) is not dependent on temperature or pressure.

1.6 DETERMINATION OF OVERALL LEVELS FROM BAND LEVELS

It is necessary often to convert sound pressure levels measured in a series of contiguous bands into a single-band level encompassing the same frequency range. The level in the all-inclusive band is called the *overall level* L(OA) given by

$$L_p(\text{OA}) = 20 \log \sum_{i=1}^{n} 10^{L_{pi}/20} \quad \text{dB} \tag{1.33}$$

$$L_p(\text{OA}) = 10 \log \sum_{i=1}^{n} 10^{L_{Ii}/10} \quad \text{dB} \tag{1.34}$$

The conversion can also be accomplished with the aid of Fig. 1.8. Assume that the contiguous band levels are given by the eight numbers across the top of Fig. 1.9. The frequency limits of the bands are not important to the method of calculation as long as the bands are contiguous and cover the frequency range of the overall band. To combine these eight levels into an overall level, start with any two, say, the seventh and eighth bands. From Fig. 1.8 we see that whenever the difference between two band levels, $L_1 - L_2$, is zero, the combined level is 3 dB higher. If the difference is 2 dB (the sixth band level minus the new level of 73 dB), the sum is 2.1 dB greater than the larger (75 + 2.1 dB). This procedure is followed until the overall band level is obtained, here, 102.1 dB.

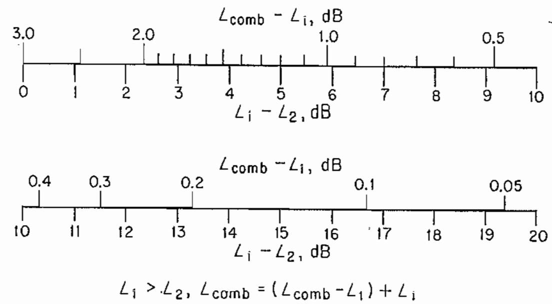

FIGURE 1.8 Nanogram for combining two sound levels L_1 and L_2 (dB). Levels may be power levels, sound pressure levels, or intensity levels. Example: $L_1 = 88$ dB, $L_2 = 85$ dB, $L_1 - L_2 = 3$ dB. Solution: $L_{comb} = 88 + 1.8 = 89.8$ dB.

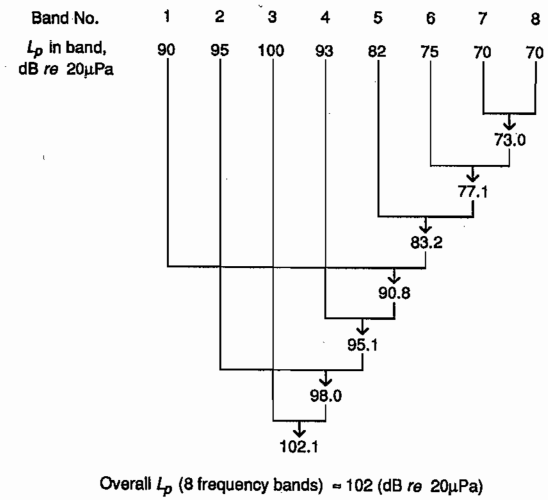

FIGURE 1.9 Determination of an overall sound pressure level from levels in frequency bands (see also Fig. 1.10).

If we set $L_{comb} - L_1 = A$, then A is the number to be added to L_1 (the larger) to get L_{comb}.

It is instructive to combine the bands in a different way, as is shown in Fig. 1.10. The first four bands are combined first; then the second four bands are combined. The levels of the two wider band levels are then combined. It is seen that the overall level is determined by the first four bands alone. This example points up the fact that characterization of a noise by its overall level may be completely inadequate for some noise control purposes because it may ignore a large

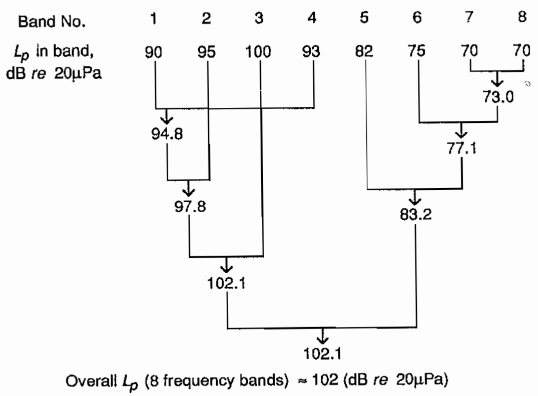

FIGURE 1.10 Alternate determination of an overall sound pressure level from levels in frequency bands (see also Fig. 1.9).

portion of the frequency spectrum. If the data of Fig. 1.10 represented a genuine noise control situation, the 102.1 overall level might be meaningless for some applications. For example, the sound pressure levels in the four highest bands might be the cause of annoyance or interference with speech communication, as is discussed in Chapter 19.

Finally, it should be remembered that in almost all noise control problems, it makes no sense to deal with small fractions of decibels. Rarely does one need a precision of 0.2 dB in measurements, and quite often it is adequate to quote levels to the nearest decibel.

2.1 THE WAVE EQUATION[1]

Sound waves must obey the laws of physics. For gases these include Newton's second law of motion, the gas law, and the law of conservation of mass. Combined, these equations produce the wave equation that governs the behavior of sound waves regardless of the surroundings in which they occur.

Equation of Motion

The equation of motion (also called the force equation) is obtained by the application of Newton's second law to a small volume of gas in a homogeneous medium. Imagine the small volume of gas to be enclosed in a packet with weightless flexible sides and assume that there is negligible drag (friction) between particles inside and outside the packet. Suppose that this small volume exists in a part of the medium where the sound pressure p [actually $p(t)$] increases at the space rate of

$$\mathbf{grad}\ p = \mathbf{i}\frac{\partial p}{\partial x} + \mathbf{j}\frac{\partial p}{\partial y} + \mathbf{k}\frac{\partial p}{\partial z} \tag{2.1}$$

where $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are unit vectors in the x, y, and z directions, respectively. Obviously, **grad** p is a vector quantity.

The difference between the forces acting on the sides of the packet is a force $\mathbf{f}$ equal to the rate at which the force changes with distance times the incremental dimensions of the box:

$$\mathbf{f} = -\left[\mathbf{i}\left(\frac{\partial p}{\partial x}\Delta x\right)\Delta y\ \Delta z + \mathbf{j}\left(\frac{\partial p}{\partial y}\Delta y\right)\Delta x\ \Delta z + \mathbf{k}\left(\frac{\partial p}{\partial z}\Delta z\right)\Delta x\ \Delta y\right] \tag{2.2}$$

Note that a positive gradient causes the packet to accelerate in the negative direction.

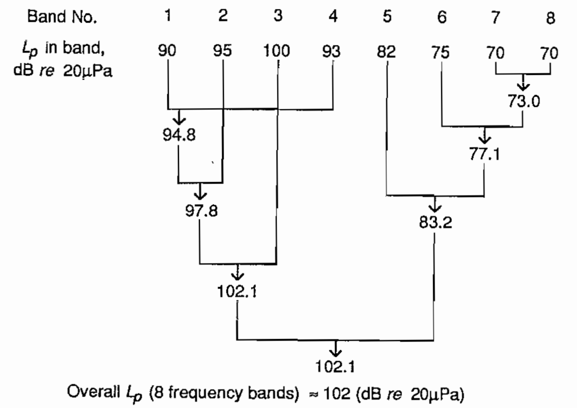

FIGURE 1.10 Alternate determination of an overall sound pressure level from levels in frequency bands (see also Fig. 1.9).

portion of the frequency spectrum. If the data of Fig. 1.10 represented a genuine noise control situation, the 102.1 overall level might be meaningless for some applications. For example, the sound pressure levels in the four highest bands might be the cause of annoyance or interference with speech communication, as is discussed in Chapter 19.

Finally, it should be remembered that in almost all noise control problems, it makes no sense to deal with small fractions of decibels. Rarely does one need a precision of 0.2 dB in measurements, and quite often it is adequate to quote levels to the nearest decibel.

CHAPTER 2

Waves and Impedances

LEO L. BERANEK

Consultant
Cambridge, Massachusetts

2.1 THE WAVE EQUATION[1]

Sound waves must obey the laws of physics. For gases these include Newton's second law of motion, the gas law, and the law of conservation of mass. Combined, these equations produce the wave equation that governs the behavior of sound waves regardless of the surroundings in which they occur.

Equation of Motion

The equation of motion (also called the force equation) is obtained by the application of Newton's second law to a small volume of gas in a homogeneous medium. Imagine the small volume of gas to be enclosed in a packet with weightless flexible sides and assume that there is negligible drag (friction) between particles inside and outside the packet. Suppose that this small volume exists in a part of the medium where the sound pressure p [actually $p(t)$] increases at the space rate of

$$\mathbf{grad}\ p = \mathbf{i}\frac{\partial p}{\partial x} + \mathbf{j}\frac{\partial p}{\partial y} + \mathbf{k}\frac{\partial p}{\partial z} \tag{2.1}$$

where $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are unit vectors in the x, y, and z directions, respectively. Obviously, **grad** p is a vector quantity.

The difference between the forces acting on the sides of the packet is a force $\mathbf{f}$ equal to the rate at which the force changes with distance times the incremental dimensions of the box:

$$\mathbf{f} = -\left[\mathbf{i}\left(\frac{\partial p}{\partial x}\Delta x\right)\Delta y\ \Delta z + \mathbf{j}\left(\frac{\partial p}{\partial y}\Delta y\right)\Delta x\ \Delta z + \mathbf{k}\left(\frac{\partial p}{\partial z}\Delta z\right)\Delta x\ \Delta y\right] \tag{2.2}$$

Note that a positive gradient causes the packet to accelerate in the negative direction.

Division of both sides of the equation by $\Delta x\ \Delta y\ \Delta z = V$ gives the force per unit volume acting to accelerate the box,

$$\frac{\mathbf{f}}{V} = -\mathbf{grad}\ p \tag{2.3}$$

By Newton's law, the force per unit volume of Eq. (2.3) equals the time derivative of the momentum per unit volume of the box. Because the box is a deformable packet, the mass inside is constant. Hence,

$$\frac{\mathbf{f}}{V} = -\mathbf{grad}\ p = \frac{M}{V}\frac{D\mathbf{q}}{Dt} = \rho'\frac{D\mathbf{q}}{Dt} \tag{2.4}$$

where $\mathbf{q}$ is the average vector velocity of the gas in the packet, ρ' is the average density of the gas in the packet, and $M = \rho' V$ is the total mass of the gas in the packet.

The partial derivative D/Dt is not a simple one but represents the total rate of the change of velocity of the particular bit of gas in the packet regardless of its position that is, because its position changes when a sound wave hits it:

$$\frac{D\mathbf{q}}{Dt} = \frac{\partial \mathbf{q}}{\partial t} + q_x\frac{\partial \mathbf{q}}{\partial x} + q_y\frac{\partial \mathbf{q}}{\partial y} + q_z\frac{\partial \mathbf{q}}{\partial z} \tag{2.5}$$

where q_x, q_y, and q_z are the components of the vector particle velocity $\mathbf{q}$.

If $\mathbf{q}$ is small enough, the rate of change of momentum of the particles in the box can be approximated by the rate of change of momentum at a fixed point $Dq/Dt \doteq \partial\mathbf{q}/\partial t$, and the instantaneous density ρ' can be approximated by the average density ρ. Then

$$-\mathbf{grad}\ p = \rho\frac{\partial \mathbf{q}}{\partial t} \tag{2.6}$$

Gas Law

At audible frequencies, the wavelength of a sound wave is long compared to the spacing between air molecules, so that expansions and contractions at two different parts of the medium occur so rapidly that there is no time for heat exchange between points of differing instantaneous pressures. Hence, the compressions and expansions are adiabatic. From elementary thermodynamics,

$$PV^{\gamma} = \text{const} \tag{2.7}$$

where γ for air, hydrogen, oxygen, and nitrogen equals 1.4. If we let $P = P_s + p$ and $V = V_s + \tau$, where P_s and V_s are the undisturbed pressure and volume of the packet, we get, for small values of incremental pressure p and incremental volume τ,

$$\frac{p}{P_s} = \frac{\gamma\tau}{V_s} \tag{2.8}$$

The time derivative of Eq. (2.8) yields

$$\frac{1}{P_s}\frac{\partial p}{\partial t} = -\frac{\gamma}{V_s}\frac{\partial \tau}{\partial t} \tag{2.9}$$

Continuity Equation

The continuity equation is a statement that the mass of the gas in the deformable packet is constant. Thus the change in the incremental volume τ depends only on the divergence of the vector displacement ξ:

$$\tau = V_s \text{ div } \xi \tag{2.10}$$

or

$$\frac{\partial \tau}{\partial t} = V_s \text{ div } \mathbf{q} \tag{2.11}$$

where $\mathbf{q}$ is the instantaneous (vector) particle velocity.

Wave Equation in Rectangular Coordinates

The three-dimensional wave equation is given by combining Eqs. (2.6), (2.9), and (2.11) and setting

$$c^2 = \frac{\gamma P_s}{\rho} \tag{2.12}$$

which yields

$$\nabla^2 p = \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} \tag{2.13}$$

where

$$\nabla^2 p = \frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} + \frac{\partial^2 p}{\partial z^2} \tag{2.14}$$

The one-dimensional wave equation is simply

$$\frac{\partial^2 p}{\partial x^2} = \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} \tag{2.15}$$

We could also have eliminated p in the combination of the three equations and retained $\mathbf{q}$, in which case we would have had

$$\nabla^2 \mathbf{q} = \frac{1}{c^2}\frac{\partial^2 \mathbf{q}}{\partial t^2} \tag{2.16}$$

2.2 SOLUTIONS TO THE ONE-DIMENSIONAL WAVE EQUATION

General Solution

The general solution to Eq. (2.15) is the sum of two terms,

$$p(x,t) = f_1\left(t - \frac{x}{c}\right) + f_2\left(t + \frac{x}{c}\right) \quad \text{Pa} \tag{2.17}$$

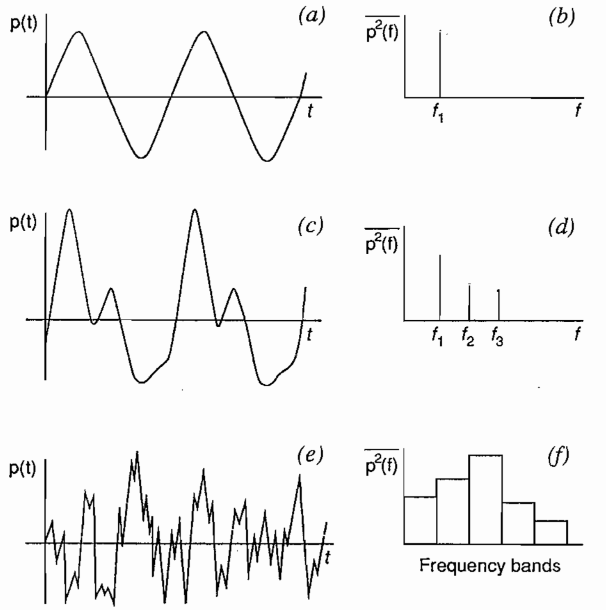

FIGURE 2.1 (*a, c, e*) Forms of time function f_1 or f_2 of Eq. (2.17). Corresponding spectra are shown on the right. (*b, d*) Line spectra. (*f*) Complex spectrum (very large number of tones in each band).

where f_1 and f_2 are arbitrary functions. As we shall illustrate shortly, the first term represents an outgoing wave and the second term a backward-traveling wave. The functions f_1 and f_2 represent the shapes of the two sound waves being propagated. Examples of typical time histories and spectra of $p(t)$ at a fixed location are given in Fig. 2.1. We also recognize c as the speed of sound in air.

Outwardly Traveling Plane Wave

An apparatus for producing an outward-traveling plane wave is shown in Fig. 2.2. A piston at the left moving sinusoidally generates a sound wave that travels outward in the positive x direction and becomes absorbed in the anechoic termination so that no reflected wave exists. Equation (2.17) becomes

$$p(x,t) = f_1\left(t - \frac{x}{c}\right) = P_R \cos k(x - ct) \quad \text{Pa} \tag{2.18}$$

where P_R is the peak amplitude of the sound pressure.

Let us choose the space and the time origins, as shown by the left-hand sine wave in Fig. 2.2, so that P_R has its maximum value at $x = 0$ and $t = 0$. After a time t_1, the wave will have traveled a distance $x_1 = ct_1$. Similarly for $x_2 = 2x_1 = 2ct_1$.

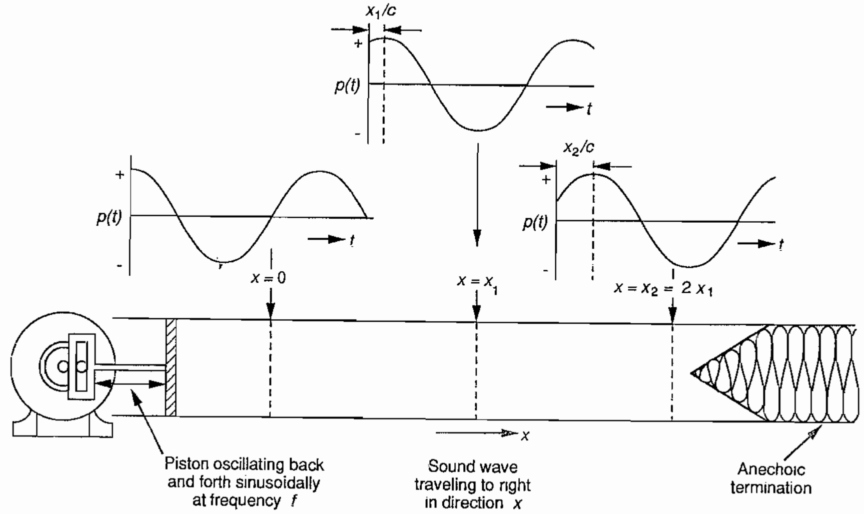

FIGURE 2.2 Apparatus for producing a plane forward-traveling sound wave. A plane wave generated by the piston at the left travels to the right and is absorbed by the anechoic termination. The three waves at the top give the variation in sound pressure with time at the three points indicated, $x = 0$, $x = x_1$, and $x = x_2 = 2x_1$.

Figure 2.3 shows a set of four spatial timeshots taken at $t = 0, \frac{1}{4}T, \frac{1}{2}T, \frac{3}{4}T$, where T is the time period of the piston machine. Each shows the sound pressure over a spatial extent of one wavelength, $\lambda = c/f = cT$. The 20 vertical lines along each snapshot enable one to observe the spatial variation of sound pressure at a given point at the four different times.

Snapshot (*a*) represents the pressure-versus-distance relation for times $t = 0, T, 2T, 3T, \ldots, nT$. The maximum value $+P_R$ exists at $x = 0$. Because the wave is periodic in space, the maximum value must also occur at $x = \lambda, 2\lambda, 3\lambda, \ldots$.

Snapshot (*b*) shows the sound pressure a quarter of a period, $\frac{1}{4}T$, later, that is, the wave in (*a*) has moved to the right a distance equal to $\frac{1}{4}\lambda$ to become the wave in (*b*). Similarly for (*c*) and (*d*). To convince yourself that the wave is traveling to the right, allow your eyes to jump successively from (*a*) to (*b*) to (*c*) to (*d*) and note that the peak, $+P_R$, moves successively to the right.

Wavenumber. The cosine function of Eq. (2.18) repeats its value every time the argument increases 2π radians (360°). From the definition of wavelength, $\lambda = c/f = cT$, we can write this periodicity condition as

$$\cos[k(x + \lambda - ct)] = \cos[k(x - ct) + 2\pi] \tag{2.19}$$

so that $k\lambda = 2\pi$ and $k = 2\pi/\lambda$ radians per meter. We see that the meaning of the parameter k, called the *wavenumber*, is a kind of "spatial frequency."

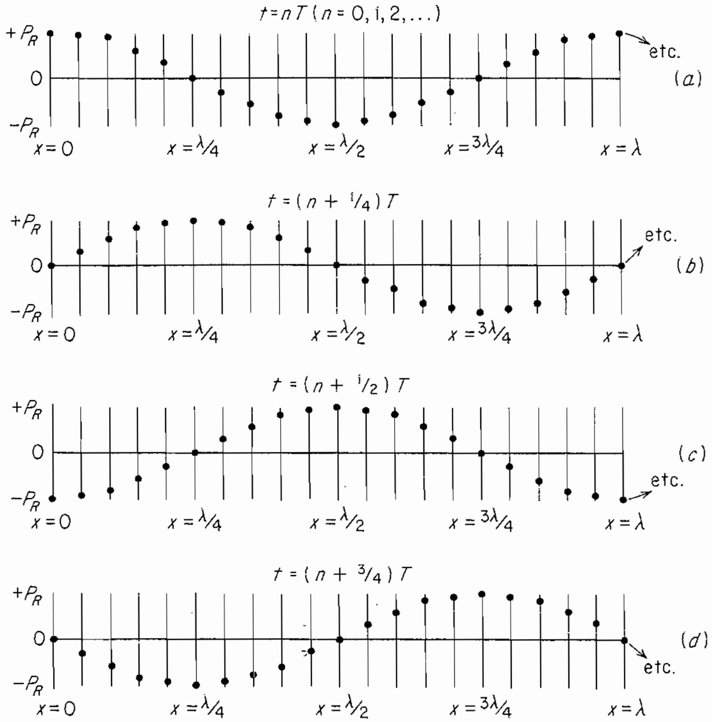

FIGURE 2.3 Graphs showing sound pressure in a plane free-progressive wave traveling from left to right at 20 equally spaced axial locations at four instants of time t. The wave is produced by a source at the left and travels to the right with the speed c. The length of time it takes a wave to travel a distance equal to a wavelength is called the period T. Forward-traveling wave: $p(x,t) = P_R \cos k(x - ct)$; $k = 2\pi/\lambda = 2\pi/(cT) = 2\pi f/c = \omega/c$.

The argument of the cosine in Eq. (2.18) may be written in any one of the following ways:

$$k(x - ct) = \frac{2\pi}{\lambda}(x - ct) = 2\pi f\left(\frac{x}{c} - t\right) = 2\pi\left(\frac{x}{\lambda} - \frac{t}{T}\right)$$
$$= \frac{2\pi x}{\lambda} - 2\pi f t = kx - \omega t$$

From Eq. (2.19) we can write the equations for the snapshots of Fig. 2.3 as

(a) $\quad t = nT \qquad p = P_R \cos \dfrac{2\pi x}{\lambda}$

(b) $\quad t = \left(n + \frac{1}{4}\right) T \qquad p = P_R \cos\left(\dfrac{2\pi x}{\lambda} - \dfrac{\pi}{2}\right)$

(c) $\quad t = \left(n + \frac{1}{2}\right) T \qquad p = P_R \cos\left(\dfrac{2\pi x}{\lambda} - \pi\right)$

(d) $\quad t = \left(n + \frac{3}{4}\right) T \qquad p = P_R \cos\left(\dfrac{2\pi x}{\lambda} - \dfrac{3\pi}{2}\right)$

where $n = 0, 1, 2, 3, \ldots$.

Root-Mean-Square Sound Pressure

As discussed in Chapter 1, a measure of the strength of a sound wave is needed that avoids the problem of directly averaging over a cycle. Such an average is zero. The measure that has been standardized is the rms sound pressure p_{rms}. Its magnitude is 0.707 times the peak value P_R [Eq. (2.18)]. The rms value is also called the *effective value*.

Particle Velocity

From Eq. (2.6) we may derive a relation between sound pressure p and particle velocity u, where u is the component of $\mathbf{q}$ in the x direction. In one dimension,

$$-\frac{\partial p}{\partial x} = \rho \frac{\partial u}{\partial t} \tag{2.20}$$

Substitution of Eq. (2.18) into Eq. (2.20) gives

$$-u = \frac{1}{\rho}\int \frac{\partial p}{\partial x}\,dt = \frac{-P_R}{\rho c}\cos\, k(x - ct) \tag{2.20a}$$

or

$$u = \frac{p}{\rho c} \tag{2.21}$$

where ρ = time-averaged density of air, = 1.18 kg/m^3 for normal room temperature $T = 22°\text{C}$ (71.6°F) and atmospheric pressure $P_s = 0.751$ m (29.6 in.) Hg

c = speed of sound [see Eqs. (1.5)–(1.8)], which at normal temperatures of 22°C equals 344 m/s (1129 ft/s)

ρc = 406 mks rayls (N · s/m^3) at normal room temperature and pressure; at other T's and P_s's, ρc is found from Fig. 1.7

Intensity

A freely traveling progressive sound wave transmits energy. We define this energy transfer as the *intensity* **I**, the energy that flows through a unit area in unit time. The units are watts per square meter (N/m · s). It has its maximum value, $I_{\max}$, when the plane of the unit area is perpendicular to the direction in which the wave is traveling. Intensity, analogous to electrical power, equals the time average of the product of sound pressure and particle velocity,

$$I_{\max} = \overline{p \cdot u} \quad \text{W/m}^2 \ (\text{N/m} \cdot \text{s}) \tag{2.22}$$

For the wave of Figs. 2.2 and 2.3,

$$I_{\max} = \lim_{T \to \infty} \frac{1}{T} \int_0^T \frac{P_R^2}{\rho c} \cos^2 k(x - ct)\, dt \tag{2.23}$$

where $I(\theta) = I_{\max} \cos\theta$, θ being the angle between the direction of travel of the wave and a line perpendicular to the plane of the unit area through which the flow of sound power is being determined.

Let $T = \infty$ be a time long enough that $I_{\max}$ has reached its asymptotic value within experimental error.

Because the time average of the cosine is zero,

$$I_{\max} = \frac{P_R^2}{2\rho c} = \frac{p_{\text{rms}}^2}{\rho c} \quad \text{W/m}^2 \tag{2.24}$$

where p_{rms} is the square root of the mean (time) square value of $p(t)$, as can be demonstrated by finding $I\rho c$ from Eq. (2.24) and W is watts.

Backward-Traveling Plane Wave

A backward-traveling plane wave may be produced by interchanging the source and termination of Fig. 2.2. The wave now travels in the $-x$ direction and is described by

$$p(x, t) = P_L \cos k(x + ct) \quad \text{Pa} \tag{2.25}$$

Comparison of Eqs. (2.18) and (2.25) show that, if the two variables x and ct are separated by a negative sign, the wave travels in the positive direction, and if the two variables are separated by a positive sign, the direction reverses.

The four "snapshots" of Fig. 2.4 illustrate the backward-traveling wave. Allowing your eyes to jump from (*a*) to (*b*) to (*c*) to (*d*) and following the movement of $+P_L$ from right to left convinces one that this is true.

One-Dimensional Spherical Wave

Sound Pressure. The equation for the sound pressure associated with a free-progressive, spherically traveling sound wave, produced as shown in Fig. 1.2 in Chapter 1, is

$$p(r, t) = \frac{A}{r} \cos k(r - ct) \quad \text{Pa} \tag{2.26}$$

where A is an amplitude factor with dimension newtons per meter. Because the sign between r and ct is negative, the wave is traveling outward in the positive

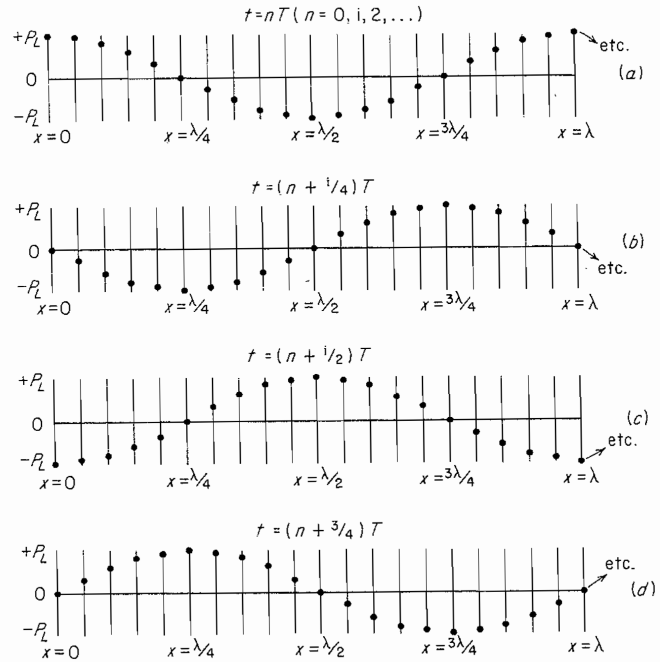

FIGURE 2.4 Graphs showing sound pressure in a plane free-progressive wave traveling from right to left at 20 equally spaced axial locations at four instants of time t. The wave is produced by a source at the right (or by being reflected from a boundary at the right) and travels to the left with a speed c. The period T is defined as for Fig. 2.3. Backward-traveling wave: $p(x, t) = P_L \cos[k(x+ct)]$; $k = 2\pi/\lambda = 2\pi/(cT) = 2\pi f/c = \omega/c$.

r direction. In a spherical wave, the pressure amplitude is inversely proportional to the radial distance r.

Particle Velocity. The particle velocity for a spherical wave, using Eq. (2.20a) with r substituted for x, is

$$u(r, t) = -\frac{1}{\rho} \int \left[\frac{A}{r} k \sin k(r - ct) + \frac{A}{r^2} \cos k(r - ct) \right] dt$$

$$= -\frac{1}{\rho} \left[\frac{-kA}{kcr} \cos k(r - ct) - \frac{A}{r^2 kc} \sin k(r - ct) \right]$$

or

$$u(r, t) = \frac{A}{\rho c r} \cos k(r - ct) \left[1 + \frac{1}{kr} \tan k(r - ct) \right] \tag{2.27}$$

For large values of kr,

$$u(r, t) \doteq \frac{p(r, t)}{\rho c} \qquad k^2 r^2 \gg 1 \tag{2.28}$$

For very small values of kr, $k^2r^2 \ll 1$,

$$u(r,t) \doteq \frac{A}{k\rho c r^2} \sin k(r-ct)$$

$$\doteq \frac{p(r,t)}{\rho c k r} \angle 90^\circ \text{ re phase of } p(r,t) \tag{2.29}$$

Equations (2.27) and (2.29) show that as one approaches the center of a spherical source, the sound pressure and particle velocity become progressively more out of phase, approaching 90° in the limit.

Intensity. For a freely traveling spherical wave, Eq. (2.26) states that for *all values of* r, the sound pressure varies as $1/r$. Because $u = p/\rho c$ [Eq. (2.28)] for the case $k^2r^2 \gg 1$, we can write for all values of r that

$$I_{\max} \text{ at radius } r = \overline{p \cdot u} = \frac{p^2_{\text{rms}} \text{at } r}{\rho c} \quad \text{W/m}^2 \tag{2.30}$$

2.3 SOUND POWER OUTPUT OF ELEMENTARY RADIATORS

Monopole (Radiating Sphere)

The total power W_M radiated from a simple source, a pulsating sphere, called a monopole, is given in Table 2.1, where

where $\hat{Q}_s$ = source strength, $= 4\pi a^2 \hat{v}_r$, m³/s
$\hat{v}_r$ = peak value of velocity of sinusoidally pulsating surface, m/s
a = radius of pulsating sphere, m
$k = 2\pi f/c$, m^{-1}
ρc = characteristic impedance of gas, 406 mks rayls (N · s/m³) for air at normal room temperature and atmospheric pressure

Dipole (Two Closely Spaced Monopoles)[2]

By definition, two monopoles constitute a dipole when $(kd)^2 \ll 1$ and when they vibrate 180° out of phase. A dipole has a figure-eight radiation pattern, with minimum radiation in the direction perpendicular to a line connecting the two monopoles. The total sound power, W_D, radiated is given in the second row of Table 2.1, where $\hat{Q}_s$, $\hat{v}_r$, a, k, and ρc are as given above and

where d = separation between monopoles, m

Oscillating Sphere[3,4]

An oscillating sphere is defined as a rigid sphere moving axially, back and forth, around its rest position. The total power, W_{OS}, radiated is given in the third row of Table 2.1, ρc and k are as defined for a monopole, and

where $\hat{v}_x$ = peak back-and-forth velocity, m/s
a = radius of oscillating sphere, m

TABLE 2.1 Sound Power Output of Elementary Radiators

Source Type	Source Behavior 180° Phase Difference	Sound Power Output, W	Auxiliary Expressions
Monopole		$W_M = \frac{\rho c k^2}{8\pi(1+k^2a^2)}\hat{Q}_s^2$	$\hat{Q}_s = 4\pi a^2 \hat{v}_r$
Dipole		$W_D = \frac{\rho c k^4 d^2}{12\pi}\hat{Q}_s^2$	d = distance between monopoles
Oscillating sphere		$W_{OS} = \frac{2\pi\rho c k^4 a^6}{3(4+k^4a^4)}\hat{v}_x^2$	$\hat{v}_x$ = peak sinusoidal vibration velocity
Baffled piston		$W_{BP} = \frac{\rho c k^2}{4\pi}\hat{Q}^2 \quad ka \ll 1$ $W_{BP} = \frac{\rho c}{2\pi a^2}\hat{Q}^2 \quad ka \gg 1$	$\hat{Q} = \pi a^2 \hat{v}_x$ where $\hat{v}_x$ is as above

Baffled Piston[5]

An axially vibrating diaphragm in an infinite plate is called a baffled piston. The total power radiated to one side of the rigid wall, W_{BP}, is given in the fourth row of Table 2.1, both for the case of a piston whose radius is small compared to a wavelength, $ka \ll 1$, and vice versa, $ka \gg 1$, where

where $\hat{v}_x$ = peak axial velocity of piston, m/s
a = radius of piston, m

The other quantities are as defined above.

2.4 INTERFERENCE AND RESONANCE

The sound pressure and incremental density in a sound wave are generally very small in comparison with the equilibrium values on which they are superposed. This is certainly true for speech and music waves. As a result, it is possible in such acoustical situations to determine the effect of two sound waves in the same space by simple linear addition of the effects of each sound wave separately. This is a statement of the principle of *superposition*.

In the previous section we presented a series of spatial snapshots for plane sound waves traveling to the right (Fig. 2.3) and to the left (Fig. 2.4). According to the principle of superposition, the effect of the sum of these two waves will be the sum of their effects, which we can see graphically by adding Figs. 2.3 and 2.4. The result is shown in Fig. 2.5, where we have set the amplitude of the forward-traveling wave P_R equal to the amplitude of the backward-traveling wave P_L.

The interference of the two waves has produced a surprising change. No longer does the sound pressure at one place occur to the right or to the left of that place at the next instant. The wave no longer travels; it is a standing wave. We see that at each point in space the sound pressure varies sinusoidally with time, except at the points $x = \frac{1}{4}\lambda$ and $\frac{3}{4}\lambda$, where the pressure is always zero. The maximum value of the pressure variation at different points is different, being greatest at $x = 0$, $x = \frac{1}{2}\lambda$, and $x = \lambda$. The sound pressures at the points between the points $x = \frac{1}{4}\lambda$ and $x = \frac{3}{4}\lambda$ always vary together, that is, increase or decrease in phase. At the same times the sound pressures for the points to the left of $x = \frac{1}{4}\lambda$ and to the right of $x = \frac{3}{4}\lambda$ decrease or increase together (in phase). Thus all pressures are in time phase in the standing wave, but there is a space difference of phase of 180° between the sound pressures at the points at $x = 0$ and $x = \frac{1}{2}\lambda$.

Remembering that $P_R = P_L = P$, that is, that the amplitude of the wave traveling to the right is equal to the amplitude of the wave traveling to the left, we find that the sum of the two waves is

$$\begin{aligned} p(x,t) &= P\cos[k(x-ct)] + P\cos[k(x+ct)] \\ &= 2P(\cos kx)(\cos 2\pi ft) \quad \text{Pa} \end{aligned} \tag{2.31}$$

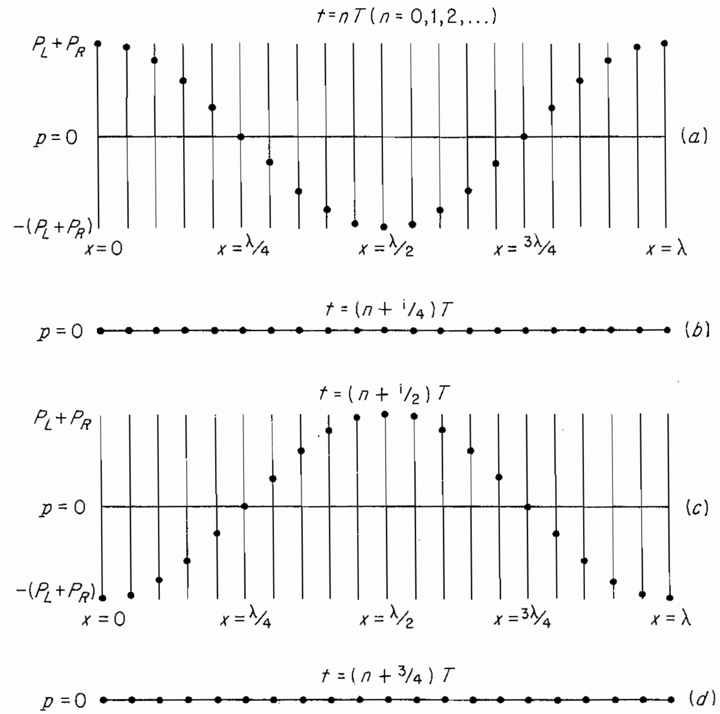

FIGURE 2.5 Graphs giving sound pressure in a plane standing wave at 20 places in space at four instants of time t. The wave is produced by two sources equal in strength at the right and left of the graphs (or the right source is a perfectly reflecting boundary that sends back a wave of equal amplitude to that produced by the source on the left). Standing wave: $p(x,t) = 2P(\cos kx)(\cos 2\pi ft)$, where k is the wavenumber.

From Eqs. (2.18), (2.20), and (2.31) we see very clearly the differences between a standing and a traveling wave. In a traveling wave distance x and time t occur as a sum or difference in the argument of the cosine. Hence, for the traveling wave, by adjusting both time and distance (according to the speed of sound) in the argument of the cosine, we can always keep the argument and thus the magnitude of the cosine the same. In Eq. (2.31) distance and time no longer appear together in the argument of a single cosine. So the same sound pressure cannot occur at an adjacent point in the space at a later time.

Standing waves will exist in any regular enclosure. In a rectangular room, for example, three classes of standing waves may exist (see Chapter 6). One class includes all waves that are perpendicular to one pair of opposing walls, that is, that travel at grazing incidence to two pairs of walls, the (n_x, 0, 0), (0, n_y, 0), (0, 0, n_z) modes of vibration. A second class travels at grazing incidence to only one pair of walls, the (n_x, n_y, 0), (n_x, 0, n_z), (0, n_y, n_z) modes of vibration. A third class involves all walls at oblique angles of incidence, the (n_x, n_y, n_z) modes of vibration. Each free-standing wave in an acoustical space is called a normal mode of vibration, or simply a resonance. The frequencies at which resonant standing waves can exist are related to the separation between the reflecting surfaces. For example, the lowest frequency for a resonant standing wave in a one-dimensional system consisting of two rigid parallel walls is given by

$$f = \frac{c}{2d} \quad \text{Hz} \tag{2.32}$$

where f = lowest frequency for resonant standing wave, Hz
c = speed of sound, m/s
d = distance separating two reflecting surfaces, m

Resonant standing waves can also exist at every integral multiple of this frequency. That is to say,

$$f = \frac{nc}{2d} \quad \text{Hz} \tag{2.33}$$

where n is an integer $1, 2, 3, \ldots$.

2.5 IMPEDANCE AND ADMITTANCE

Reference to Eqs. (2.18) and (2.21) reveals that the magnitudes of sound pressure and particle velocity are directly proportional to each other. Also, in the special case of plane-wave sound propagation, the time dependence of sound pressure is exactly the same as the time dependence of particle velocity, and at any point in the wave there is no phase difference between the two quantities. Thus, in a plane sound wave the ratio of sound pressure to particle velocity at all instants of time is a constant equal to ρc.

In general, however, for linear (small-signal) acoustical phenomena in the steady state, there is a difference in the time functions of sound pressure and particle velocity, leading to a phase difference of one relative to the other. Thus, at any point the particle velocity may lead or lag the sound pressure. In many situations, both the ratio of the magnitudes and the relative phase may be functions of frequency.

In several of the chapters that follow, it is convenient in acoustical design to avoid separate consideration of steady-state sound pressure and steady-state particle velocity (or other quantities that may be derived from them, such as force and volume velocity) and instead to deal with either one and with their complex ratio, as defined below.

Complex Notation

The foundations for the designation of steady-state signals with the same frequency but different phases by complex notation are expressed in the identities

$$|A| \cos(\omega t + \theta_1) \equiv \text{Re}\ \overline{A} e^{j\omega t} \tag{2.34}$$

where $|A| \equiv$ amplitude of cosine function
$\theta_1 \equiv$ phase shift at time $t = 0$
Re $\equiv$ "real part of"
$j \equiv \sqrt{-1}$

and

$$\overline{A} \equiv A_{\text{Re}} + jA_{\text{Im}} = |A|\ e^{j\theta_1} \tag{2.35}$$

$$|A| \equiv \sqrt{A_{\text{Re}}^2 + A_{\text{Im}}^2} \tag{2.36}$$

$$\theta_1 \equiv \tan^{-1}\left(\frac{A_{\text{Im}}}{A_{\text{Re}}}\right) \tag{2.37}$$

We note also that

$$e^{j\theta} \equiv \cos\theta + j \sin\theta \tag{2.38}$$

so that

$$A_{\text{Re}} \equiv |A| \cos\theta \tag{2.39}$$

$$A_{\text{Im}} \equiv |A| \sin\theta \tag{2.40}$$

These equations say that a cosinusoidal time-varying function, given by the left-hand side of Eq. (2.34), can be represented by the real-axis projection of a vector of magnitude $|A|$ given by Eq. (2.36), rotating at a rate ω radians per second. The angle θ_1 is the angle of the vector (in radians) relative to the positive real axis at the instant of time $t = 0$.

We might therefore express a time-varying steady-state sound pressure or force by

$$\overline{A} e^{j\omega t} = |A|\ e^{j\omega t} e^{j\theta_1} \tag{2.41}$$

Also, a time-varying steady-state velocity or volume velocity might be expressed by

$$\overline{B} e^{j\omega t} = |B|\ e^{j\omega t} e^{j\theta_2} \tag{2.42}$$

Definitions of Complex Impedance

Complex Impedance Z. In general, complex impedance is defined as

$$\overline{Z} \equiv \frac{\overline{A}}{\overline{B}} = \frac{|A|\ e^{j(\omega t + \theta_1)}}{|B|\ e^{j(\omega t + \theta_2)}} = \frac{|A|\ e^{j\theta_1}}{|B|\ e^{j\theta_2}} = |Z|\ e^{j\theta} \tag{2.43}$$

and

$$\overline{Z} \equiv R + jX = \sqrt{R^2 + X^2}\ e^{j\theta} = |Z|\ e^{j\theta} \tag{2.44}$$

where $\overline{Z}$ = *complex impedance as given above*
A = steady-state pressure or force

B = steady-state velocity or volume velocity
$|Z|$ = magnitude of complex impedance
θ = phase angle between the time functions A and B, $= \theta_1 - \theta_2$
R, X = real and imaginary parts, respectively, of complex impedance $\overline{Z}$
R = resistance, Re Z
X = reactance, Im $\overline{Z}$

Often $|A|$ and $|B|$ are taken to be the rms values of the phenomena they represent, although, if so taken, a factor of $\sqrt{2}$ must be added to both sides of Eq. (2.34) to make them correct in a physical sense. Whether amplitudes or rms values are used makes no difference in the impedance ratio.

Complex impedances are of several types, according to the quantities involved in the ratios. Types common in acoustics are given below.

Acoustical Impedance Z_A. The acoustical impedance at a given surface S is defined as the complex ratio of (a) sound pressure averaged over the surface to (b) volume velocity through it. The volume velocity $U = uS$. The surface may be either a hypothetical surface in an acoustical medium or the moving surface of a mechanical device. The unit is N · s/m^5, also called the mks acoustical ohm. That is,

$$Z_A = \frac{p}{U} \quad \text{N} \cdot \text{s/m}^5 \text{ (mks acoustical ohms)} \tag{2.45}$$

Specific Acoustical Impedance Z_s. The specific acoustical impedance is the complex ratio of the sound pressure at a point of an acoustical medium or mechanical device to the particle velocity at that point. The unit is N · s/m^3, also called the mks rayl. That is,

$$Z_s = \frac{p}{u} \quad \text{N} \cdot \text{s/m}^3 \text{ (mks rayls)} \tag{2.46}$$

Mechanical Impedance Z_M. The mechanical impedance is the complex ratio of the force acting on a specific area of an acoustical medium or mechanical device to the resulting linear velocity through or of that area, respectively. The unit is the N · s/m, also called the mks mechanical ohm. That is,

$$Z_M = \frac{f}{u} \quad \text{N} \cdot \text{s/m (mks mechanical ohms)} \tag{2.47}$$

Characteristic Resistance ρc. The characteristic resistance is the ratio of the sound pressure at a given point to the particle velocity at that point in a free, plane, progressive sound wave. It is equal to the product of the density of the medium and the speed of sound in the medium (ρc). It is analogous to the characteristic impedance of an infinitely long, dissipationless transmission line. The unit is the N · s/m^3, also called the mks rayl. In the solution of problems in this book we shall assume for air that $\rho c = 406$ mks rayls, which is valid for a temperature of 22°C (71.6°F) and a barometric pressure of 0.751 m (29.6 in.) Hg.

Idaho Power/1206
Ellenbogen/27

Normal Specific Acoustical Impedance Z_{sn}. At the boundary between air and a denser medium (such as a porous acoustical material) we find a further definition necessary, as follows: When an alternating sound pressure p is produced at the surface of an acoustical material, an alternating velocity u of the air particles is produced through the surface. The to-and-fro motions of the air particles may be at any angle relative to the surface. The angle depends both on the angle of incidence of the sound wave and on the nature of the acoustical material. For example, if the material is porous and has very low density, the particle velocity at the surface is nearly in the same direction as that in which the wave is propagating. By contrast, if the surface were a large number of small-diameter tubes packed side by side and oriented perpendicular to the surface, the particle velocity would necessarily be only perpendicular to the surface. In general, the direction of the particle velocity at the surface has both a normal (perpendicular) component and a tangential component.

The normal specific acoustical impedance (sometimes called the unit-area acoustical impedance) is defined as the complex ratio of the sound pressure p to the *normal component* of the particle velocity u_n at a plane, in this example at the surface of the acoustical material. Thus

$$Z_{sn} = \frac{p}{u_n} \quad \text{N} \cdot \text{s/m}^3 \text{ (mks rayls)} \tag{2.48}$$

Definition of Complex Admittance

Complex admittance is the reciprocal of complex impedance. In all ways, it is handled by the same set of rules as given by Eqs. (2.34)–(2.44). Thus, the complex admittance corresponding to the complex impedance of Eq. (2.43) is

$$\overline{Y} \equiv \frac{\overline{B}}{\overline{A}} = \frac{|B|\, e^{j\theta_2}}{|A|\, e^{j\theta_1}} = |Y|\, e^{j\phi} \tag{2.49}$$

where $|Y| = 1/|Z|$
$\phi = -\theta$

The choice between impedance and admittance is sometimes made according to whether $|A|$ or $|B|$ is held constant during a measurement. Thus, if $|B|$ is held constant, $|Z|$ is directly proportional to $|A|$ and is used. If $|A|$ is held constant, $|Y|$ is directly proportional to $|B|$ and is used.

CHAPTER 3

Data Analysis

ALLAN G. PIERSOL

Piersol Engineering Company
Woodland Hills, California

For studies related to noise and vibration control engineering, the analysis of measured acoustical noise and/or vibration data may be accomplished with a number of goals in mind. The most important of these goals can be divided into four broad categories: (a) an assessment of the severity of an environment, (b) the identification of system response properties, (c) the identification of sources, and (d) the identification of transmission paths. The first goal is commonly accomplished using one-third-octave-band-level calculations, or perhaps frequency-weighted overall level measurements, as described in Chapter 1. The other goals often require more advanced data analysis procedures. Following a brief discussion of the general types of acoustical and vibration data of common interest, the most important data analysis procedures for accomplishing goals (b)–(d) are outlined, and important applications of the results from such analyses are summarized. Because of the broad and intricate nature of the subject, heavy use of references is employed to cover details.

3.1 TYPES OF DATA SIGNALS

Acoustical and vibration data are commonly acquired in the form of analog time history signals produced by appropriate transducers (details of acoustical and vibration transducers and signal conditioning equipment are available from the data acquisition documents listed in the Bibliography and the literature published by acoustical and vibration measurement system manufacturers). The signals are generally produced with the units of volts but can be calibrated into appropriate engineering units (g, m/s, Pa, etc.) as required. From a data analysis viewpoint, it is convenient to divide these time history signals into two broad categories, each with two subcategories, as follows:

1. Deterministic data signals: (a) steady-state signals; (b) transient signals.
2. Random data signals: (a) stationary signals; (b) nonstationary signals.

For studies related to noise and vibration control engineering, the analysis of measured acoustical noise and/or vibration data may be accomplished with a number of goals in mind. The most important of these goals can be divided into four broad categories: (a) an assessment of the severity of an environment, (b) the identification of system response properties, (c) the identification of sources, and (d) the identification of transmission paths. The first goal is commonly accomplished using one-third-octave-band-level calculations, or perhaps frequency-weighted overall level measurements, as described in Chapter 1. The other goals often require more advanced data analysis procedures. Following a brief discussion of the general types of acoustical and vibration data of common interest, the most important data analysis procedures for accomplishing goals (b)–(d) are outlined, and important applications of the results from such analyses are summarized. Because of the broad and intricate nature of the subject, heavy use of references is employed to cover details.

3.1 TYPES OF DATA SIGNALS

Acoustical and vibration data are commonly acquired in the form of analog time history signals produced by appropriate transducers (details of acoustical and vibration transducers and signal conditioning equipment are available from the data acquisition documents listed in the Bibliography and the literature published by acoustical and vibration measurement system manufacturers). The signals are generally produced with the units of volts but can be calibrated into appropriate engineering units (g, m/s, Pa, etc.) as required. From a data analysis viewpoint, it is convenient to divide these time history signals into two broad categories, each with two subcategories, as follows:

1. Deterministic data signals: (a) steady-state signals; (b) transient signals.
2. Random data signals: (a) stationary signals; (b) nonstationary signals.

Deterministic Data

Deterministic data signals are those for which it is theoretically feasible to determine a mathematical equation that would predict future time history values of the signal (within reasonable experimental error), based upon a knowledge of the applicable physics or past observations of the signal. The most common type of deterministic signal, called a periodic signal, has a time history $x(t)$ that exactly repeats itself after a constant time interval T_p, called the period of the signal; that is,

$$x(t) = x(t \pm T_p) \tag{3.1}$$

The most common sources of periodic acoustical and vibration signals are constant-speed rotating machines, including propellers and fans. Ideally, such signals would have only one dominant frequency, allowing them to be represented by a simple sine wave. However, it is more likely that the periodic source will produce a complex signal that must be described, using a Fourier series representation,[1] by a collection of harmonically related sine waves, as illustrated in Fig. 3.1. In any case, periodic signals are called steady state because their average properties (mean value, mean-square value, and spectrum) do not vary with time.

There are steady-state acoustical and vibration signals that are not rigorously periodic, for example, the data produced by a collection of independent (unsynchronized) periodic sources, such as the propellers on a multiengine propeller airplane. Such nonperiodic steady-state signals are referred to as almost periodic. Most nonperiodic deterministic signals, however, are also not steady state; that is, their average properties change with time. An important type of time-varying

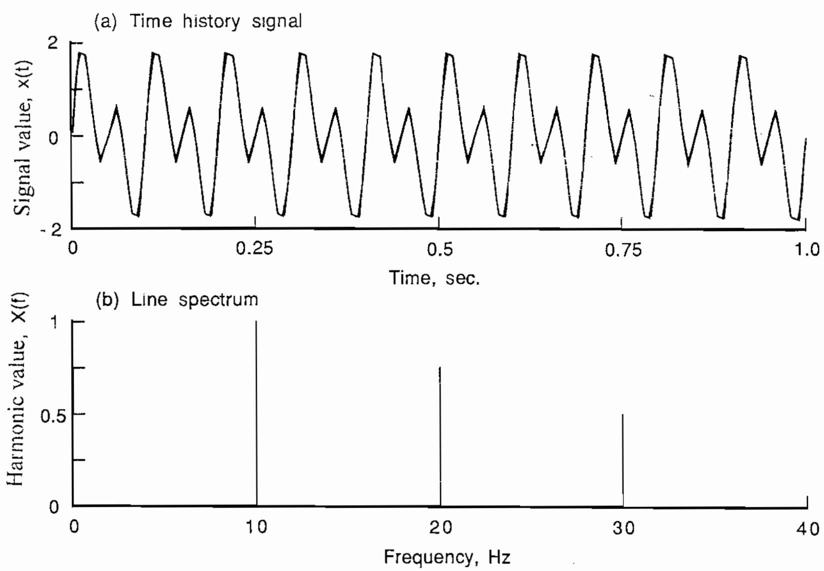

FIGURE 3.1 Time history and line spectrum for periodic signal.

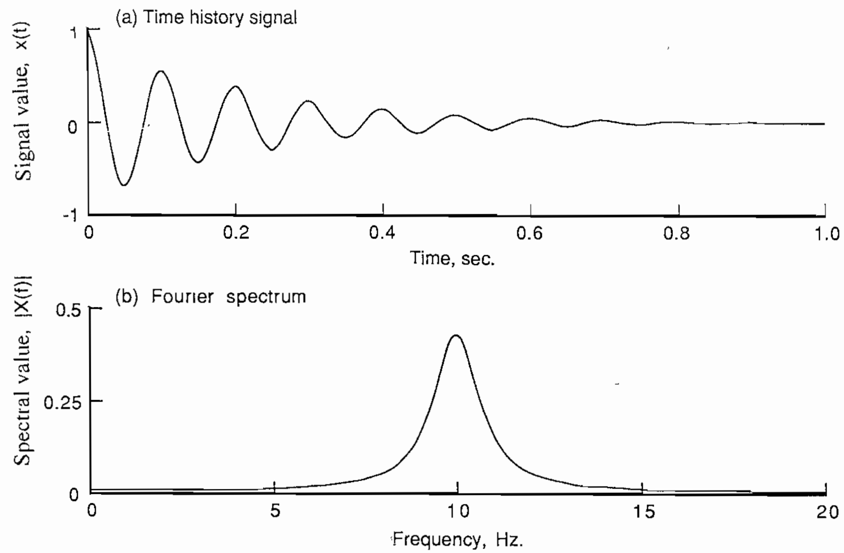

FIGURE 3.2 Time history and Fourier spectrum for deterministic transient signal.

signal is one that begins and ends within a reasonable measurement time interval. Such signals are called transient signals. Examples of deterministic transient signals include well-controlled impacts, sonic booms, and aircraft landing loads. Such data can be described, using a Fourier integral representation,[1] by a continuous spectrum, as illustrated for an exponentially decaying oscillation in Fig. 3.2.

Random Data

Random acoustical and vibration data signals may be broadly defined as all signals that are not deterministic, that is, where it is not theoretically feasible to predict future time history values based upon a knowledge of the applicable physics or past observations. In some cases, the border between deterministic and random signals may be blurred. For example, the pressure field produced by a high-speed fan at its blade passage rate with a uniform inflow would be deterministic, but turbulence in the inflow would introduce a random property to the pressure signal. In other cases, the data will be more fully random in character (sometimes called "strongly mixed"). Examples include the pressure fields generated by fluid dynamic boundary layers (flow noise), the loads produced by atmospheric turbulence, and the acoustical noise caused by the exhaust gas mixing from an air blower. These sources of acoustical and vibration signals cover a wide frequency range and have totally haphazard time histories, as illustrated in Fig. 3.3.

When the mechanisms producing random acoustical or vibration data are time invariant, the average properties of the resulting signals will also be time invariant. Such random data are said to be stationary. Unlike steady-state deterministic data, stationary random data must be described by a continuous spectrum.

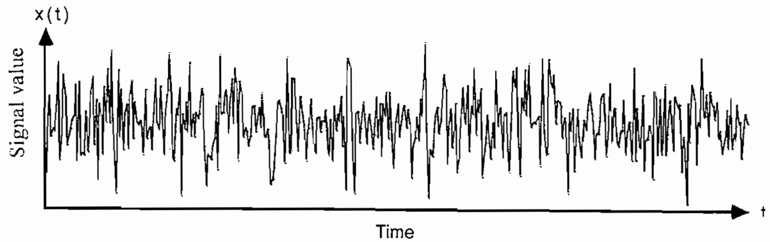

FIGURE 3.3 Time history for stationary random signal.

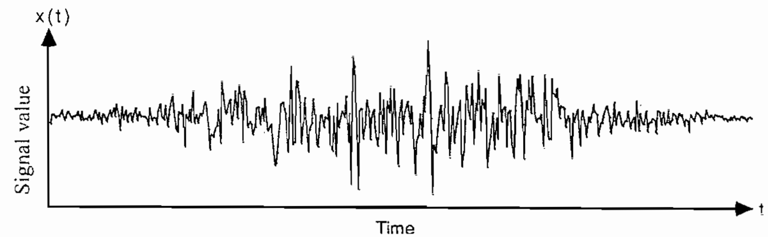

FIGURE 3.4 Time history for nonstationary random signal.

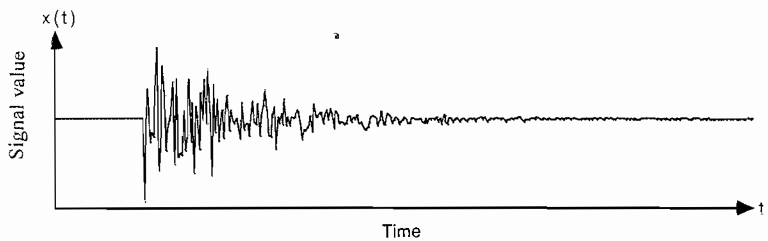

FIGURE 3.5 Time history for stochastic transient signal.

Furthermore, because of the probabilistic character of the data, the measurement of the spectrum and all other signal properties of interest will involve statistical sampling errors that do not occur in the analysis of deterministic signals. These statistical errors will be summarized later.

If the average properties of random signals vary with translations in time, the signals are said to be nonstationary. An illustration of nonstationary data is shown in Fig. 3.4. Although there is a well-developed theoretical methodology for the analysis of arbitrary nonstationary signals,[1] the analysis procedures often require more data than are commonly available and further involve extensive and complex computer calculations. An exception is a special class of nonstationary signals, called stochastic transients, that begin and end within a reasonable measurement time interval. Common sources of stochastic transients are hard impact loads and pyrotechnic devices. An illustration of a stochastic transient signal is shown in Fig. 3.5. Such data can be analyzed by procedures similar to those used to describe deterministic transients discussed earlier, except now there will be a statistical sampling error problem that must be addressed.

3.2 MEAN AND MEAN-SQUARE VALUES

The most rudimentary measures of any steady-state or stationary data signal are the mean value and the mean-square (ms) value (or variance), which provide single-valued descriptions of the central tendency and dispersion of the signal. Mean and ms values of signals can be measured using either digital computations[1] or analog instruments.[2] Hence, appropriate algorithms are presented for both digital and analog analysis procedures.

Mean Values

For acoustical and vibration signals, the mean value is commonly zero, simply because most transducers used for acoustical pressure and vibration acceleration measurements do not sense static values. However, if a transducer is used that senses static values and the central tendency of the signal is of interest, the mean value for a time history measurement, $x(t)$, of duration T_r is computed by

$$m_x = \frac{1}{T_r}\int_0^{T_r} x(t)\,dt \qquad (3.2a)$$

For digital data with a sampling interval of Δt, $x(t) = x(n\,\Delta t)$, $n = 1, 2, \ldots, N$, and the mean value is computed by

$$m_x = \frac{1}{N}\sum_{n=1}^{N} x(n\,\Delta t) \qquad (3.2b)$$

The mean value m_x in Eq. (3.2) has units of volts and is essentially the quantity computed by a direct current (DC) voltmeter. If the data signal is periodic, the calculation in Eq. (3.2) will be accurate as long as T_r (or $N\,\Delta t$) is an integer multiple of the period T_p. For random data, the calculation will involve a statistical sampling error that is a function of T_r (or N) and the spectral characteristics of the signal,[1] to be discussed later.

Mean-Square Values

The ms value of a steady-state or stationary acoustical or vibration signal $x(t)$ [or a digitized signal $x(n\,\Delta t)$] is defined by

$$w_x = \frac{1}{T_r}\int_0^{T_r} x^2(t)\,dt = \frac{1}{N}\sum_{n=1}^{N} x^2(n\,\Delta t) \qquad (3.3)$$

The ms value w_x in Eq. (3.3) has the units of volts squared, which is proportional to power or power per unit area, and hence w_x is often referred to as the overall "power" or "intensity" of the acoustical or vibration signal. If the mean value of the signal is zero, the ms value in Eq. (3.3) is equal to the variance of $x(t)$, defined as

$$s_x^2 = \frac{1}{T_r}\int_0^{T_r}[x(t) - \mu_x]^2\,dt = \frac{1}{N}\sum_{n=1}^{N}[x(n\ \Delta t) - \mu_x]^2 \tag{3.4}$$

where μ_x is the true mean value of the signal (m_x as $T_r \to \infty$). The positive square roots of the quantities defined in Eqs. (3.3) and (3.4), $w_x^{1/2}$ and s_x, are called the rms value and the standard deviation, respectively, of the signal $x(t)$. Again, $w_x^{1/2} = s_x$ if the mean value of the signal is zero, as will be assumed henceforth. The value s_x in Eq. (3.4), or $w_x^{1/2}$ in Eq. (3.3) when $\mu_x = 0$, is essentially the quantity measured by a true rms voltmeter (not to be confused with an alternating current (AC) voltmeter that employs a linear rectifier calibrated to measure the correct rms value for a sine wave and reads about 1 dB low when measuring random noise). As for mean-value calculations, the ms value calculation in Eq. (3.3) will be precise for periodic data if T_r is an integer multiple of the period T_p. For random data, however, there will be a statistical sampling error that is a function of T_r (or N) and the spectral characteristics of the signal,[1] to be discussed later.

Weighted Averages

The averaging operation indicated in Eqs. (3.2)–(3.4) is a simple linear sum of prior values over a specific time interval. This type of average, referred to as an unweighted or linear average, is the natural way one would average any set of discrete data values and is the simplest way for a digital computer to calculate an average value. However, some acoustical and vibration data analyses are still performed using analog instruments, where a relatively expensive operational amplifier is required to accomplish an unweighted average. Hence, the averaging operation in analog instruments is commonly weighted so that it can be accomplished using inexpensive passive circuit elements.[2] The most common averaging circuit used by analog instruments is a simple low-pass filter consisting of a series resistor and shunt capacitor (commonly called an RC filter) that produces an exponentially weighted average. For a ms value estimate (assuming the mean value is zero), the exponentially weighted average estimate is given by

$$w_x(t) = \frac{1}{K}\int_0^t x^2(\tau)\exp\left(-\frac{t-\tau}{K}\right)d\tau \tag{3.5}$$

where $K = RC$ is the product of the numerical values of the resistance in ohms and capacitance in farads used in the averaging circuit. The term K has units of time (seconds) and is referred to as the *time constant* of the averaging circuit. An exponentially weighted averaging circuit provides a continuous average value estimate versus time, which is based on all past values of the signal. It follows that after starting the average calculation, a period of time must elapse before the indicated average value is accurate. As a rule of thumb, when averaging a steady-state or stationary signal, at least four time constants ($t > 4K$) must elapse to obtain an average value estimate with an error of less than 2%. The error in question is a bias error. For the analysis of random data signals, there will also be a statistical sampling error, to be discussed later.

Running Averages

When the acoustical or vibration data of interest have average properties that are time varying (nonstationary data), "running" time averages are often used to describe the data. For the case of a ms value estimate, this could be accomplished by executing Eq. (3.3) repeatedly over short, contiguous time segments of duration $T \ll T_r$. Exponentially weighted averaging is particularly convenient for the computation of running averages because it produces a continuous average value estimate versus time. However, a near-continuous estimate can also be generated using an unweighted average (as is more desirable for digital data analysis) by simply recomputing an average value every data-sampling interval Δt rather than only at the end of the averaging time T. An illustration of a running average for the rms value of typical nonstationary acoustical data measured near an airport during an aircraft flyover is shown in Fig. 3.6 (the measurement in this illustration is a frequency-weighted rms value called *perceived noise level*).

The basic requirement in the computation of a running average is to select an averaging time T (or averaging time constant K) that is short enough not to smooth out the time variations of the data property being measured but long enough to suppress statistical sampling errors in the average value estimate at any time (assuming the data are at least partially random in character). Analytical procedures for selecting the averaging time T that provides an optimum compromise between the smoothing and statistical sampling errors have been formulated,[1] but trial-and-error procedures coupled with experience will usually provide adequate results. Also, many of the simpler acoustical and vibration

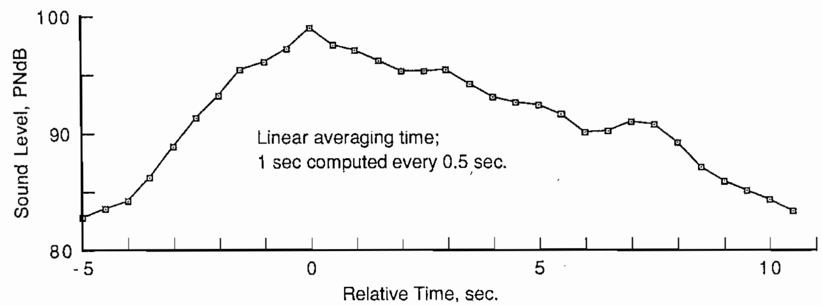

FIGURE 3.6 Running average for weighted rms value of aircraft flyover noise. (Courtesy of Acoustic Analysis Associates, Inc., Canoga, Park, CA.)

measurement instruments used in the field have fixed averaging times ("fast" and "slow" averaging circuits) built into the instrument.[2]

Statistical Sampling Errors

As mentioned earlier, there are no fundamental errors (other than instrument and calibration errors) associated with the calculation of mean and ms values of periodic data signals, assuming the averaging time is an integer multiple of the period of the signal. For random data signals, however, there will be a statistical sampling error due to the fact that the record duration and averaging time can never be long enough to cover all unique signal values. It is convenient to describe this statistical sampling error in terms of a normalized standard deviation of the resulting estimate, called the normalized random error (also called the coefficient of variation). The normalized random error of an estimate, $\hat{\theta}$, for a signal property θ is defined as

$$\epsilon_r[\hat{\theta}] = \frac{\sigma[\hat{\theta}]}{\theta} \tag{3.6}$$

where $\sigma[\cdot]$ denotes the standard deviation as defined in Eq. (3.4) with $T_r \to \infty$ and the hat denotes an estimate. The interpretation of the normalized random error is as follows. If a signal property θ is repeatedly estimated with a normalized random error of, say, 0.1, then about two-thirds of the estimates, $\hat{\theta}$, will be within $\pm 10\%$ of the true value of θ.

The normalized random errors of the mean, ms, and rms value estimates are summarized in Table 3.1.[1] In these error equations, B_s is a measure of the spectral bandwidth of the data signal, defined as[1]

$$B_s = \frac{w^2}{\int_0^\infty G^2(f)\,df} \tag{3.7}$$

where w is the ms value and $G(f)$ is the auto (power) spectrum of the data signal, to be addressed later. The error formulas in Table 3.1 are approximations that are valid for $\epsilon_r \leq 0.20$. Note in Table 3.1 that the random error for mean-value estimates is dependent on the true mean (μ_x) and standard deviation (σ_x) of the signal as well as the bandwidth (B_s) and averaging time (T or K). However, the

TABLE 3.1 Normalized Random Errors for Mean, ms, and rms Value Estimates

	Normalized Random Error, ϵ_r	
Signal Property	Linear Averaging with Averaging Time T	*RC* Weighted Averaging with Time Constant K
Mean value, m_x	$\sigma_x/[\mu_x(2B_sT)^{1/2}]$	$\sigma_x/[\mu_x(4B_sK)^{1/2}]$
ms value, w_x	$1/(B_sT)^{1/2}$	$1/(2B_sK)^{1/2}$
rms value, $w_x^{1/2}$	$1/(4B_sT)^{1/2}$	$1/(8B_sK)^{1/2}$

random error for ms and rms value estimates is a function only of the bandwidth and averaging time.

Synchronous Averaging

Periodic vibration and acoustical data signals produced by rotating machinery (including propellers and fans) are sometimes contaminated by additive, extraneous noise such that the measured signal is $x(t) = p(t) + n(t)$, where $p(t)$ is the periodic signal of interest and $n(t)$ is the noise. In such cases, the signal-to-noise ratio of the periodic signal can be strongly enhanced by the procedure of synchronous averaging,[3] where the data record is divided into a collection of segments $x_i(t)$, $i = 1, 2, \ldots, q$, each starting at exactly the same phase angle during a period of $p(t)$. The collection of segments can then be ensemble averaged to extract $p(t)$ from the extraneous noise as well as other periodic components that are not harmonically related to $p(t)$ as follows:

$$p(t) \approx \frac{1}{q} \sum_{i=1}^{q} x_i(t) \tag{3.8}$$

Synchronous averaging is illustrated in Fig. 3.7 for the pressure field generated in the plane of the propeller on the sidewall of a propeller airplane powered by a reciprocating engine. With 1000 ensemble averages (accomplished in less than 2 min), the procedure extracts the propeller pressure signal cleanly from the engine and boundary layer turbulence noise.

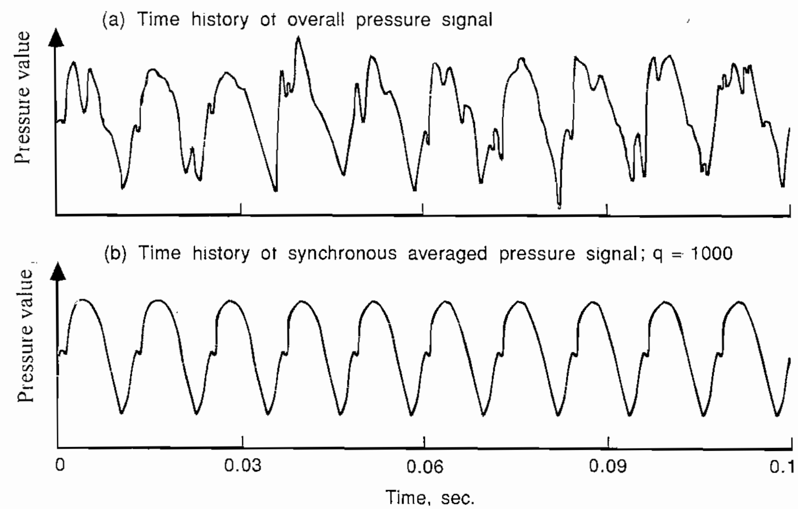

FIGURE 3.7 Original and synchronous averaged time histories for pressure measurement on sidewall of propeller airplane.

The primary requirement for synchronous averaging is the ability to initiate new records at a desired instant during a period of $p(t)$. This is most effectively accomplished using a trigger signal that is a noise-free indicator of the phase during each period of $p(t)$. For rotating machines, a noise-free trigger signal is commonly obtained using either an optical detector or a magnetic pulse generator on the rotating element of the machine. The time base accuracy of the trigger signal determines the accuracy of the magnitude of the resulting synchronous averaged signal; that is, time base errors in the trigger signal cause a reduction in the indicated signal amplitude with increasing frequency. The signal-to-noise ratio enhancement for the synchronous averaged signal is given in decibels by $10 \log_{10} q$, where q is the number of segments used in the ensemble-averaging operation[3].

3.3 SPECTRAL FUNCTIONS

The ms value of a digital signal constitutes an overall measure of the "power" or "intensity" represented by the measured quantity, but much more useful information is provided by a frequency decomposition of the signal values. As noted in Chapter 1, the computation of rms values in one-third-octave bands is widely used for the frequency analysis of acoustical data and sometimes for vibration data as well. However, the more advanced signal-processing techniques needed for system, source, and path identification problems require the computation of frequency spectra with a much finer resolution than one-third-octave bands. Furthermore, if the data are random in character, a frequency analysis in terms of power quantities per unit frequency (hertz) greatly facilitates the desired evaluations of the data signals.

Prior to 1965, most analysis of acoustical and vibration data signals, including the calculation of frequency spectra, was accomplished by analog instruments. Highly resolved frequency spectra were generally computed using narrow-band width analog filters, often employing mechanical elements such as resonant crystals or magnetostrictive devices.[2] Of course, narrow-bandwidth frequency spectra could also be computed, even at that time, on a digital computer using Fourier transform software, but the computations were time consuming and expensive because of the large number of data values needed to represent wide-bandwidth acoustical and vibration signals. In 1965, this situation changed dramatically with the introduction of an algorithm for the fast computation of Fourier series coefficients[4] that reduced the required computer calculations by several orders of magnitude. Various versions of this algorithm have since come into wide use and are generally referred to as fast Fourier transform (FFT) algorithms. The vast majority of all current narrow-bandwidth spectral analysis of acoustical and vibration data signals are performed using FFT algorithms.

The FFT Algorithm

Using lowercase letters for functions of time and uppercase letters for functions of frequency, the Fourier transform of a time history signal, $x(t)$, which is measured

over the time interval $0 \le t \le T$, is defined for all frequencies (both positive and negative) by

$$X(f, T) = \int_0^T x(t) e^{-j2\pi ft}\, dt \tag{3.9a}$$

In terms of a digital time series of N data values where $x(t) = x(n\ \Delta t)$, $n = 0, 1, \ldots, N-1$ (starting the indexing at $n = 0$ is helpful in maintaining consistent relationships between time and frequency functions), the Fourier transform may be written as

$$X(f, T) = X(k\ \Delta f, N) = \Delta t \sum_{n=0}^{N-1} x(n\ \Delta t)\ \exp(-j2\pi fn\ \Delta t) \tag{3.9b}$$

where the spectral components are generally complex valued and are defined only at N discrete frequencies given by

$$f_k = k\ \Delta f = \frac{k}{N\ \Delta t} \qquad k = 0, 1, 2, \ldots, N-1 \tag{3.9c}$$

The finite Fourier transform defined in Eq. (3.9), when divided by T (or $N\ \Delta t$), essentially yields the conventional Fourier series coefficients for a periodic function under the assumption that the time history record $x(t)$ is one period (or an integer multiple of one period) of the periodic function being analyzed. The Fourier components are unique only out to $k = \frac{1}{2}N$, that is, out to the frequency $f_k = 1/(2\ \Delta t)$, commonly called the Nyquist frequency, f_N, of the digitized signal. The Nyquist frequency is that frequency for which there are only two sample values per cycle and, hence, aliasing will initiate.[1] Comparing the digital result in Eq. (3.9b) with the analog formulation in Eq. (3.9a), the first $\frac{1}{2}N + 1$ Fourier coefficients, from $k = 0$ to $k = \frac{1}{2}N$, define the spectral components at nonnegative frequencies, while the last $\frac{1}{2}N - 1$ Fourier coefficients, from $k = \frac{1}{2}N + 1$ to $k = N - 1$, essentially define the spectral components at negative frequencies.

The details of the various FFT algorithms are fully documented in the literature (see refs. 1 and 4 and the signal analysis documents listed in the Bibliography). It is necessary here only to note a few basic characteristics of the most common algorithm used for acoustical and vibration work, which is commonly referred to as the *Cooley–Tukey algorithm* in recognition of the authors of the 1965 paper[4] that initiated the wide use of such algorithms:

1. It is convenient to restrict the number of data values for each FFT to a power of 2, that is, $N = 2^p$, where values of $p = 8$ to $p = 12$ are commonly used.
2. The fundamental frequency resolution of the Fourier components will be $\Delta f = 1/(N\ \Delta t)$.
3. The Nyquist frequency where aliasing will initiate, denoted by f_N, occurs at the $k = \frac{1}{2}N$ Fourier component, that is, $f_N = 1/(2\ \Delta t)$.

4. The first $\frac{1}{2}N+1$ Fourier components up to the Nyquist frequency are related to the last $\frac{1}{2}N-1$ components above the Nyquist frequency by $X(k)=X^*(N-k)$, $k=0,1,2,\ldots,N-1$, where the asterisk denotes complex conjugate.
5. The Fourier components defined only for positive frequencies (called a one-sided spectrum) are given by $X(0)$, $X(N/2)$, and $2X(k)$; $k=1,2,\ldots,N/2-1$.

Line and Fourier Spectral Functions

For deterministic signals that are periodic, a frequency decomposition or spectrum of the signal is directly obtained by computing the Fourier series coefficients of the signal over at least one period of the signal using an FFT algorithm. Assuming the mean value equals zero, the one-sided spectra of Fourier components for a periodic signal, $p(t)$, are given by

$$P(f)=\frac{2X(f,T)}{T} \qquad f>0 \text{ or } k=1,2,\ldots,\frac{N}{2}-1 \tag{3.10}$$

where $X(f,T)$ is as defined in Eq. (3.9). The Fourier component magnitudes, $|P(f)|$, are usually plotted versus frequency in the form of a discrete-frequency spectrum (often called a *line spectrum*), as illustrated earlier in Fig. 3.1*b*. Of course, each Fourier component is a complex number that defines a phase as well as a magnitude (the phases for the Fourier components in Fig. 3.1 are all zero). However, the phase information is generally retained only in those applications where there may be a need to reconstruct the signal time history or determine peak values.

Aliasing. Because of the aliasing problem inherent in digital spectral analysis,[1] it is important to assure there are no spectral components in the data signal being analyzed above the Nyquist frequency $[f_N=1/(2\,\Delta t)]$ for the analysis. This can be guaranteed only when the analog signal is low-pass filtered prior to the digitization to remove any spectral components that may exist in the signal above f_N. The low-pass filters employed to accomplish this task are commonly referred to as *antialiasing* filters and should always be used for all spectral analysis.

Leakage Errors and Tapering. Ideally, in the anaysis of periodic data, the spectral computations should be performed over an exact integer multiple of one period to avoid truncation errors in the Fourier series calculation. In practice, however, the computations are often terminated at a time that is convenient for the FFT algorithm and not related to the exact period of the data. The resulting truncation error leads to a phenomenon called side-lobe leakage[1,5] that can severely distort the desired results. To suppress this leakage, it is common to taper the measured time history signal in a manner that forces the values at the start and finish of the measurement to be zero, so as to eliminate the discontinuity between the beginning and ending data values. Numerous tapering functions (often called "windows") have been proposed over the years,[5] but one of the earliest and still most widely used is the *cosine-squared* taper (commonly called the *Hanning* window) given by

$$u_h(t)=1-\cos^2\frac{\pi t}{T} \qquad 0\le t\le T \tag{3.11}$$

The FFT is then performed on the signal, $y(t)=x(t)u_h(t)$, rather than directly on the original measured signal, $x(t)$. Leakage suppression can also be accomplished by equivalent operations in the frequency domain.

For deterministic signals that are not periodic and further have a well-defined beginning and end (transients), a spectrum of the signal is directly obtained by computing the Fourier transform of the signal over the entire duration of the signal, again using an FFT algorithm (to obtain a one-sided spectrum, the actual computation is $2X(k\,\Delta f)$, $k=1,2,\ldots,N/2-1$. The Fourier spectrum magnitude is plotted as a continuous function of frequency, as illustrated previously in Fig. 3.2*b*. Similar to the spectra for periodic signals, there is also a phase function associated with Fourier spectra, but it is generally retained only if the signal time history is to be reconstructed or peak values are of interest. As long as the FFT computation is performed over a measurement duration that covers the entire duration of the transient event, there is no side-lobe leakage problem in the analysis.

As a final point on transient signal analysis, it should be mentioned that transient data signals, particularly those produced by short-duration mechanical shocks, are often analyzed by a technique called the *shock response spectrum*,[6] which essentially defines the peak response of a hypothetical collection of single-degree-of-freedom mechanical systems to the transient input. The shock response spectrum can be a valuable tool for assessing the damaging potential of mechanical shock loads on equipment but is not particularly useful for noise and vibration reduction applications.

Auto (Power) Spectral Density Functions

The autospectral density function (also called the "power" spectral density function) provides a convenient and consistent measure of the frequency composition of random data signals. The autospectrum, denoted by $G_{xx}(f)$, is most easily visualized as the ms value of the signal passed through a narrow-bandpass filter divided by the filter bandwidth, as illustrated in Fig. 3.8. In equation form,

$$\hat{G}_{xx}(f)=\frac{1}{T\,\Delta f}\int_0^T x^2(f,\Delta f,t)\,dt \tag{3.12}$$

where $x(f,\Delta f,t)$ denotes the signal passed by the narrow-bandpass filter with a center frequency f and a bandwidth Δf. To obtain the exact autospectral density function, the operations in Fig. 3.8 would theoretically be carried out in the limit as $T\to\infty$ and $\Delta f\to 0$ such that $T\,\Delta f\to\infty$. It is clear from Fig. 3.8 and

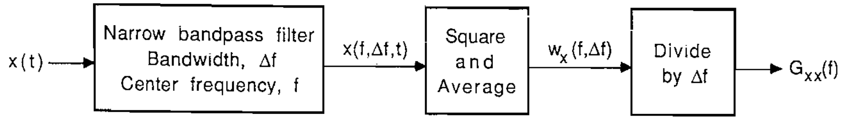

FIGURE 3.8 Autospectral density function measurement by analog filtering operations.

Eq. (3.12) that the units of the autospectral density function are volts squared per hertz.

The operations shown in Fig. 3.8 represent the way autospectra were computed by analog instruments[2] prior to the introduction of FFT algorithms and the transition to digital data analysis procedures. Today, with the ready availability of FFT hardware and software, the autospectral density function (at positive frequencies only) is estimated directly by[1]

$$G_{xx}(f) = \frac{2}{n_d T}\sum_{i=1}^{n_d} |X_i(f,\ T)|^2 \qquad f > 0 \tag{3.13}$$

where $X_i(f, T)$ is the FFT of $x(t)$ computed over the ith data segment of duration T, as defined in Eq. (3.9), and n_d is the number of disjoint (statistically independent) data segments used in the calculation. To obtain the exact autospectral density function, the operations in Eq. (3.13) would theoretically be carried out in the limit as $T \to \infty$ and $n_d \to \infty$. As will be seen later, the number of averages n_d determines the random error in the estimate, while the segment duration T for each FFT computation determines the resolution and, hence, a potential bias error in the estimate. The collection of disjoint data segments needed to estimate a statistically reliable autospectrum is usually created by dividing the total available measurement duration T_r into a sequence of contiguous segments of duration T, as illustrated in Fig. 3.9. It follows that $n_d = T_r/T = \Delta f\ T_r$, often referred to as the *BT product* of the estimate. It can be shown[1] that Eq. (3.13) is equal to the result in Eq. (3.12) when the appropriate limits are imposed, that is, when $T \to \infty$ and $\Delta f \to 0$ in Eq. (3.12) and $T \to \infty$ and $n_d \to \infty$ in Eq. (3.13). Note that the autospectral density function is always a real number (there is no phase information associated with autospectra).

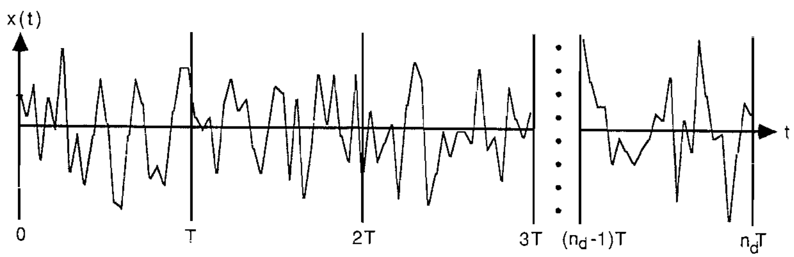

FIGURE 3.9 Subdivision of measured time history into n_d contiguous segments.

A number of grooming operations are commonly employed to enhance the quality of autospectral density estimates. A few of the more important ones are as follows (see the noted references for details).

Antialiasing Filters. As for periodic data analysis, to avoid aliasing, it is important that the random signal being analyzed have no spectral values above the Nyquist frequency, $f_N = 1/(2\ \Delta t)$. Hence, the analog signal must always be low-pass filtered prior to digitization to suppress any spectral content that may exist above f_N.[1]

Tapering Windows. Since random data signals essentially have an infinite period, there will always be a truncation error associated with the selected segment duration T. Hence, tapering operations (windows) are commonly used in random signal analysis to suppress the side-lobe leakage problem. Of the numerous available tapering functions,[5] the cosine-squared (Hanning) window defined in Eq. (3.11) is the most widely used.

Overlapped Processing. Although tapering operations on segments of the measured signal are desirable to suppress leakage, they also increase the bandwidth of the effective spectral window associated with the analysis.[5] If it is desired to maintain the same spectral window bandwidth with tapering that would have been achieved without tapering, the segment duration T for the analysis must be increased. However, assuming the total duration of the measurement T_r is fixed, this will reduce the number of disjoint averages n_d and increase the random error of the spectral estimates. This increase in random error can be counteracted by computing the spectrum with overlapped segments, rather than contiguous segments.[7,8] A 50% overlap is commonly used in such cases.

Zoom Transforms. As discussed earlier, FFT algorithms are usually implemented with a fixed number of data points. Hence once a desired upper frequency limit for an analysis (the Nyquist frequency f_N) has been chosen, the resolution of the analysis, Δf, as defined in Eq. (3.9c), is also fixed. Situations often arise when the desired upper frequency limit and frequency resolution are not compatible with the number of data points used by the FFT computation. In these cases, a finer resolution for a given value of f_N can be achieved using computation techniques referred to as *zoom transform* procedures.[1] The most common zoom transform techniques employ a complex demodulation calculation that essentially segments the frequency range of the signal into contiguous bands that are then analyzed separately.

Cross-Spectral Density Functions. The solution of acoustical and vibration control problems involving random processes is often facilitated by the identification of a linear dependence (correlation) between two measurements at different locations. The basic parameter that defines the linear dependence between two measured random signals, $x(t)$ and $y(t)$, as a function of frequency is the cross-spectral density function, which is estimated (at positive frequencies only) by[1]

$$G_{xy}(f) = \frac{2}{n_d T} \sum_{i=1}^{n_d} X_i^*(f, T) Y_i(f, T) \qquad f > 0 \tag{3.14a}$$

where $X_i(f, T)$ and $Y_i(f, T)$ are the FFTs of $x(t)$ and $y(t)$, respectively, computed over the ith simultaneous data segments of duration T, n_d is the number of disjoint records used in the calculation, and the asterisk denotes complex conjugate. As for autospectra, the exact cross-spectral density function would be obtained in the limit as $T \to \infty$ and $n_d \to \infty$. All of the computational considerations and grooming procedures discussed for autospectra apply to cross-spectra as well. Unlike the autospectrum, however, the cross-spectrum is generally a complex number that includes both magnitude and phase information and, hence, may be denoted in complex polar notation as

$$G_{xy}(f) = |G_{xy}(f)| e^{j\theta_{xy}(f)} \tag{3.14b}$$

Coherence Functions

For many applications, it is more convenient to work with a normalized version of the cross-spectral density function, called the coherence function (sometimes called coherency squared), which is defined as[1]

$$\gamma_{xy}^2(f) = \frac{|G_{xy}(f)|^2}{G_{xx}(f) G_{yy}(f)} \tag{3.15}$$

The coherence function is a real-valued quantity bounded by zero and unity, that is,

$$0 \le \gamma_{xy}^2(f) \le 1 \tag{3.16}$$

where a value of zero means there is no linear dependence and a value of unity means there is a perfect linear dependence between the signals $x(t)$ and $y(t)$ at the frequency f. A coherence value that is less than unity at one or more frequencies is usually indicative of one of the following situations[9]:

1. Extraneous noise is present in the measurements.
2. The frequency resolution of the spectral estimates is too wide.
3. The system relating $y(t)$ to $x(t)$ has time-dependent parameters.
4. The system relating $y(t)$ to $x(t)$ is not linear.
5. The output $y(t)$ is due to other inputs besides $x(t)$.

By carefully designing an experiment to minimize the first four possible reasons for a low coherence, the fifth reason provides the basis for a powerful procedure to identify acoustical noise and/or vibration sources. Specifically, if it is known that a constant-parameter linear system exists between a source and a receiver location, the source signal is measured with an adequate signal-to-noise ratio, and the spectra of the source and receiver signals are estimated with an adequate frequency resolution, then the coherence function defines the fractional portion of the receiver signal autospectral density that is due to the measured source signal. This is the basis for the coherent output power relationship, which is discussed and illustrated in Section 3.5.

Statistical Sampling Errors

There are no statistical sampling errors associated with the calculation of spectra for periodic signals, assuming the averaging time is an integer multiple of the period of the signal. The same is true of the calculation of Fourier spectra for deterministic transient signals, assuming the averaging time is longer than the transient. The calculation of spectral density quantities for random signals, however, will involve a random sampling error, as discussed previously in Section 3.2. First-order approximations for these random errors in autospectra, cross-spectra, and coherence function estimates are summarized in Table 3.2.[1] The random errors are presented in terms of the normalized random error (coefficient of variation) defined in Eq. (3.6), except for estimates of the cross-spectrum phase where the random error is given in terms of the standard deviation of the estimated phase angle in radians.

Beyond the random errors, there is also a bias error problem in the estimation of spectral density functions that occurs at peaks and valleys in the estimates. This bias error is caused by the finite-resolution bandwidth used for the calculations. For auto- and cross-spectral density magnitude estimates, the bias error is approximated in normalized terms by[1,9]

$$\epsilon_b[\hat{G}(f)] = \frac{b[\hat{G}(f)]}{G(f)} = -\frac{1}{3}\left(\frac{\Delta f}{B_r}\right)^2 \tag{3.17}$$

where $b[\cdot]$ denotes the bias error incurred by estimating $G(f)$ by its biased value $\hat{G}(f)$, Δf is the frequency resolution of the analysis, and B_r is the half-power-point bandwidth of a spectral peak in either $G_{xx}(f)$ or $|G_{xy}(f)|$ at that frequency. There is no general bias error equation for coherence function estimates, but error relationships have been formulated for special cases.[10]

TABLE 3.2 Normalized Random Errors for Autospectra, Cross-Spectra, and Coherence Function Estimates

Signal Property	Normalized Random Error ϵ_r or Standard Deviation σ_r
Autospectral density function, $G_{xx}(f)$	$\epsilon_r = 1/n_d^{1/2}$
Cross-spectral density magnitude, $\lvert G_{xy}(f)\rvert$	$\epsilon_r = 1/[n_d \gamma_{xy}^2(f)]^{1/2}$
Cross-spectral density phase, $\theta_{xy}(f)$	$\sigma_r = [1-\gamma_{xy}^2(f)]^{1/2}/[2n_d\gamma_{xy}^2(f)]^{1/2}$
Coherence function, $\gamma_{xy}^2(f)$	$\epsilon_r = [1-\gamma_{xy}^2(f)]/[0.5 n_d \gamma_{xy}^2(f)]^{1/2}$

3.4 CORRELATION FUNCTIONS

Certain noise and vibration control problems that involve relatively wide bandwidth random data signals are beast addressed using time domain signal-processing procedures, as opposed to the frequency domain spectral analysis techniques discussed in the previous section. The basic calculation of interest is the correlation function between two random data signals, $x(t)$ and $y(t)$, which is estimated by

$$R_{xy}(\tau) = \frac{1}{T-\tau}\int_0^{T-\tau} x(t)y(t+\tau)\,dt \tag{3.18a}$$

where τ is a time delay. In digital notation,

$$R_{xy}(r\ \Delta t) = \frac{1}{N-r}\sum_{n=1}^{N-r} x[n\ \Delta t]y[(n+r)\ \Delta t] \tag{3.18b}$$

where r is a lag number corresponding to a time delay of $r\ \Delta t$. The general quantity estimated in Eq. (3.18) is called the cross-correlation function between the signals $x(t)$ and $y(t)$. For the special case where $x(t) = y(t)$,

$$R_{xx}(\tau) = \frac{1}{T-\tau}\int_0^{T-\tau} x(t)x(t+\tau)\,dt \tag{3.19}$$

is called the autocorrelation function of $x(t)$. Note that for $\tau = 0$, the autocorrelation function is simply w_x, the ms value of the signal. In both Eqs. (3.18) and (3.19), the estimated quantities will become exact in the limit as the averaging time $T \to \infty$. For finite values of T, there will be a random sampling error in the estimates, to be discussed later.

The correlation function is related to the spectral density function through a Fourier transform,[1]

$$G_{xy}(f) = 2\int_{-\infty}^{\infty} R_{xy}(\tau)e^{-j2\pi f\tau}\,d\tau \tag{3.20}$$

Equation (3.20), often called the *Wiener–Khinchine relationship*, is the basis for computing correlation functions in practice. Specifically, the spectral density function is first computed by the FFT procedures outlined in Section 3.3. An inverse Fourier transform of the spectral density function is then computed to obtain the correlation function. Due to the remarkable efficiency of the FFT algorithm, this approach requires substantially fewer calculations than that needed to compute Eq. (3.18b) directly. However, due to the *circular effects* associated with the FFT algorithm, a number of special operations are needed to obtain correct results, as detailed in reference 1.

Correlation Coefficient Function

For many applications, it is more convenient to work with the normalized cross-correlation function between $x(t)$ and $y(t)$, called the correlation coefficient

function, which is given by (assuming the mean value is zero)

$$\rho^2(\tau) = \frac{R_{xy}^2(\tau)}{R_{xx}(0)R_{yy}(0)} = \frac{R_{xy}^2(\tau)}{w_x w_y} \tag{3.21}$$

The correlation coefficient function (sometimes called the squared correlation coefficient function) is similar to the coherence function, defined in Section 3.3, in that it is a real-valued quantity bounded by zero and unity, that is,

$$0 \le \rho_{xy}^2(\tau) \le 1 \tag{3.22}$$

where a value of zero means there is no linear dependence and a value of unity means there is a perfect linear dependence[1] between $x(t)$ and $y(t)$ at the time displacement τ. Hence, the correlation coefficient function is interpreted much like the frequency domain coherence function discussed in Section 3.3, except the correlation coefficient function applies to the entire frequency range of the two signals while the coherence function applies to specific frequencies. Also, from Eq. (3.14b), time delay information in the correlation coefficient function is related to the phase information in the cross-spectral density function by

$$\theta(f) = 2\pi f\tau \tag{3.23}$$

Hence, the phase of the cross-spectrum can be valuable for extracting time delay information when the time delay is a function of frequency.[11]

Statistical Sampling Errors

When applied to random data signals, the computation of correlation functions will involve a statistical sampling error. In terms of a normalized random error defined in Eq. (3.6), the error in a cross-correlation estimate can be approximated by[1]

$$\epsilon_r[\hat{R}_{xy}(\tau)] = \left(\frac{1 + 1/\rho_{xy}^2(\tau)}{2B_sT_r}\right)^{1/2} \tag{3.24}$$

where $\hat{R}_{xx}(\tau)$ is an estimate of $R_{xx}(\tau)$, T_r is the total measurement duration over which the computations are performed, and B_s is the smallest statistical bandwidth for the two data signals, as defined in Eq. (3.7).

3.5 DATA ANALYSIS APPLICATIONS

The applications for signal analysis in noise and vibration studies are extensive and can become quite elaborate.[9] However, as mentioned in the introduction to this chapter, there are three specific application areas of special interest for noise and vibration control problems: (a) the identification of system response properties, (b) the identification of excitation sources, and (c) the identification of transmission paths.

Identification of System Response Properties

The control of noise and vibration is often facilitated by the determination of gain factors between excitation sources and receiver location responses. The fundamental measurement of interest here is the frequency response function (sometimes called the transfer function) between the two points of interest. Given an excitation source signal $x(t)$ and a simultaneously measured response signal $y(t)$, the frequency response function between the source and receiver signal is given by[1]

$$H_{xy}(f) = \frac{G_{xy}(f)}{G_{xx}(f)} \tag{3.25a}$$

where the auto- and cross-spectral density functions are as defined in Eqs. (3.13) and (3.14), respectively. The frequency response function is generally a complex-valued quantity that is more conveniently expressed in complex polar notation as

$$H_{xy}(f) = |H_{xy}(f)|\ e^{i\phi_{xy}(f)} \tag{3.25b}$$

where the magnitude function $|H_{xy}(f)|$ is the gain factor and the argument $\phi_{xy}(f)$ is the phase factor between $x(t)$ and $y(t)$. In the more advanced applications, such as normal-mode analysis,[12] both the gain and phase factor are needed. In many elementary applications, however, only the gain factor may be of interest.

The normalized random error in frequency response magnitude (gain factor) estimates is approximated by[1]

$$\epsilon_r[|\hat{H}_{xy}(f)|] \approx \frac{[1-\gamma_{xy}^2(f)]^{1/2}}{[2n_d\gamma_{xy}^2(f)]^{1/2}} \tag{3.26}$$

where $\hat{H}_{xy}(f)$ is an estimate of $H_{xy}(f)$, $\gamma_{xy}^2(f)$ is the coherence function between the source and receiver signals, and n_d is the number of disjoint averages used to compute the autospectra and cross-spectra from which the gain factor is calculated. The random error in frequency response phase estimates is the same as given for the phase of cross-spectral density estimates in Table 3.2.

Like coherence function estimates, the random error in a gain factor estimate approaches zero as the coherence function approaches unity, even for a small number of averages in the spectral density estimates. Hence, if the coherence function is large, the gain factor can be estimated with greater accuracy than the spectral density estimates used in its computation.

There are several sources of bias errors in gain factor estimates,[1,9] but the most significant is due to the frequency resolution bias error in the spectral density functions used to compute the gain factor, as given by Eq. (3.17). As a rule of thumb, if there are at least four spectral components between the half-power points of peaks in the spectral data, that is, if $\epsilon_b[G(f)] < 0.02$ in Eq. (3.17), then the bias error in the gain factor estimate should be negligible.

As an illustration of the application of gain factor estimates, consider the experiment illustrated in Fig. 3.10, involving two vibration measurements made on a

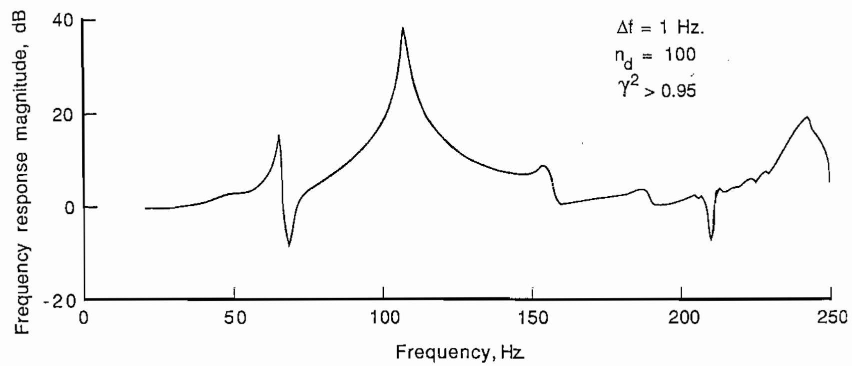

FIGURE 3.10 Gain factor estimate for component in space vehicle payload.

simulated spacecraft payload during a vibration test. One of the measurements is near the mounting point of the payload, and the other is on a critical payload element where vibration may adversely affect the payload performance. The gain factor clearly reveals a frequency region (around 110 Hz) where vibration at the mounting point is greatly magnified at the critical element of concern, due to a strong normal-mode response (resonance) of the payload at this frequency. It follows that efforts to reduce the vibration should be concentrated in this frequency region.

Identification of Periodic Excitation Sources

The identification of periodic acoustical and vibration excitations can usually be accomplished by a straightforward narrow-bandwidth spectral analysis plus a knowledge of the rpm of all rotating machinery producing the acoustical noise and/or vibration. This is illustrated in Fig. 3.11, which shows the spectrum for the vibration on the floor of a microelectronics manufacturing facility with extensive

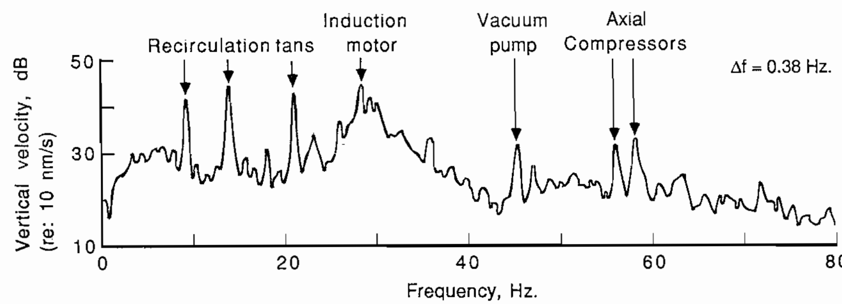

FIGURE 3.11 Fourier spectrum of floor vibration in microelectronics facility. (Courtesy of BBN Laboratories, Inc., Canoga Park, CA.)

air conditioning equipment. It is seen that the more intense spectral peaks in the vibration data can be directly identified with specific rotating machines simply through a knowledge of the rotational frequencies. Of course, this approach cannot separate the vibration contributions of two rotating machines that operate at exactly the same frequency. However, as long as there is some difference in the rotational speed between two machines, say, Δg hertz, the contributions of the machines can theoretically be separated by a spectral analysis with a frequency resolution Δf that is less than Δg. In practice, it is desirable to have

$$\Delta f = \frac{1}{T} < \frac{\Delta g}{3} \tag{3.27}$$

where T is the segment duration for the spectral computation. Since the signals are periodic or almost periodic, there is no random error associated with the resulting spectral estimates.

Identification of Random Excitation Sources

When two or more sources of an acoustical and/or vibration environment are random in character and further cover essentially the same frequency range, the identification of the contributions of the individual sources is more difficult. If possible, the contribution of each source of excitation should be identified by turning off all but one of the sources so that the effects of each source can be measured individually. If this is not possible, then the principle of coherent output power might be applied. Specifically, measure the acoustical or vibration signal produced at the source location for each of a collection of q suspected sources, denoted by $x_i(t)$, $i = 1, 2, \ldots, q$. For each individual source signal, simultaneously measure the receiver signal $y(t)$ and compute the coherence function between the ith source and receiver signals using Eq. (3.15). Under proper conditions, the autospectrum of the receiver signal due solely to the contribution of the ith source signal is given by

$$G_{y:i}(f) = \gamma_{iy}^2(f) G_{yy}(f) \tag{3.28}$$

where $G_{y:i}(f)$ reads "the portion of the autospectrum of the receiver signal that is due only to the source signal $x_i(t)$." Equation (3.28) is called the coherent output power relationship. If used properly, it can be a powerful tool for separating the contributions of various possible sources of random excitation in acoustical noise and vibration problems. The primary requirements for the proper application of the coherent output power relationship are as follows[9]:

1. The candidate sources of excitation (or the responses in the immediate vicinity of the sources) must be measured accurately and with negligible measurement noise. However, since the coherence function is dimensionless, any type of transducer (pressure, velocity, acceleration, or displacement) can be used for the source measurements as long as it generates a signal that has a linear relationship with the excitation phenomenon.

2. The candidate sources must be statistically independent, and there must be no interference (crosstalk) in the measurement of any one source due to energy propagating from the other sources; that is, the coherence functions among the measured source signals must all be zero.
3. There must be no significant feedback or nonlinear effects between the candidate source and receiver signals.

The normalized random error for coherent output power measurements is approximated by[1]

$$\epsilon_r[\hat{G}_{y:i}(f)] \approx \frac{[2 - \gamma_{iy}^2(f)]^{1/2}}{[n_d \gamma_{iy}^2(f)]^{1/2}} \tag{3.29}$$

where $\hat{G}_{y:i}(f)$ is an estimate of $G_{y:i}(f)$, $\gamma_{iy}^2(f)$ is the coherence function between the ith source signal and the receiver signal, and n_d is the number of disjoint averages used to compute the autospectra and cross-spectra from which the coherent output is calculated. It is clear from Eq. (3.29) that the number of disjoint records (and hence the total measurement duration, $T_r = n_d T$) required for an accurate coherent output power calculation will be substantial when $\gamma_{iy}^2(f) \ll 1$, as will commonly occur if there are numerous independent sources contributing to $y(t)$.

A serious bias error can occur in coherent output power calculations due to time delays between the source and receiver signals that may arise when there is a substantial distance between the source and receiver measurement positions[1,9,10,13] or the measurements are made in a reverberant environment[9,14] Since the two measurements are usually recorded and analyzed on a common time base, time delays between the source and receiver signals will cause a portion of the received signal to be uncorrelated with the source signal. These time-delay-induced bias errors can be suppressed by the use of precomputation delays or the selection of an appropriately long block duration T in the data analysis, as detailed in references 9, 13, and 14.

To illustrate the coherent output power calculation, consider the experiment outlined in Fig. 3.12, where a panel section excited by a broadband random vibration source radiates acoustical noise to a receiver microphone. The autospectrum of the radiated noise, $y(t)$, as seen by the receiver microphone with no other

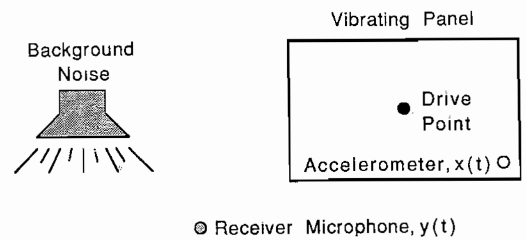

FIGURE 3.12 Acoustical source identification experiment with radiating panel in background noise.

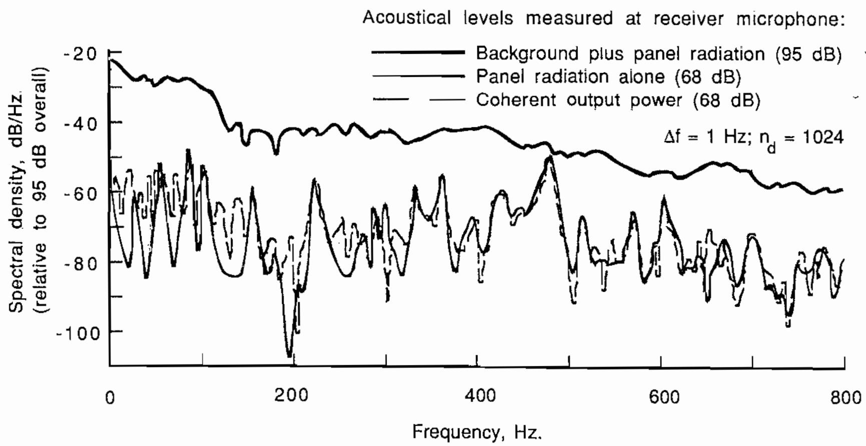

FIGURE 3.13 Overall and coherent output power spectra for radiating panel in background noise. (From Ref. 9 with the permission of the authors.)

noise sources present, is shown by the thin solid line in Fig. 3.13. Statistically independent background noise is now introduced by a speaker to produce acoustical energy with an overall value that is about 500 times more intense (27 dB higher) than the panel-radiated noise. The autospectrum of the total received microphone signal due to both the panel radiation plus the background noise is also shown in Fig. 3.13, by the heavy solid line. Finally, the coherent output power between the microphone and an accelerometer mounted on the panel is computed with the background noise present. This result is shown by the dashed line in Fig. 3.13. It is seen that the coherent output power calculation extracts the autospectrum of the radiated panel noise, as measured by an accelerometer, from the intense background noise with reasonable accuracy at most frequencies. The reason the procedure works in this example is that the radiated noise from the panel has a linear relationship with the panel motion measured by the accelerometer. Furthermore, since the panel is driven from only one point, the vibration response at any one point on the panel is representative of the vibration at all points.

Identification of Propagation Paths

Another analysis of great importance in acoustical noise and vibration control problems is the identification of the physical path or paths by which energy from a source of excitation travels to a receiver location. For those cases involving broadband random energy that propagates in a nondispersive manner (with a frequency-independent propagation speed), such as airborne noise, the identification of propagation paths can often be accomplished by a cross-correlation analysis. Specifically, assume a source signal $x(t)$ propagates in a nondispersive manner through r paths to produce a receiver signal $y(t)$. For simplicity, further

assume the propagation paths have uniform (frequency-independent) gain factors denoted by H_i, $i = 1, 2, \ldots, r$. It follows that

$$y(t) = H_1 x(t - \tau_1) + H_2 x(t - \tau_2) + \cdots + H_r x(t - \tau_r) \tag{3.30}$$

where τ_i, $i = 1, 2, \ldots, r$, are the propagation times through each of the paths. Then, from Eqs. (3.18) and (3.19),

$$R_{xy}(\tau) = H_1 R_{xx}(\tau - \tau_1) + H_2 R_{xx}(\tau - \tau_2) + \cdots + H_r R_{xx}(\tau - \tau_r) \tag{3.31}$$

In words, the cross-correlation function between the source and receiver signals will be a series of superimposed autocorrelation functions, each associated with a nondispersive propagation path and centered on a time delay equal to the propagation time along that path. Referring to Eq. (3.20), if the source signal has a wide bandwidth, these autocorrelation peaks will decay rapidly when τ deviates from τ_i and will be sharply defined in the cross-correlation estimate, as illustrated in Fig. 3.14. Noting that the propagation time for each path is the ratio of distance to propagation speed, the physical path associated with each correlation peak can usually be identified from a knowledge of the length of the path and the propagation speed of the nondispersive waves in the medium forming the path. Finally, the portion of the receiver signal ms value that propagated through a specific path is proportional to the square of the magnitude of the correlation peak associated with that path. The normalized random error associated with the estimate of $R_{xy}(\tau)$ in Eq. (3.31) is given by Eq. (3.24).

For a cross-correlation analysis to be effective in identifying different nondispersive propagation paths, several requirements must be met, as follows.

1. The source $x(t)$ must be a broadband random signal.
2. The propagation paths must have reasonably uniform gain factors.
3. The propagation time through each path must be different from all other paths.

As a rule of thumb,[9] the difference in the propagation times through any pair of paths must be $\Delta t > 1/B_s$, where B_s is the spectral bandwidth of the receiver

FIGURE 3.14 Cross-correlation function between source and receiver signals with two nondispersive propagation paths.

signal, as defined in Eq. (3.7). As the spectral bandwidth becomes small, the peaks in the cross-correlation function spread, and the ability to identify peaks representing individual propagation paths diminishes. There are a number of other signal-processing operations that will enhance the ability to detect individual propagation paths between two signals when the bandwidth is not wide.[9] Also, the use of envelope functions generated by Hilbert transforms can further enhance such detections.[1] Nevertheless, in the limiting narrow-band case where the source signal is a sine wave (or any periodic function), the identification of individual propagation paths cannot be achieved by any signal-processing procedure no matter how large a difference there is between the propagation times through the various paths.

To illustrate this application of cross-correlation analysis to a propagation path identification problem, consider the experiment shown in Fig. 3.15, which involves a speaker that produces acoustical noise with a bandwidth of approximately 8 kHz. Two microphones are used to measure the noise, one located in front of the speaker and another located 0.68 m from the speaker. There is a wall behind the receiver microphone that causes a back reflection producing a second path between the source and receiver microphones with a length of 1.7 m. The computed cross-correlation function between the source and receiver signals is shown in Fig. 3.16. It is seen that two maxima appear in the cross-correlation estimate at 2 and 5 ms. Noting that the speed of sound in air at room

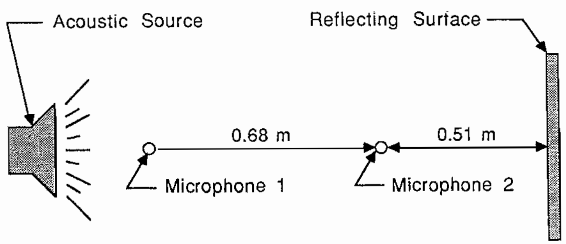

FIGURE 3.15 Acoustical propagation path experiment with back reflection.

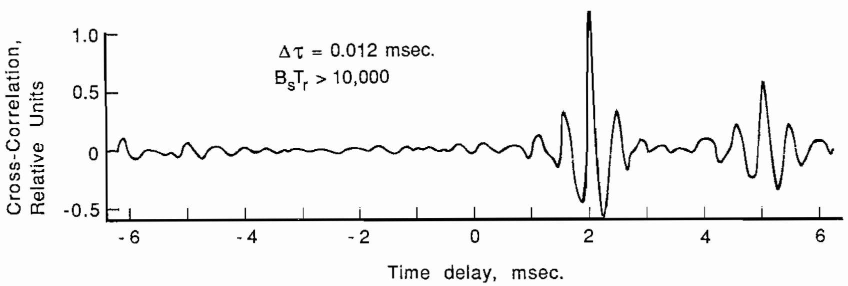

FIGURE 3.16 Cross-correlation function between two microphone signals with back reflection. (From Ref. 9 with the permission of the authors.)

temperature is about 340 m/s, these two peaks clearly identify the direct path and the back reflection. The magnitude of the correlation peak corresponding to the back reflection is only about 40% of the magnitude of peak corresponding to the direct path, as would be expected due to spherical spreading loss; that is, the reflected path is 2.5 times longer than the direct path and, hence, should be about 8 dB lower in level.

The cross-correlation analysis procedure often works well in multipath acoustical problems where the propagation is in the form of longitudinal waves that are nondispersive. In structural vibration problems, there may also be some nondispersive longitudinal wave propagation, but most vibratory energy in structures propagates in the form of flexural waves, which are dispersive,[15] that is, the propagation velocity is a function of frequency. Also, flexural waves strongly reflect and/or scatter at locations where there are changes in either the material properties or the geometry of the structural path. These facts greatly complicate the detection of individual propagation paths in multipath structural vibration problems. Nevertheless, meaningful results can sometimes be obtained through the judicious use of bandwidth-limited cross-correlation analyses[1,9] if the structural paths are reasonably homogeneous.

4.1 INTRODUCTION

Noise control can be considered as a system problem, the system containing three major parts: the source, the path, and the receiver.[1]

In any noise control problem, sound energy from the source or sources travels over a multiplicity of paths, both in solid structures and in air, to reach the receiver—an individual, a group of people, a microphone or other instrument, or a structure that is affected by the noise. Three action words are associated with the source–path–receiver model: *emission, transmission*, and *immission*. Sound energy that is emitted by a noise source is transmitted to a receiver where it is immitted. Transmission is treated in Chapters 5–7, 10, and 11. Immission is treated in Chapter 19.

Sound pressure level is the physical quantity usually used to describe a sound field quantitatively because the ear responds to sound pressure. A sound-level meter may be used to readily measure the sound pressure level at the location in the sound field occupied by the receiver. Therefore, the preferred descriptor of immission is the sound pressure level in decibels. However, the sound pressure

4.1 INTRODUCTION

Noise control can be considered as a system problem, the system containing three major parts: the source, the path, and the receiver.[1]

In any noise control problem, sound energy from the source or sources travels over a multiplicity of paths, both in solid structures and in air, to reach the receiver—an individual, a group of people, a microphone or other instrument, or a structure that is affected by the noise. Three action words are associated with the source–path–receiver model: *emission, transmission*, and *immission*. Sound energy that is emitted by a noise source is transmitted to a receiver where it is immitted. Transmission is treated in Chapters 5–7, 10, and 11. Immission is treated in Chapter 19.

Sound pressure level is the physical quantity usually used to describe a sound field quantitatively because the ear responds to sound pressure. A sound-level meter may be used to readily measure the sound pressure level at the location in the sound field occupied by the receiver. Therefore, the preferred descriptor of immission is the sound pressure level in decibels. However, the sound pressure level by itself is not a satisfactory quantity to describe the strength of a noise source (emission) because the sound pressure level varies with distance from the source and with the acoustical environment in which the source operates.

Two quantities are needed to describe the strength of a noise source, its *sound power level* and its *directivity*. The sound power level is a measure of the total sound power radiated by the source in all directions and is usually stated as a function of frequency, for example, in one-third-octave bands. The sound power level is then the preferred descriptor for the emission of sound energy by noise sources. The sound power level is usually expressed in decibels.*

The directivity of a source is a measure of the variation in its sound radiation with direction. Directivity is usually stated as a function of angular position around the acoustical center of the source and also as a function of frequency. Some sources radiate sound energy nearly uniformly in all directions. These are called nondirectional sources (see Fig. 4.1). Generally, such sources are small in size compared to the wavelength of the sound radiated. Most practical sources are somewhat directional (see Fig. 4.2); that is, they radiate more sound in some directions than in others. Measures of source directivity are presented in Section 4.12.

From the sound power level and directivity, it is possible to calculate the sound pressure levels produced by the source in the acoustical environment in which it operates. This is not an easy task, however, because the resulting sound

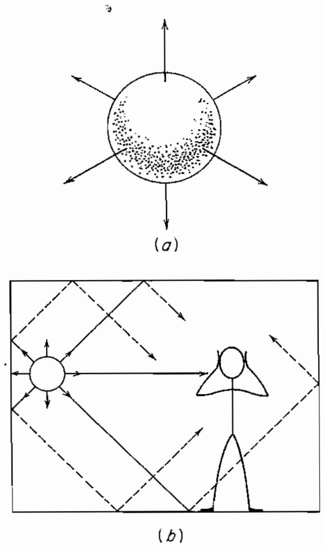

FIGURE 4.1 Sound source that radiates uniformly in all directions: *(a)* sound source in free space; *(b)* same source in enclosure showing reflections from interior surfaces. Solid lines show the direct sound; dashed lines show the reflected (reverberant) sound.

*Some industries have adopted the use of the bel, where 1 bel = 10 dB, as the unit of sound power level to distinguish clearly between sound pressure level in decibels and sound power level in bels.

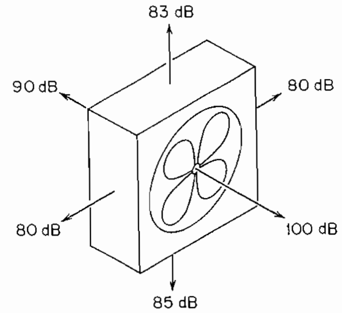

FIGURE 4.2 Sound source with directive radiation into free space. This behavior is typical of equipment noise.

pressure levels at points in the room depend not only on the characteristics of the source but also on the characteristics of the room itself. The sound energy from the source is reflected, absorbed, and scattered by the room boundaries, and some energy is transmitted through these boundaries to adjacent spaces. Thus, the same source could produce quite different sound pressure levels in different rooms or environments. This underscores the difference between *emission* and *immission* and illustrates why sound pressure level is not a good descriptor for noise emission from a source. Sound fields outdoors and in rooms are discussed in detail in Chapters 5–7.

A source may set a nearby surface into vibration if it is rigidly attached to that surface, causing more sound power to be radiated than if the source were vibration isolated. Both the operating and mounting conditions of the source therefore influence the amount of sound power radiated as well as the directivity of the source. Nonetheless, the sound power level alone is useful for comparing the noise radiated by machines of the same type and size as well as by machines of different types and sizes; determining whether a machine complies with a specified upper limit of noise emission; planning in order to determine the amount of transmission loss or noise control required; and engineering work to assist in developing quiet machinery and equipment.

4.2 SOUND POWER LEVELS OF SOURCES

Even though the sound power produced by a noisy machine is only a very small fraction of the total mechanical power that the machine produces, the range of sound powers produced by sources of practical interest is enormous—from less than a microwatt to megawatts. Shaw[2] has estimated the radiation ratio of a wide variety of noise sources.

A single-number descriptor for noise source emission is obtained when the sound power as a function of frequency is weighted using the A-frequency weighting curve. The result is the A-weighted sound power (Table 1.4). The

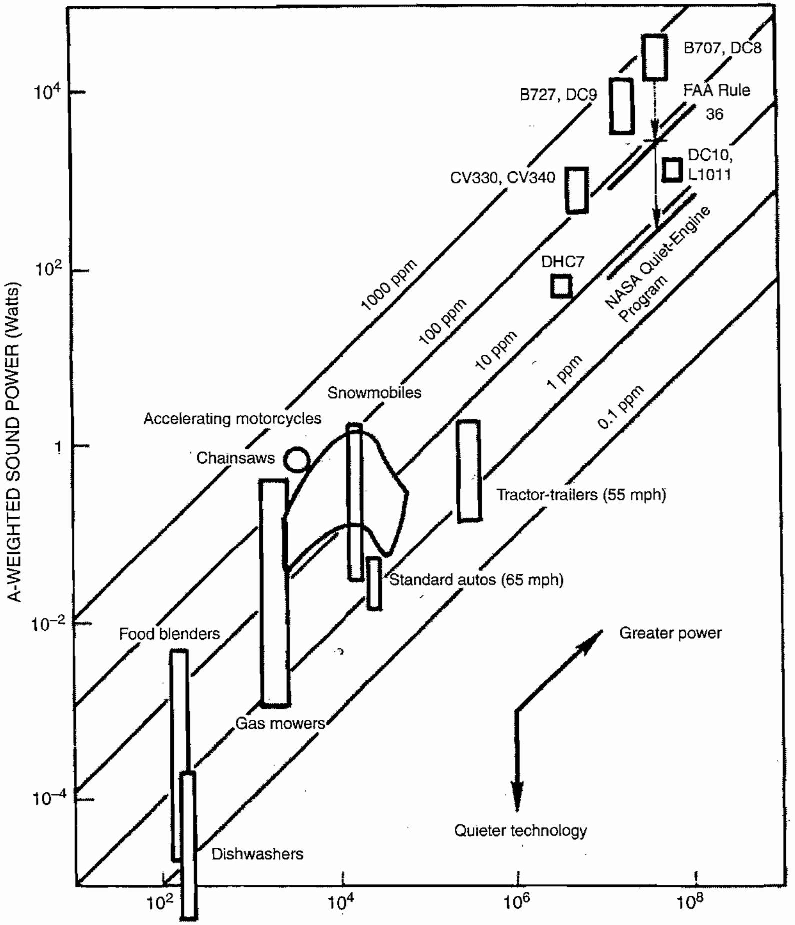

FIGURE 4.3 Estimated values of A-weighted sound power versus mechanical power for various machines. The diagonal lines are lines of constant mechanoacoustical efficiency (sound power per mechanical power) in parts per million. The line labeled FAA Rule 36 approximates 1975 noise levels for new aircraft designs, while the goal of a research program in progress at the time the figure was published is labeled NASA Quiet-Engine Program.

radiation ratio is the ratio of the A-weighted sound power level of the source and the mechanical power.

Estimates of the conversion ratio are shown in Fig. 4.3. The diagonal lines in the figure give conversion ratios ranging from 10^{-3} to 10^{-7}.

The sound powers of sources of practical interest cover a range of more than 12 orders of magnitude. Hence, it is convenient to express a sound power on a

logarithmic scale using an internationally agreed-upon sound power, 10^{-12} W (watts), as the reference for the logarithm (see Chapter 1). The A-weighted sound power level* in decibels is defined as

$$L_{WA} = 10 \log \left(\frac{W_A}{W_0} \right) \tag{4.1}$$

where W_A = A-weighted sound power
L_{WA} = A-weighted sound power level, dB
W_0 = reference sound power, internationally agreed upon as 10^{-12} W

Consequently

$$L_{WA} = 10 \log W_A + 120 \quad \text{dB re } 10^{-12} \text{ W} \tag{4.2}$$

The A-weighted sound power level (L_{WA}) is usually expressed in decibels but may be expressed in bels. Since there is an order-of-magnitude difference between sound power levels in bels (emission) and sound pressure levels in decibels (immission), the ambiguity of expressing both emission and immission values in decibels is avoided. Use of this convention is particularly important in dealing with the public. In many countries, people who are unfamiliar with the technical details of acoustics are unable to distinguish between different quantities that are expressed in decibels. Nonetheless, noise control engineers and other practitioners in the field usually find it convenient to express sound power levels in decibels.

Example 4.1. A sound source radiates an A-weighted sound power of 3 W. Find the A-weighted sound power level in decibels.

Solution

$$L_{WA} = 10 \log 3 + 120$$
$$= 4.8 + 120 = 124.8 \text{ dB re } 10^{-12} \text{ W}$$

A level is a dimensionless quantity, and it is imperative that the reference be stated to avoid confusion.

4.3 RADIATION FIELD OF A SOUND SOURCE

Near Field, Far Field, and Reverberant Field

Since the sound power emitted by a source must be determined by measurement of a field quantity such as sound pressure or sound intensity (the sound energy

*In the past, the A-weighted sound power level was sometimes designated by the term *noise power emission level*, abbreviated NPEL. This usage is no longer common.

flowing through a unit area in a unit time), it is important to understand the radiation field of a sound source when it is placed in various acoustical environments. The character of the radiation field of a typical noise source usually varies with distance from the source. In the vicinity of the source, the particle velocity is not necessarily in the direction of propagation of the sound wave, and an appreciable tangential velocity component may exist at any point. This is the near field. It is characterized by appreciable variations of the sound pressure with distance from the source along a given radius, even when the source is in a free unbounded space commonly referred to as a free field. Moreover, in the near field, the sound intensity is not simply related to the mean-square value of the sound pressure.

The distance from the source to which the near field extends is dependent on the frequency, on a characteristic source dimension, and on the phases of the radiating parts of the surface of the source. The characteristic dimension may vary with frequency and angular orientation. It is difficult, therefore, to establish limits for the near field of an arbitrary source with any degree of accuracy. It is often necessary to explore the sound field experimentally.

In the far field, the sound pressure level decreases by 6 dB for each doubling of the distance from the source, provided that either the source is in free space (no boundaries to reflect the sound) or the reverberant field has not yet been reached (see Fig. 4.4). In this free-field part of the far field, the particle velocity is primarily in the direction of propagation of the sound wave.

If the source is radiating inside an enclosure, fluctuations of sound pressure with position are observed in the reverberant part of the far field, that is, in the region

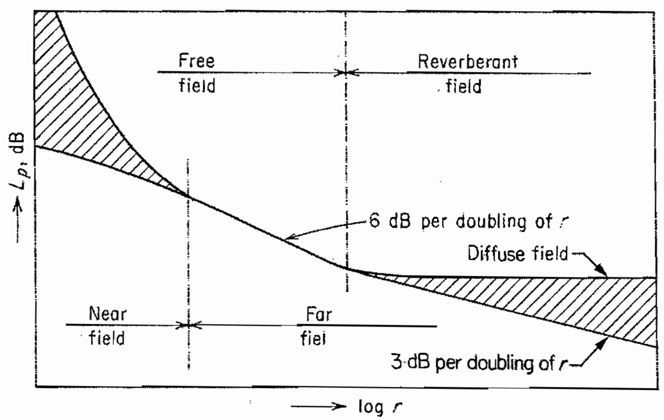

FIGURE 4.4 Variation of sound pressure level in an enclosure along a radius r from a typical noise source. The free field, reverberant field, near field, and far field are shown. The free far field indicates the region where the sound pressure level L_p decreases at the rate of 6 dB for each doubling of distance from the acoustical center of the source, although this region is often very short. In the reverberant far field, the sound pressure level in a highly reverberant room is constant. The lower edge of the shaded region is typical of sound fields in furnished rooms of dwellings and offices.

where the waves reflected from the boundaries of the enclosure are superimposed upon the direct field from the source (see Fig. 4.4). In a highly reverberant room in the region where the direct sound pressure from the source is considerably smaller than the contribution from the reflected sound, the sound pressure level reaches a value essentially independent of the distance from the source. This region may approximate an ideal *diffuse field* in which reflected energy propagates equally in all directions and the sound energy density is uniform.

As discussed in more detail in Chapter 7, in furnished rooms in dwellings and offices where the sound field is neither a free field nor a diffuse field, the sound pressure level decreases by about 3 dB for each doubling of distance from the source.

4.4 SOUND INTENSITY, SOUND POWER, AND SOUND PRESSURE

Sound Intensity and Sound Power

The sound energy (in joules, 1 J = 1 N · m) or the sound power (in joules per second or watts) radiated into free space by a source spreads out over a larger and larger area as the sound wave travels outward from the source. As a result, the sound intensity (in watts per square meter) and the sound pressure (in pascals) at a point in the sound field decreases as the distance from the source increases. Sound intensity, defined in Section 2.2 as the amount of sound energy flowing through a unit area per unit time, is a vector quantity $\mathbf{I}$ having magnitude $I = |\mathbf{I}|$ and direction $\hat{\mathbf{r}}$ pointing in the direction of sound energy propagation. If a closed surface that surrounds the source is selected, the sound power radiated by the source can be calculated from the following integral:

$$W = \int_S \mathbf{I} \cdot d\mathbf{S} \tag{4.3}$$

where W = sound power, W
$\mathbf{I}$ = time-average sound intensity vector, W/m^2
$d\mathbf{S}$ = infinitesimal element of surface area (a vector oriented normal to surface)
S = area of closed surface that surrounds source

Expanding the dot product in Eq. (4.3) allows the surface integral to be written in terms of scalar quantities as follows:

$$\begin{aligned} W &= \int_S \mathbf{I} \cdot d\mathbf{S} = \int_S (|\mathbf{I}|\hat{\mathbf{r}}) \cdot (|d\mathbf{S}|\hat{\mathbf{n}}) \\ &= \int_S (I\, dS) \times (\hat{\mathbf{r}} \cdot \hat{\mathbf{n}}) = \int_S I\, dS \cos\theta = \int_S I_n\, dS \end{aligned} \tag{4.4}$$

where $I_n = I\cos\theta$ is the component of sound intensity *normal* to the surface at the location of $d\mathbf{S}$; dS is the magnitude of the elemental surface area vector;

$\hat{\mathbf{r}}$ is the unit vector in the direction of sound propagation; $\hat{\mathbf{n}}$ is the unit vector normal to the surface; and θ is the angle between $\hat{\mathbf{r}}$ and $\hat{\mathbf{n}}$. It should be noted that the maximum value of the intensity is equal to its magnitude, $I_{\max} = I$, and is attained in the direction $\hat{\mathbf{r}}$; in general, components of the intensity vector, such as I_n (or components in the Cartesian directions $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, or $\hat{\mathbf{z}}$) are less than $I_{\max}$.

The integral may be carried out over a spherical or hemispherical surface that surrounds the source. Other regular surfaces, such as a parallelepiped or a cylinder, are also used in practice, and, in principle, any closed surface can be used. If the source is nondirectional and the integration is carried out over a spherical surface having a radius r and centered on the source, sound intensity and sound power are related by

$$I\,(\text{at } r) = I_n\ (\text{at } r) = \frac{W}{S} = \frac{W}{4\pi r^2} \quad \text{W/m}^2 \tag{4.5}$$

where I = magnitude of intensity on the surface (at radius r)
I_n = normal component of intensity on the surface (at radius r)
W = sound power, W
S = area of spherical surface, $= 4\pi r^2$, m^2
r = radius of sphere, m

In general, a source is directional, and the sound intensity is not the same at all points on the surface. Consequently, an approximation must be made to evaluate the integral of Eq. (4.4). It is customary to divide the measurement surface into a number of subsegments each having an area S_i and to approximate the normal component of the sound intensity on each surface subsegment. The sound power of the source may then be calculated by a summation over all of the surface subsegments:

$$W = \sum_i I_{n_i} S_i \quad \text{W} \tag{4.6}$$

where I_{n_i} = normal component of sound intensity averaged over ith segment of area, W/m ^{2}
S_i = ith segment of area, m^2
i = number of segments

Equation (4.6) may be expressed logarithmically as

$$L_W = 10 \log \sum_i S_i \times 10^{L_{I_i}/10} \tag{4.7}$$

where L_W = sound power level, dB re 10^{-12} W
S_i = area of the ith segment, m^2
L_{I_i} = normal sound intensity level averaged over the ith area segment, dB re 10^{-12} W/m^2 (where the subscript n has been omitted for simplicity)

When each of the subareas S_i on the measurement surface has the same area, S_ε, Eq. (4.7) reduces to

$$W = \sum_{i=1}^{N} I_{n_i} S_i = S_\varepsilon \sum_{i=1}^{N} I_{n_i} = \left(\frac{1}{N}\sum_{i=1}^{N} I_{n_i}\right) \times (N \times S_\varepsilon) = \overline{I}_n \times S \quad \text{W} \tag{4.8}$$

where $\overline{I}_n = (1/N)\sum_{i=1}^{N} I_{n_i}$, average normal sound intensity over the measurement surface, W/m^2
S = total area of the measurement surface, m^2

Equation (4.8) may be expressed logarithmically as

$$L_W = 10 \log \frac{\overline{I}_n}{I_0} + 10 \log \frac{S}{S_0} \tag{4.9}$$

$$L_W = L_I + 10 \log \frac{S}{S_0} \tag{4.10}$$

where L_W = sound power level, dB re 10^{-12} W
L_I = normal sound intensity level, dB re 10^{-12} W/m^2
S = area of measurement surface, m^2
S_0 = 1 m^2
I_0 = reference sound intensity, internationally agreed upon as 10^{-12} W/m^2

Equation (4.10) is usually used to determine the sound power level of a source from the sound intensity level except when the source is highly directional. For directional sources, the subareas of the measurement surface may be selected to be unequal and Eq. (4.7) should be used.

Free-Field Approximation for Sound Intensity

From Eq. (2.24) or (2.30), for the far field of a source radiating into free space, the magnitude of the intensity at a point a distance r from the source is

$$I\,(\text{at } r) = \frac{p_{\text{rms}}^2(\text{at } r)}{\rho c} \quad \text{W/m}^2 \tag{4.11}$$

where ρc = characteristic resistance of air (see Section 2.5), N · s/m^3, equal to about 406 mks rayls at normal room conditions
p_{rms} = rms sound pressure at r, N/m^2

Strictly speaking, this relationship is only correct in the far field of a source radiating into free space. Good approximations to free-space, or "free-field," conditions can be achieved in properly designed anechoic or hemi-anechoic rooms, or outdoors. Hence, Eq. (4.11) is approximately correct in the far field of a source over a reflecting plane provided that the space above the reflecting plane remains essentially a free field at distance r (see Section 4.3). Even if the free field is not perfect and a small fraction of the sound is reflected from the walls and ceiling of the room, an "environmental correction" may be introduced to allow valid measurements to be taken in the room. Environmental corrections are introduced in Section 4.9. The relations below are widely used in standards that determine the sound power of a source from a measurement of sound pressure level.

If a closed measurement surface is placed around a source so that all points on the surface are in the far field and the intensity vector is assumed to be essentially normal to the surface so that $I = I_n$ at all points on the surface, then Eqs. (4.7) and (4.11) can be combined to yield

$$W = \frac{1}{\rho c}\sum_i p_i^2 S_i \tag{4.12}$$

where p_i = average rms sound pressure over area segment S_i, N/m^2

We may express Eq. (4.12) logarithmically as

$$L_W = 10 \log \sum_i S_i \times 10^{L_{pi}/10} - 10 \log D \tag{4.13}$$

where
L_W = sound power level, dB re 10^{-12} W
L_{pi} = sound pressure level over the ith area segment, dB re 2×10^{-5} N/m²
S_i = area of ith segment, m²
$10^{L_{pi}/10} = p_i^2/p_{\text{ref}}^2$
$p_{\text{ref}} = 2 \times 10^{-5}$ N/m²
$D = \rho c W_0/p_{\text{ref}}^2 = \rho c/400$

and values for 10 log D may be found from Fig. 1.7; at normal temperatures and pressures, the 10 log D term is negligible.

Note that in Eq. (4.13), if the A-weighted sound power level in bels were being computed, the constant 10 in front of the logarithm would disappear, and the result (with $D = 1$) would be

$$L_{WA} = \log \sum_i S_i \times 10^{L_{pAi}/10} \tag{4.14}$$

When each subsegment S_i has an equal area and 10 log $D = 0$, in analogy with Eqs. (4.8)–(4.10), Eq. (4.13) can be expressed as

$$L_W = \langle L_p \rangle_S + 10 \log \left(\frac{S}{S_0}\right) \tag{4.15}$$

where
L_W = sound power level, dB re 10^{-12} W
$\langle L_p \rangle_S$ = sound pressure level averaged on a mean-square basis over the measurement surface (surface sound pressure level, dB re 2×10^{-5} N/m²)
S = area of the measurement surface, m²
S_0 = 1 m²

Equation (4.15) is usually used to determine the sound power level of a source from the sound pressure level except when the source is highly directional. For directional sources, the subareas of the measurement surface may be selected to be unequal; Eq. (4.13) should be used (usually with 10 log $D = 0$).

Hence, the sound power level of a source can be computed from sound pressure level measurements made in a free field. Equations (4.13) and (4.15) are widely used in standardized methods for determination of sound power levels in a free field or in a free field over a reflecting plane.

Sound Power Determination in a Diffuse Field

The sound power level of a source can also be computed from sound-pressure-level measurements made in an enclosure with a diffuse sound field because in such a field the sound energy density is constant; it is directly related to the mean-square sound pressure and, therefore, to the sound power radiated by the source. The sound pressure level in the reverberant room builds up until the total sound power absorbed by the walls of the room is equal to the sound power generated by the source. The sound power is determined by measuring the mean-square sound pressure in the reverberant field. This value is either compared with the mean-square pressure of a source of known sound power output *(comparison method)* or calculated directly from the mean-square pressure produced by the source and a knowledge of the sound-absorptive properties of the reverberant room *(direct method)*. Depending on the method used, either Eq. (4.16) or Eq. (4.18) is used to determine the sound power level of the source in a diffuse field.

Diffuse sound fields can be obtained in laboratory reverberation rooms. Sufficiently close engineering approximations to diffuse-field conditions can be obtained in rooms that are fairly reverberant and irregularly shaped. When these environments are not available or when it is not possible to move the noise source under test, other techniques valid for in situ determination of sound power level may be used and are described later in this chapter.

All procedures described in this chapter apply to the determination of sound power levels in octave or one-third-octave bands. The techniques are independent of bandwidth. The A-weighted sound power level is obtained by summing (on a mean-square basis) the octave-band or one-third-octave-band data after applying the appropriate A-weighting corrections. A-weighting values are listed in Table 1.4.

Nonsteady and impulsive noises are difficult to measure under reverberant-field conditions. Measurements on such noise sources should be made either under free-field conditions or using one of the techniques described in Chapter 18.

4.5 MEASUREMENT ENVIRONMENTS

Three different types of laboratory environments in which noise sources are measured are found in modern laboratories: anechoic rooms (free field), hemi-anechoic rooms (free field over a reflecting plane), and reverberation rooms (diffuse field). In an anechoic room, all of the boundaries are highly absorbent, and the free-field region extends very nearly to the boundaries of the room. Because the "floor" itself is absorptive, anechoic rooms usually require a suspended wire grid or other mechanism to support the sound source, test personnel, and measurement instruments. A hemi-anechoic room has a hard, reflective floor, but all other boundaries are highly absorbent. Both anechoic and hemi-anechoic environments are used to determine the sound power level of a source, but the hemi-anechoic room is clearly more practical for testing large, heavy sources. The sound power level is derived from Eq. (4.7) if the sound intensity on a surface surrounding the source is measured directly or from Eq. (4.13) if the sound pressure level is measured on a surface surrounding the source and located in the far field.

In a reverberation room, where all boundaries are acoustically hard and reflective, the reverberant field extends throughout the volume of the room except for a small region in the vicinity of the source. The sound power level of a source may be determined from an estimate of the average sound pressure level in the diffuse-field region of the room coupled with a knowledge of the absorptive properties of the boundaries.

The sound pressure field in an ordinary room such as an office or laboratory space that has not been designed for acoustical measurements is neither a free field nor a diffuse field. Here the relationship between the sound intensity and the mean-square pressure is more complicated. Instead of measuring the mean-square pressure, it is usually more advantageous to use a sound intensity analyzer that measures the sound intensity directly (see Section 4.10). By sampling the sound intensity at defined locations in the vicinity of the source, the sound power level of the source can be determined. Equation (4.10) is used to determine the sound power levels from the sound intensity levels. If the subareas of the measurement surface are unequal, Eq. (4.7) may be used.

4.6 INTERNATIONAL STANDARDS FOR DETERMINATION OF SOUND POWER USING SOUND PRESSURE

ISO Standards

The International Organization for Standardization (ISO) has published a series of international standards, the ISO 3740 series,[3–13] which describes several methods for determining the sound power levels of noise sources. Table 4.1 summarizes the applicability of each of the basic standards of the ISO 3740 series. The most important factor in selecting an appropriate noise measurement method is the ultimate use of the sound-power-level data that are to be obtained.

TABLE 4.1 Description of the ISO 3740 Series of Standards for Determination of Sound Power

ISO Standard	Test Environment	Criteria for Suitability of Test Environment	Volume of Source	Character of Noise	Limitation on Background Noise	Sound Power Levels Obtainable	Optional Information Available
ISO 3741 Precision (Grade 1)	Reverberation room meeting specified requirements	Room volume and reverberation time to be qualified	Preferably less than 2% of room volume	Steady, broadband, narrow-band, or discrete frequency	$\Delta L \geq 10$ dB, $K_1 \leq 0.5$ dB	A weighted and in one-third-octave or octave bands	Other frequency-weighted sound power levels
ISO 3743-1 Engineering (Grade 2)	Hard-walled room	Volume ≥ 40 m^3, $\alpha \leq 0.20$	Preferably less than 1% of room volume	Any, but no isolated bursts	$\Delta L \geq 6$ dB, $K_1 \leq 1.3$ dB	A weighted and in octave bands	Other frequency-weighted sound power levels
ISO 3743-2 Engineering (Grade 2)	Special reverberation room	70 m$^3 \leq V \leq$ 300 m^3, 0.5 s $\leq T_{nom} \leq$ 1.0 s	Preferably less than 1% of room volume	Any, but no isolated bursts	$\Delta L \geq 4$ dB, $K_1 \leq 2.0$ dB	A weighted and in octave bands	Other frequency-weighted sound power levels
ISO 3744 Engineering (Grade 2)	Essentially free field over a reflecting plane	$K_2 \leq 2$ dB	No restrictions; limited only by available test environment	Any	$\Delta L \geq 6$ dB, $K_1 \leq 1.3$ dB	A weighted and in one-third-octave or octave bands	Source directivity; SPL as a function of time; single-event SPL; other frequency-weighted sound power levels

(continued overleaf)

TABLE 4.1 (*continued*)

ISO Standard	Test Environment	Criteria for Suitability of Test Environment	Volume of Source	Character of Noise	Limitation on Background Noise	Sound Power Levels Obtainable	Optional Information Available
ISO 3745 Precision (Grade 1)	Anechoic or hemi-anechoic room	Specified requirements; measurement surface must lie wholly inside qualified region	Characteristic dimension not greater than 1/2 measurement surface radius	Any	$\Delta L \geq 10$ dB, $K_1 \leq 0.5$ dB	A weighted and in one-third-octave or octave bands	Same as above plus sound energy level
ISO 3746 Survey (Grade 3)	No special test environment	$K_2 \leq 7$ dB	No restrictions; limited only by available test environment	Any	$\Delta L \geq 3$ dB, $K_1 \leq 3$ dB	A weighted	Sound pressure levels as a function of time
ISO 3747 Engineering or Survey (Grade 2 or 3)	Essentially reverberant field in situ, subject to stated qualification requirements	Specified requirements	No restrictions; limited only by available test environment	Steady, broadband, narrow-band, or discrete frequency	$\Delta L \geq 6$ dB, $K_1 \leq 1.3$ dB	A weighted from octave bands	Sound pressure levels as a function of time

Notes: ΔL is the difference between the sound pressure levels of the source-plus-background noise and the background noise alone; K_1 is the correction for background noise, defined in the associated standard; V is the test room volume; α is the sound absorption coefficient; T_{nom} is the nominal reverberation time for the test room, defined in the associated standard; K_2 is the environmental correction, defined in the associated standard; SPL is an abbreviation for "sound pressure level."

The principal uses of sound-power-level data include the development of quieter machines and equipment, compliance testing of products in production, acoustical comparisons of several products that may be of the same or different type and size, and preparing acoustical noise declarations for the general public.

In making a decision on the appropriate measurement method to be used, several factors should be considered: (a) the size of the noise source, (b) the movability of the noise source, (c) the test environments available for the measurements, (d) the character of the noise emitted by the noise source, and (e) the grade (classification) of accuracy required for the measurements. The methods described in this chapter are consistent with those of the ISO 3740 series. A set of standards with the same objectives is available from the ANSI or the Acoustical Society of America (ASA).

4.7 DETERMINATION OF SOUND POWER IN A DIFFUSE FIELD

Characteristics of Reverberation Rooms

Measurements of the sound power level of a device or machine may be performed in a laboratory reverberation room (see Section 7.8). The determination of the sound power level of a noise source in such a room is based on the premise that the measurements are performed entirely in the diffuse (reverberant) sound field (see Fig. 4.4). In the reverberant field, the average sound pressure level is essentially uniform, although there are fluctuations from point to point, and it is related to the sound power radiated by the source [see (Eq. 4.18)]. Information in regard to the directivity of the source cannot be obtained in a diffuse sound field.

The minimum volume of the room depends on how low in frequency valid measurements are to be taken. For example, if measurements in the 100-Hz one-third-octave band are desired, the minimum volume is recommended to be 200 m^3 in ISO 3741. On the other hand, if measurements are only needed down to the 200-Hz band, 70 m^3 will be adequate. Maximum room volume is constrained by the adverse effects of air absorption and the ability to make valid high-frequency measurements; a volume less than 300 m^3 is generally recommended. The equipment being tested should have a volume no greater than 2% of the room volume. The absorption coefficient of the surface that is closest to the equipment being evaluated (usually the floor) should not exceed 0.06, and the remaining surfaces of the room should be highly reflective, such that the reverberation time (in seconds) is greater than the ratio of volume V (m^3) to surface area S (m^2): $T_{60} > V/S$. In addition to these requirements on room volume and absorption, ISO 3741 includes requirements for background noise levels; temperature, humidity, and atmospheric pressure; instrumentation and calibration; installation and operation of the source under test; minimum distance between microphone and source; and performance requirements for the reference sound source, if used.

If the room is to be used to measure equipment that has discrete-frequency components in its noise emissions, it is often necessary to use additional microphone positions and additional source positions, and ISO 3741 includes detailed procedures to determine whether or not such positions are required. These procedures must be followed for each source tested, or, alternatively, the reverberation room itself can be "qualified" for the measurement of discrete-frequency components (see below). The need for additional source positions may be reduced by adding low-frequency sound absorption to the room or through the use of rotating diffusers.

Room Qualification

The ISO 3741 standard contains two detailed procedures for the qualification of reverberation rooms for the determination of sound power levels, one for qualifying the room for the measurement of broadband sound (Annex E) and one for qualifying the room for the measurement of discrete-frequency components (Annex A). For sources of broadband sound, the room is qualified by using a reference sound source placed at different positions in the room and determining the standard deviation of the measured space-averaged sound pressure levels in the room for each position. A minimum of six positions of the source are required, each with specified constraints on the distance between them, the distance from walls, and the distance from the microphone. The room is qualified according to ISO 3741 for the measurement of broadband sound if the standard deviation does not exceed the values given in Table 4.2.

The qualification of reverberation rooms for the measurement of noise that contains discrete-frequency components in the spectrum is complicated and time consuming. However, this only has to be performed once, and the benefit can be great. If the chamber is qualified for the measurement of discrete tones, there is no longer a need to perform initial tests to determine the number of microphone and source positions for each source under investigation.

Essentially, a "calibrated" loudspeaker is placed in the reverberation room and is driven by a series of discrete-frequency tones in each one-third-octave band. For example, there are 22 frequencies spaced 1 H apart in the 100-Hz one-third-octave band and 23 frequencies spaced 5 H apart in the 500-Hz octave band. The average sound pressure level in the room is determined at each frequency and corrected for the loudspeaker response (previously determined in a hemi-anechoic room). The room is qualified according to ISO 3741 if the standard deviation of the level in each one-third-octave band does not exceed the values given in Table 4.3.

TABLE 4.2 Qualification Requirements for Reverberation Room Used for Measurement of Broadband Noise Sources

Octave-Band Center Frequencies, Hz	One-Third-Octave-Band Center Frequencies, Hz	Maximum Allowable Standard Deviation, dB
125	100–160	1.5
250, 500	200–630	1.0
1000, 2000	800–2500	0.5
4000, 8000	3150–10,000	1.0

Source: ISO 3741: 1999.
Note: Annex A of ISO 3741 contains detailed procedures for the discrete-frequency qualification.

TABLE 4.3 Qualification Requirements for Reverberation Room Used for Measurement of Narrowband Noise Sources

Octave Band Center Frequency, Hz	One-Third-Octave-Band Center Frequency, Hz	Maximum Allowable Standard Deviation, dB
125	100–160	3.0
250	200–315	2.0
500	400–630	1.5
1000, 2000	800–2500	1.0

Experimental Setup

An array of fixed microphone positions or a single microphone that traverses a path (often circular) in the reverberant room may be used to determine the average sound pressure level in the reverberant field. The number of fixed microphone positions, N_M, required depends on the results of an initial series of sound-pressure-level measurements using six positions. If the standard deviation of these initial measurements, s_M, is less than or equal to 1.5, then the original six microphone positions will suffice (i.e., the noise is essentially broadband). If $s_M > 1.5$, it is assumed that the source emits discrete tones and a larger number of microphone positions is usually required to obtain an adequate sampling of the sound field. In this case, N_M could range anywhere from 6 to 30 depending on the frequency and the magnitude of s_M. When a traversing microphone is used, the path length l must be at least $(\lambda/2)N_M$, where λ is the wavelength of sound at the lowest midband frequency of interest. The microphone path or array should be positioned in the room so that no microphone position is within a minimum distance $d_{\min}$ of the equipment being evaluated. The distance $d_{\min}$ is determined differently in the comparison method and the direct method for determination of sound power. These requirements are discussed below.

If the noise source under test is typically associated with a hard floor, wall, edge, or corner, it should be placed in a corresponding position in the reverberation room. Otherwise, it should be placed no closer than 1.5 m from any wall of the room. The source should not be placed near the geometric center of the room since in that location many of the resonant modes of the room would not be excited. For rectangular reverberation rooms, the source should be placed asymmetrically relative to the boundaries. ISO 3741 gives further information for special source locations and installation conditions.

Near the boundaries of the room and close to other reflecting surfaces such as stationary or rotating diffusers, the sound field will depart from the ideal state of diffusion. ISO 3741 prescribes the following conditions on the microphone positions used during the measurements:

When using fixed microphone positions:

1. No position shall be closer than 1.0 m from any surface of or within the room.
2. No position shall be closer than d_{min} from the source (defined below).
3. The distance between microphone positions shall be at least $\lambda/2$, where λ is the wavelength of sound at the lowest midband frequency of interest.

When using one or more continuous microphone traverses:

1. No point on the traverse shall be closer than 1.0 m from any surface of the room.
2. No point on the traverse shall be closer than 0.5 m from any surface of a rotating diffuser.
3. No position shall be closer than d_{min} from the source (defined below).
4. The microphone traverse should not lie in any plane within 10° of a room surface.
5. The length of the traverse shall be at least $l \geq 3\lambda$, where λ is the wavelength of sound at the lowest midband frequency of interest.
6. If multiple traverses are used, the minimum distance between their paths shall be at least $\lambda/2$.

Comparison Method

The procedure for determining the sound power level of a noise source by the comparison method[6] requires the use of a reference sound source (see Fig. 4.5 and ref. 13) of known sound power output. Using microphone positions that meet the above requirements, the procedure is essentially as follows:

1. With the equipment being evaluated at a suitable location in the room, determine, in each frequency band, the average sound pressure level (on a mean-square basis) in the reverberant field using the microphone array or traverse described above.
2. Replace the source under test with the reference sound source and repeat the measurement to obtain the average level for the reference sound source.

The sound power level of the source under test, L_W, for a given frequency band is calculated as

$$L_W = L_{Wr} + (\langle L_p \rangle - \langle L_p \rangle_r) \tag{4.16}$$

where L_W = one-third-octave-band sound power level for source being evaluated, dB re 10^{-12} W

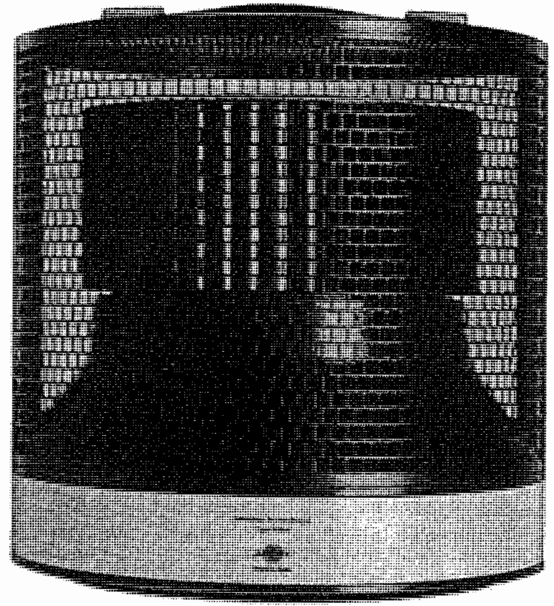

FIGURE 4.5 Reference sound source, Brüel and Kjær Type 4204. (Courtesy of Brüel and Kjær, Inc.)

$\langle L_p \rangle$ = space-averaged one-third-octave-band sound pressure level of source being evaluated, dB re 2×10^{-5} N/m^2

L_{Wr} = calibrated one-third-octave-band sound power level of reference source, dB re 10^{-12} W

$\langle L_p \rangle_r$ = space-averaged one-third-octave-band sound pressure level of reference sound source, dB re 2×10^{-5} N/m^2

To make certain that the reverberant sound field predominates in the determination of the average sound pressure level, the minimum distance d_{min} between the microphone(s) and the equipment being evaluated should be at least

$$d_{min} = 0.4 \times 10^{(L_{Wr} - L_{pr})/20} \tag{4.17}$$

where L_{Wr} and L_{pr} are as defined for Eq. (4.16). [Note that although Eq. (4.17) states the actual requirement, ISO 3741 also recommends that the constant be 0.8 instead of 0.4 to ensure that the microphone is in the reverberant field.]

Direct Method

The direct method does not use a reference sound source. Instead, this method requires that the sound-absorptive properties of the room be determined by measuring the reverberation time in the room for each frequency band. Measurement of T_{60} is described in ISO 3741.

With this method, the space-averaged sound pressure level for each frequency band of the source being evaluated is determined as described above for the comparison method. The sound power level of the source is found from[4]

$$L_W = \overline{L_p} + \left\{10\log\frac{A}{A_0} + 4.34\frac{A}{S} + 10\log\left(1 + \frac{S\times c}{8\times V\times f}\right)\right.$$
$$\left. -25\log\left[\frac{427}{400}\sqrt{\frac{273}{273+\theta}}\times\frac{B}{B_0}\right] - 6\right\} \quad \text{dB re } 10^{-12}\text{ W} \qquad (4.18)$$

where L_W = band sound power level of sound source under test
$\overline{L_p}$ = band space-averaged sound pressure level of sound source under test, dB re 2×10^{-5} N/m^2
A = equivalent absorption area of the room, $= (55.26/c)(V/T_{\text{rev}}), m^2$
V = room volume, m^3
T_{rev} = reverberation time for particular band
A_0 = reference absorption area, 1 m^2
S = total surface area of room, m^2
V = room volume, m^3
f = midband frequency of measurement, Hz
c = speed of sound at temperature θ, $= 20.05\sqrt{273+\theta}$, m/s
θ = temperature, °C
B = atmospheric pressure, Pa
$B_0 = 1.013\times 10^5$ Pa
$V_0 = 1$ m^3
$T_0 = 1$ s

To make certain that the reverberant sound field predominates in the determination of the average sound pressure level, the minimum distance $d_{\min}$ between the microphone(s) and the equipment being evaluated should be at least[4]

$$d_{\min} = 0.08\sqrt{\frac{V/V_0}{T/T_0}} \quad \text{m} \qquad (4.19)$$

where V and T_{rev} are as defined above. [Note that although Eq. (4.19) states the actual requirement, ISO 3741 also recommends that the constant be 0.16 instead of 0.08 to ensure that the microphone is in the reverberant field.]

Example 4.2. Assume a room at temperature 21.4°C with a volume of 200 m^3, a surface area $S = 210$ m^2, and a reverberation time at 100 Hz of 3 s. The space-averaged sound pressure level $\langle L_p\rangle$ in the diffuse field with a given machine operating is 100 dB. Find the sound power level for this machine. Assume a discrete-frequency spectrum and an atmospheric pressure of 1000 mbars.

Solution Use Eq. (4.18) to determine the sound power. The wavelength corresponding to 100 Hz is 3.44 m:

$$c = 20.05\sqrt{273+21.4} = 344 \text{ m/s}$$
$$A = \frac{55.26}{344}\left(\frac{200}{3}\right) = 10.7 \text{ m}^2$$

The sound power level is

$$L_W = 100 + \left\{10\log\frac{10.7}{1} + 4.34\frac{10.7}{210} + 10\log\left(1 + \frac{210\times 344}{8\times 200\times 100}\right)\right.$$
$$\left. -25\log\left[\frac{427}{400}\sqrt{\frac{273}{273+21.4}}\right] - 6\right\}$$
$$= 100 + (10.3 + 0.22 + 1.62 - 0.3 - 6)$$
$$= 106.4 \text{ dB re } 10^{-12}\text{ W(100 Hz mean frequency)}$$

4.8 DETERMINATION OF SOUND POWER IN A FREE FIELD USING SOUND PRESSURE MEASUREMENTS

Determination of the sound power level produced by a device or a machine may be performed in a laboratory anechoic or hemi-anechoic room. Alternatively, a hemi-anechoic environment may be provided at an open-air site above a paved area, distant from reflecting surfaces such as buildings, and with a low background noise level. This environment approximates a large room with sound-absorptive treatment on ceilings and walls with the equipment under test mounted on the hard, reflecting floor. Detailed information on anechoic and hemi-anechoic rooms is presented in Section 7.9.

The determination of the sound power level radiated in an anechoic or hemi-anechoic environment is based on the premise that the reverberant field is negligible at the positions of measurement for the frequency range of interest. Thus, the total radiated sound power may be obtained by a spatial integration, over a hypothetical surface that surrounds the source, of the component of sound intensity normal to the surface of the source [see Eq. (4.3)]. When all points of the measurement surface are in the far field of the source, the magnitude of the intensity can be assumed to be equal to $p^2/\rho c$ [see Eq. (4.11)]. With the additional assumption that the magnitude of the intensity is equal to the normal component of sound intensity (i.e., the direction of sound propagation is essentially normal to the surface at the measurement points), the relationships given in Eqs. (4.12) and

(4.13) can be used to determine the sound power level of a source from simple measurements of sound pressure level. This is the basis for two key international standards for the determination of sound power levels of noise sources, ISO 3744[8] and ISO 3745,[9] discussed below. Essentially, a measurement surface is chosen and microphone positions are defined over this surface. Sound-pressure-level measurements are taken at each microphone position for each frequency band, and from these, the sound power levels are computed.

Selection of a Measurement Surface

The international standards discussed below allow a variety of measurement surfaces to be used; some are discussed here. In selecting the shape of the measurement surface to be used for a particular source, an attempt should be made to choose one where the direction of sound propagation is approximately normal to the surface at the various measurement points. For example, for small sources that approximate a point source, the selection of a spherical or hemispherical surface may be the most appropriate—the direction of sound propagation will be essentially normal to this surface. For machines in a hemi-anechoic environment that are large and in the shape of a box, the parallelepiped measurement surface may be preferable. For "tall" machines in a hemi-anechoic environment having a height much greater than the length and depth, a cylindrical measurement surface[14,15] may be the most appropriate.

Measurement in Hemi-Anechoic Space

The sound power determination in a hemi-anechoic space may be performed according to ISO 3744[8] for engineering-grade accuracy or according to ISO 3745[9] for precision-grade accuracy. ISO 3744 is strictly for hemi-anechoic environments, while ISO 3745 includes requirements for both hemi-anechoic and fully anechoic environments. These standards specify requirements for the measurement surfaces and locations of microphones, procedures for measuring the sound pressure levels and applying certain corrections, and the method for computing the sound power levels from the surface-average sound pressure levels. In addition, they provide detailed information and requirements on criteria for the adequacy of the test environment and background noise, calibration of instrumentation, installation and operation of the source, and information to be reported. Several annexes in each standard include information on measurement uncertainty and the qualification of the test rooms.

In terms of allowable measurement surfaces, ISO 3744 currently specifies the hemisphere and the parallelepiped,* while ISO 3745 explicitly defines only the hemisphere and the sphere. However, ISO 3745 includes a clause for "other microphone arrangements" and cites as an example papers describing the cylindrical measurement surface.[14,15] If a hemisphere is used to determine the location

*At the time of this writing, a revision to ISO 3744 was under consideration, which included the cylindrical measurement surface as well.

of the microphone positions, it has its center on the reflecting plane beneath the acoustical center of the sound source. To ensure that the measurements are carried out in the far field, the radius of the hemisphere for ISO 3744 measurements should be equal to at least two "characteristic" source dimensions and generally not less than 1.0 m. For ISO 3745, the requirements are slightly more stringent with the radius being at least twice the *largest* source dimension or three times the distance of the acoustical center of the source from the reflecting plane (whichever is larger) and at least $\lambda/4$ of the lowest frequency of interest. No microphone position can lie outside of the region qualified for measurements (the free-field region), and this requirement generally prevents microphones from being located too close to the walls. Outdoors, atmospheric effects are likely to influence the measurements if the radius of the test hemisphere is much greater than about 15 m, even in favorable weather.

Figure 4.6 gives an array of 20 microphone positions that may be used for measurements according to ISO 3744[8] for sources that emit predominantly broadband sound. The concern when measuring in a hemi-anechoic room is that reflections of sound from the hard floor may cause far-field interference at the microphone positions. This becomes more problematic when the noise emissions contain discrete tones; a small change in the position of the microphone may result in large variations in measured sound pressure level in those bands containing the tones. Therefore, for sources that emit discrete tones, ISO 3744 specifies a different microphone array, one having a greater distribution in the vertical direction. For precision measurements made in a hemi-anechoic environment according to ISO 3745,[9] a microphone array of at least 20 positions, each with a different vertical height, is required. The coordinates of this array are given in Table 4.4. Procedures are specified in both standards for determining whether or not the number of microphones is sufficient and for defining additional positions, if required. Note that the simultaneous deployment of a very large number of microphones may result in a situation where the support structures of these microphones become effective scatterers of the direct sound at high frequencies and can introduce substantial errors. Scanning the sound field with a single microphone can eliminate this error.

A parallelepiped array of microphone positions is frequently used for the determination of sound power levels for box-shaped machines and equipment. Detailed requirements for the selection of microphone positions and the criteria for the sufficiency of the number of microphones are given in ISO 3744.[8] A minimum of nine positions is required, but this number rapidly increases as the size of the source under test increases. The basic nine-position parallelepiped arrangement is illustrated in Fig. 4.7. As can be seen, this array is limited in its sampling in the vertical direction and so should be used with caution if the source is directional or emits discrete tones.

Another convenient measurement surface standardized in at least one industry test code[16] is the cylindrical microphone array illustrated in Fig. 4.8. The use of this array facilitates the measurement of tall-aspect-ratio sound sources such as data-processing equipment installed in racks. Since the array is usually

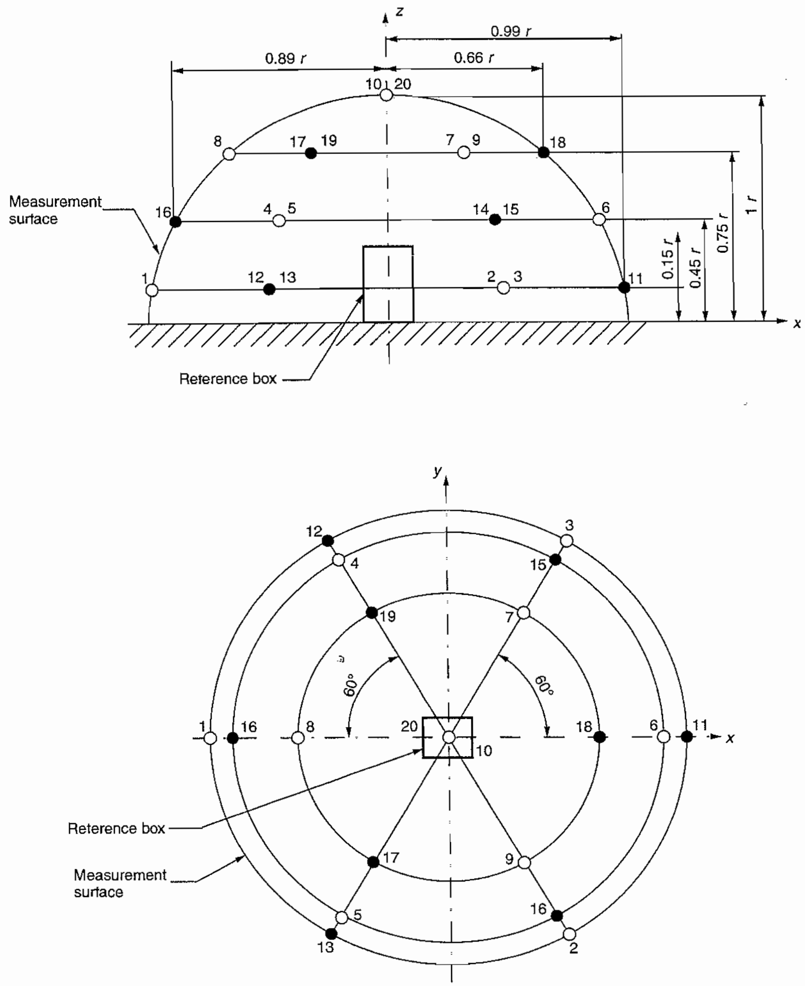

FIGURE 4.6 Microphone positions for a hemispherical measurement surface according to ISO CD 3744 (N1497). (Courtesy of the International Organization for Standardization, Geneva, Switzerland.)

implemented using continuously traversing microphones and a sufficient number of vertical heights, the accuracy is generally improved over that of the parallelepiped.[14,15]

The general procedure for determining the sound power level of the source according to either ISO 3744 or ISO 3745 can be summarized as follows:

1. The test room is set up and checked out and all environmental conditions are recorded.

TABLE 4.4 Twenty Microphone Positions on Surface of Hemisphere As Defined in ISO 3745

Position Number	x/r	y/r	z/r
1	−1.00	0	0.025
2	0.50	−0.86	0.075
3	0.50	0.86	0.125
4	−0.49	0.85	0.175
5	−0.49	−0.84	0.225
6	0.96	0	0.275
7	0.47	0.82	0.325
8	−0.93	0	0.375
9	0.45	−0.78	0.425
10	0.88	0	0.475
11	−0.43	0.74	0.525

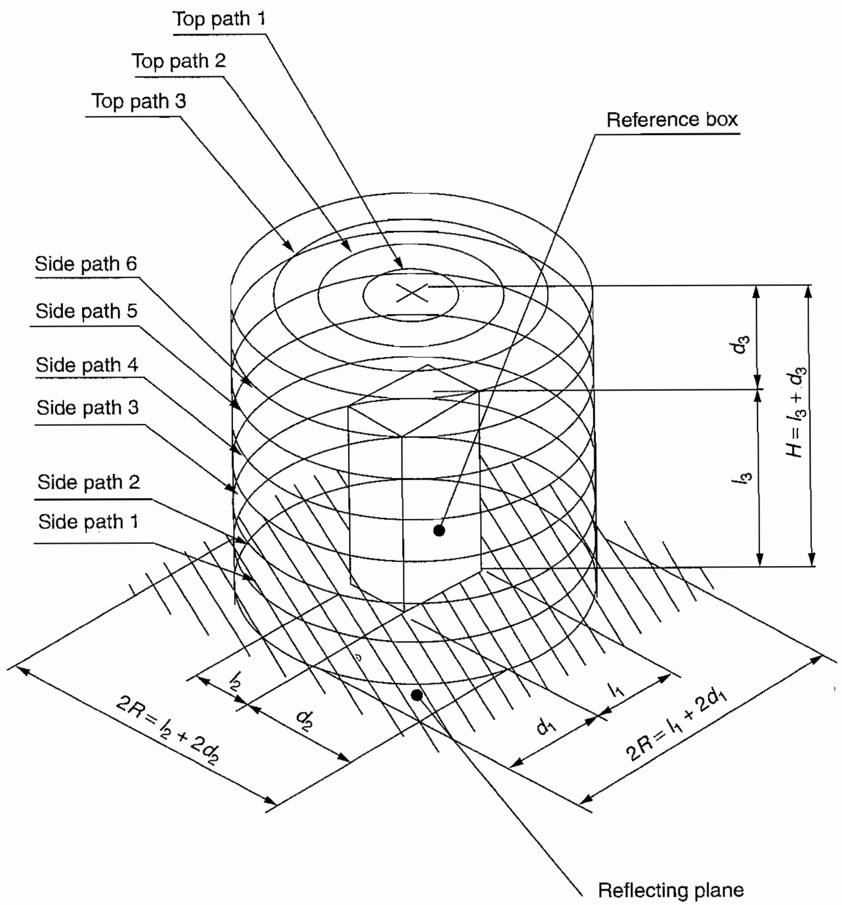

FIGURE 4.8 Microphone positions for a cylindrical measurement surface according to ISO CD 3744 (N1497). (From ISO CD 9997: 1999 Amended, Revision of Annex B (N1479). Courtesy of the International Organization for Standardization, Geneva, Switzerland.)

2. The microphones and instrumentation are calibrated.
3. The sound source is installed.
4. The measurement surface is selected and the microphones are set up in their proper positions.
5. The sound source under test is operated under specified conditions and sound pressure levels are measured at each microphone position for each frequency band of interest.
6. The sound source is turned off and the background noise levels are measured.

7. The sound pressure data are corrected for background noise and for environmental conditions (see below), if necessary.
8. The surface average band sound pressure levels are calculated.
9. The band sound power levels are calculated from the latter, taking into account corrections for meteorological conditions.

Equation (4.15) is used to determine the sound power level of the source when the subareas of the measurement surface associated with each microphone position are all equal. For highly directional sources, the standards require to increase the number of subareas of the measurement surface in the region of high directivity and to measure the sound pressure levels associated with each subarea. The sound power level can then be determined by using Eq. (4.13) for unequal subareas. The correction for background noise, denoted K_1, is specified in terms of the difference between the sound pressure levels measured with and without the source running, ΔL_i, as

$$K_1 = -10 \log(1 - 10^{-0.1\Delta L_i}) \quad \text{dB} \tag{4.20}$$

Measurement in Anechoic Space

In certain instances, the sound power level of a noise source must be determined in a totally free field, without the influence of a reflecting plane beneath the source. The reflecting plane not only causes constructive and destructive interference patterns in the far field—especially pronounced when the noise emissions contain discrete frequency components—but also may affect the radiated sound power of the source itself, especially at low frequencies.[17] Thus for critical measurements of tonal sources, measurements of noise sources that in normal use are not mounted over a hard surface, measurements of directivity, and other specialized measurements, a fully anechoic test environment may be desirable. In this case, the space-averaged mean-square sound pressure level is generally determined over a spherical measurement surface, and measurements are made according to ISO 3745.[9] Most of the procedures and requirements discussed above for hemi-anechoic measurements apply here also, with the exception of the measurement surfaces.

An array of at least 20 microphone positions is specified in ISO 3745, defined over the spherical surface by the Cartesian coordinates given in Table 4.5. If requirements on the sufficiency of the number of microphones given in ISO 3745 are not met, then the number of positions must be doubled, to 40. If the sound source is highly directional, the number of subareas in the regions of high directivity should be increased, as mentioned above. When measurements are made in an anechoic space according to ISO 3745, the sound power level of each frequency band is computed according to either Eq. (4.15) for equal subareas or Eq. (4.13) for unequal subareas. For the precision measurements of ISO 3745, however, two constants are included (instead of the single constant D), one to correct for meteorological conditions and one to "normalize" the measurements to specified "reference" meteorological conditions.

4.9 ENVIRONMENTAL CORRECTIONS AND DETERMINATION OF SOUND POWER LEVEL

In the previous sections, the only corrections applied for the determination of the average sound pressure level on the measurement surface were for the presence of background noise. However, if reflections from the room surfaces affect the measured surface sound pressure levels in any of the frequency bands of interest, a second correction may be required to account for these reflections. This so-called environmental correction, denoted K_2, is computed for both A-weighted values and individual frequency bands and is subtracted directly from the measured sound pressure level (after corrections for background noise are applied). The ISO 3744 standard[8] generally limits the environmental correction to a maximum of 2 dB. The correction may be determined in several ways:

1. By comparing the calibrated sound power level of a reference source, L_{Wr}, with the measured sound power level of the same source in the room, L_W. The environmental correction is then computed as $K_2 = L_W - L_{Wr}$.

TABLE 4.5 Twenty Microphone Positions on Sphere As Defined in ISO 3745

Position Number	x/r	y/r	z/r
1	−1.00	0	0.05
2	0.49	−0.86	0.15
3	0.48	0.84	0.25
4	−0.47	0.81	0.35
5	−0.45	−0.77	0.45
6	0.84	0	0.55
7	0.38	0.66	0.65
8	−0.66	0	0.75
9	0.26	−0.46	0.85
10	0.31	0	0.95
11	1.00	0	−0.05
12	−0.49	0.86	−0.15
13	−0.48	−0.84	−0.25
14	0.47	−0.81	−0.35
15	0.45	0.77	−0.45
16	−0.84	0	−0.55
17	−0.38	−0.66	−0.65
18	0.66	0	−0.75
19	−0.26	0.46	−0.85
20	−0.31	0	−0.95

2. By first determining the "equivalent sound absorption area" of the room, A, and computing the environmental correction as $K_2 = 10\ \log[1 + 4(S/A)]$ decibels, where S is the area of the measurement surface. There are two methods currently specified in ISO 3744 for determining the value of A: a method using the measured reverberation time in the room and the so-called two-surface method. There is also a third method under consideration for standardization, a direct method using a calibrated reference sound source. The latest version of ISO 3744 should be consulted for details of using these methods.
3. By using the "approximate" method for determining A, which is then used only for determining an A-weighted value of the environmental correction, $K_{2A} = 10\ \log[1 + 4(S/A)]$. Here the mean sound absorption coefficient α is estimated from Table 4.6.[10] The equivalent sound absorption area A is then calculated from $A = \alpha S_V$, where S_V is the total area of the boundary surfaces of the test room (walls, floor, ceiling) in square meters.

Reference should also be made to ISO 3746[10], a survey-grade standard for the determination of A-weighted sound power in rooms where the environmental correction may range up to 7 dB. This standard may be useful for taking measurements in situ, that is, when the source cannot be moved into a laboratory environment. The uncertainty of the A-weighted sound power level determined according to ISO 3746 is greater than that obtained when ISO 3744 or ISO 3745 is used. The average A-weighted sound pressure level is determined either on the parallelepiped measurement surface of Fig. 4.9 or the hemispherical measurement surface of Fig. 4.10, each shown with the minimum number of microphones required. Table 4.7 gives the coordinates for the four key microphone positions

TABLE 4.6 Approximate Values of Mean Sound Absorption Coefficient α

Mean Sound Absorption Coefficient α	Description of Room
0.05	Nearly empty room with smooth hard walls made of concrete, brick, plaster, or tile
0.1	Partly empty room; room with smooth walls
0.15	Room with furniture; rectangular machinery room; rectangular industrial room
0.2	Irregularly shaped room with furniture; irregularly shaped machinery room or industrial room
0.25	Room with upholstered furniture; machinery or industrial room with a small amount of sound-absorbing material on ceiling or walls (e.g., partially absorptive ceiling)
0.35	Room with sound-absorbing materials on both ceiling and walls
0.5	Room with large amounts of sound-absorbing materials on ceiling and walls

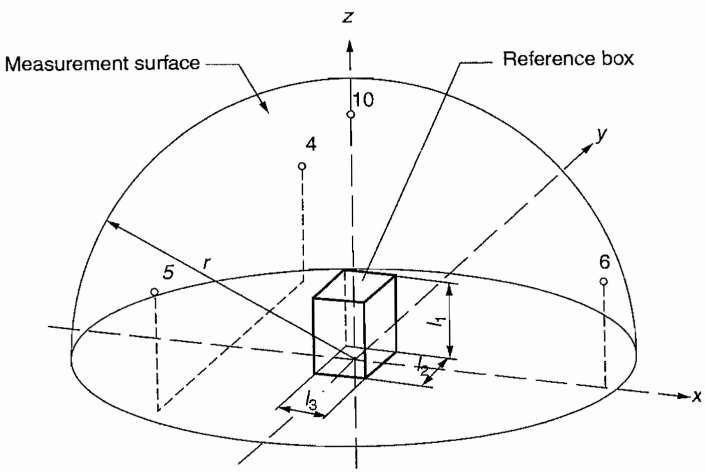

FIGURE 4.10 Microphone positions for a hemispherical measurement surface according to ISO 3746. (Courtesy of the International Organization for Standardization, Geneva, Switzerland.)

TABLE 4.7 Microphone Positions on Hemisphere for Survey Measurements According to ISO 3746

Microphone Position	Microphone Positions (All Heights, $z = 0.6R$)		
	x/r	y/r	z/r
4	−0.45	0.77	0.45
5	−0.45	−0.77	0.45
6	0.89	0	0.45
10	0	0	1.0
14	0.45	−0.77	0.45
15	0.45	0.77	0.45
16	−0.89	0	0.45
20	0	0	1.0

Note: The key microphone positions are 4, 5, 6, and 10. Additional microphone positions are 14, 15, 16, and 20.

shown in Fig. 4.10 for the hemisphere, along with the four additional positions that might be required under certain circumstances.

The measured sound pressure levels are first corrected for background noise according to Eq. (4.20), but for ISO 3746 only the A-weighted value, K_{1A}, is needed. The environmental correction, K_{2A}, is determined using methods similar to those mentioned above for ISO 3744, including the approximate method. The value of K_{2A} should not exceed 7 dB (or, the ratio *S/A* should be less than or equal to 1). The A-weighted sound power level is finally calculated according to Eq. (4.15).

4.10 DETERMINATION OF SOUND POWER USING SOUND INTENSITY

The fundamental procedures for the determination of sound power from sound intensity are formulated in Section 4.4. The sound intensity is measured over a selected surface enclosing the source. In principle, the integral over any surface totally enclosing the source of the scalar product (dot product) of the sound intensity vector and the associated elemental area vector provides a measure of the sound power radiated directly into the air by all sources located within the enclosing surface.

The precision of sound power determination based on sound intensity when the value of the intensity is calculated from measurements of sound pressure in a free field strongly depends on a number of factors. These include source type, measurement area related to source size, and presence of standing waves. The relationship between sound intensity and sound pressure in Eq. (4.11) is valid only in the far field of the free waves radiated by a source. Experience with the measurements on real sources has revealed that errors as large as 10 dB can occur if the selection of the measurement surface is unsuitable or if standing waves affect the measured sound pressure.

In recent years, methods and techniques for direct measurement of sound intensity have been developed. This direct measurement has made it possible to determine the sound power of a variety of source configurations and to make measurements in environments which are not suitable for use in sound power determinations based on measurement of sound pressure. These include sound power determination from measurements in the near field of large sources on test stands, elimination of the adverse effects of standing waves when measuring in enclosures, partial sound power determination of parts of the source with the entire source operating, and the analysis of the source behavior by finding the areas of sound radiation and absorption.

Other acoustical quantities are, by definition, based on sound power. These quantities include sound transmission coefficient, sound absorption coefficient, and radiation efficiency. Either the direct or indirect method described here can be used to determine the sound power for these purposes.

Sound intensity is defined as the sound power that propagates perpendicularly through a unit area. The sound power radiated by a source can be calculated using Eq. (4.5). Sound intensity can be calculated from the product of the sound pressure and particle velocity at a given field point. Because both of these quantities are functions of time, the sound intensity calculated from this time-dependent product is called instantaneous intensity. However, in noise control, it is more practical to work with time-averaged quantities so that acoustic intensity for periodic sound of frequency f and period $T = 1/f$ is defined at point r by

$$\mathbf{I}(r) = \frac{1}{T}\int_0^T p(r,t)\,\mathbf{u}(r,t)\,dt \qquad (4.21)$$

where $\mathbf{u}$ is the particle velocity and p is the sound pressure. The sound intensity $\mathbf{I}$ is a vector describing the time-averaged flow of power per unit area in watts per square meter normal to the intensity direction. This is typically applicable to the tonal components of the noise spectrum. The random components of the noise spectra usually consist of stationary noise and the length of the averaging time T is, in principle, related to the required measurement precision. In most situations, the sound power is determined in octave bands or one-third-octave bands, and the averaging time depends on the filter response—as specified in the instrumentation standards.

To determine the sound intensity, both the pressure and the particle velocity have to be measured. While good pressure microphones are available, precision measurement microphones for the particle velocity are not available. Recently, prototypes of velocity microphones that can measure all three components of the velocity vector by means of a hot-wire technique have been developed.[18] However, the standards for sound power measurements are based on a two-microphone (pressure microphones) technique for the velocity determination. This is based on Euler's equation, which links the particle velocity with the sound pressure

gradient. This equation has the form

$$\mathbf{u} = -\int_0^t \frac{1}{\rho}\nabla p\,dt \qquad (4.22)$$

where ρ is the density of the medium, ∇p is the pressure gradient, and t is the integration time, which, as before, depends on the time function defining the noise. When measuring sound power, we are usually interested in the intensity vector component that is normal to the measurement surface. In this case, the gradient of p is replaced by $\partial p/\partial x$, where x is the direction of the normal to the measurement surface. The measurement of this gradient is approximated by $\partial p/\partial x \cong \Delta p/\Delta x \cong (p_1 - p_2)/\Delta x$. The pressure difference $p_1 - p_2$ is measured using two microphones spaced a distance Δx apart, which must be much smaller than the wavelength of sound. Figure 4.11 shows a two-microphone probe used to measure the pressure gradient. The magnitude of the measured sound intensity vector component $\hat{I}_x$ in the direction x is determined from

$$\hat{I}_x = -\frac{1}{2\rho\,\Delta x}E\left\{[p_2(t) + p_1(t)]\int_0^t [p_2(t) - p_1(t)]\,dt\right\} \qquad (4.23)$$

where E is the expected value representing the time averaging and the pressures are on the two microphone diaphragms spaced a distance Δx apart. Figure 4.12 shows a block diagram of an intensity measurement instrument which calculates the intensity component $\hat{I}_x$ using Eq. (4.23).

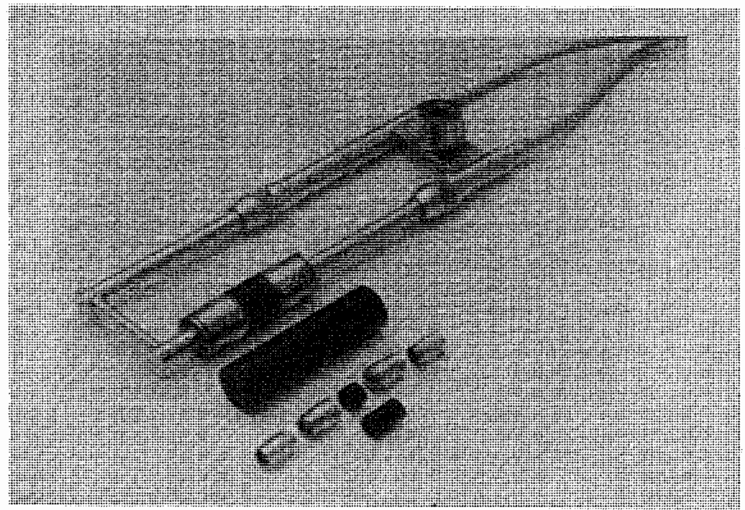

FIGURE 4.11 Sound intensity probe showing two $\frac{1}{2}$-in.-diameter microphones separated precisely by a 1.2-cm spacer. Just beneath is a 5-cm spacer. Below are two $\frac{1}{4}$-in. microphones separated by a 0.6-cm spacer. (Courtesy of Brüel and Kjær, Inc.)

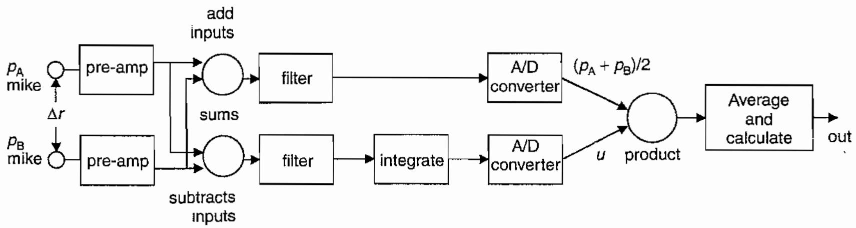

FIGURE 4.12 Block diagram of an analog/digital sound intensity analyzer using octave-band filters. Alternatively, the preamplifier outputs could be suitably amplified and converted to digital format. Then all further processing would be done digitally.

The instrument is also provided with filters with selectable bandwidths to be able to measure the sound power in frequency bands and also to calculate the total power with A-frequency weighting, as required by some standards. Because sound intensity is often used to locate the areas of sound energy radiation or absorption from the surface of a noise source, it is also very practical to measure the sound intensity in very narrow bands. This is conveniently accomplished by using a dual-channel FFT analyzer. The sound intensity measurement is based on a Fourier transform of Eq. (4.23):

$$\hat{I}_x(\omega) = \frac{1}{\omega\rho\ \Delta x}\mathrm{Im}[S_{p_1p_2}(\omega)] \tag{4.24}$$

where $\mathrm{Im}[S_{p_1p_2}(\omega)]$ is the imaginary part of the cross-spectra of the output from the two microphones as measured by the FFT analyzer. This measurement is particularly suitable to analyze the sound power radiation from sources with pronounced line spectra. All sound sources which operate with mechanical periodicity such as rotating engines, fans, vehicles, and similar equipment usually have strong line spectra. The output of the FFT analyzer is usually connected to a computer, which executes the desired postprocessing. The most common calculations are the energy in the lines, in octave or one-third-octave bands, and the total energy, either linear or with A-frequency weighting, as required by some standards. To determine the energy in a band, at least 10 lines of the FFT analysis are generally needed.

The precision of intensity measurements depends on many factors, which can be summarized into two groups: the precision of the instrumentation and the precision of the sampling of the radiated intensity and subsequent calculation of the total radiated power.

There are two standards that define instrumentation requirements for intensity measurements: International Electrotechnical Commission (IEC) 1043[19] and ANSI 1.9–1996.[20] In principle, the intensity measured by an intensity meter should be the same as the intensity in a plane wave measured by a pressure microphone and calculated from the equation $I = p^2/\rho c$. An intensity meter consists

of an intensity probe and a processor. The standards define allowable tolerances for both the probe and the processor for class 1 and 2 intensity instruments.

The probe shown in Fig. 4.11 consists of two pressure microphones separated by a spacer of a length selected by the user. The sound pressure is calculated from the arithmetic average of the microphone pressures. As shown in Eq. (4.23), the particle velocity is approximated by the pressure gradient, which depends on the difference of the microphone pressures. The selected microphone distance must be small enough to avoid a bias error at high frequencies. Figure 4.13 shows the bias error as a function of frequency and microphone distance. This type of bias error cannot be corrected.

Another bias error can occur at low frequencies if the microphones are too close together and not sufficiently phase matched. Figure 4.14 shows the bias error for a 0.3° microphone phase mismatch. The lower the frequency, the greater is the error. Increasing the microphone distance will decrease this error, but a large distance will cause, as mentioned above, a finite distance bias error. Fortunately, modern processors and signal processing can compensate for the phase mismatch error. Essential details are provided in the standards. Due to the existence of these two different bias errors, when the frequency range of the measured noise is large, the measurement usually needs to be repeated using two different microphone separations.

Another important quantity defining the useful frequency range of the instrument is the dynamic capability L_d, defined as

$$L_d = \theta_{pIR} - K \tag{4.25}$$

where θ_{pIR} is the pressure minus residual intensity index and $K = 7$ for a 1-dB allowable measurement error. The importance and usefulness of L_d are shown and

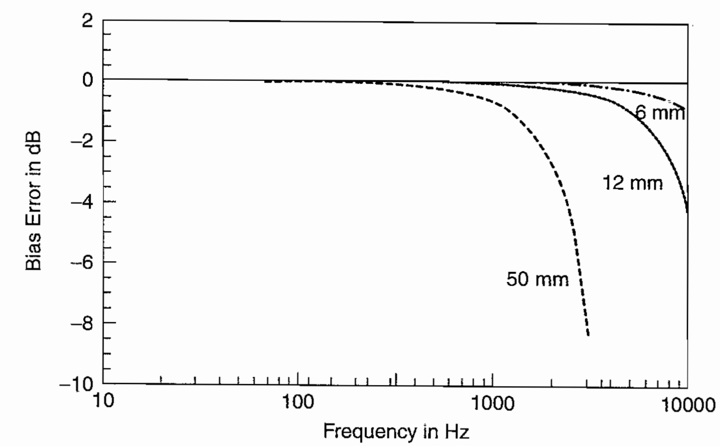

FIGURE 4.13 Intensity probe bias error as a function of frequency with different microphone distances as a parameter.

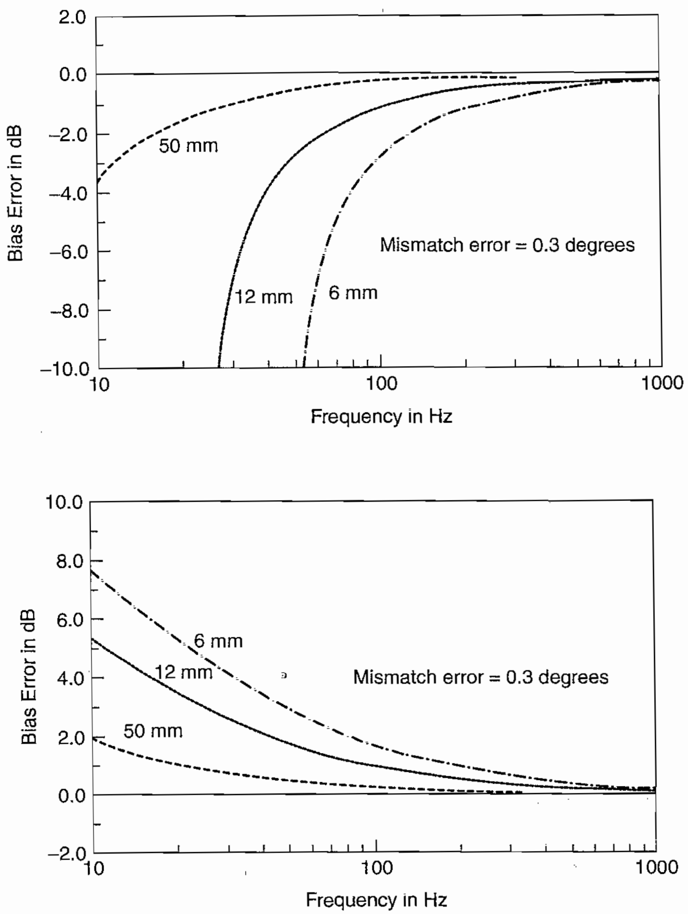

FIGURE 4.14 Intensity probe relative bias error as a function of frequency for different microphone distances as a parameter and mismatch error of 0.3° (plus and minus).

explained in Fig. 4.15. The pressure–residual intensity index θ_{pIR} can be obtained by placing both microphones in a small cavity in which the sound field is excited by an external source. In this way, both microphones are exposed to an identical sound pressure level L_p and the residual intensity level L_{IR} is measured using the intensity meter (usually a FFT analyzer). Ideally, the measured residual intensity should be zero, but due to the microphone mismatch, noise, and measurement instrumentation channel mismatch and other factors, L_{IR} is finite (see Fig. 4.15).

Both L_p and L_I are measured for an actual noise source and the pressure minus intensity index $L_{pI} = L_p - L_I$ is calculated. The intersection of the dynamic capability curve with L_I determines the lowest usable frequency. A phase mismatch will increase L_{IR} and shift the lowest usable frequency higher.

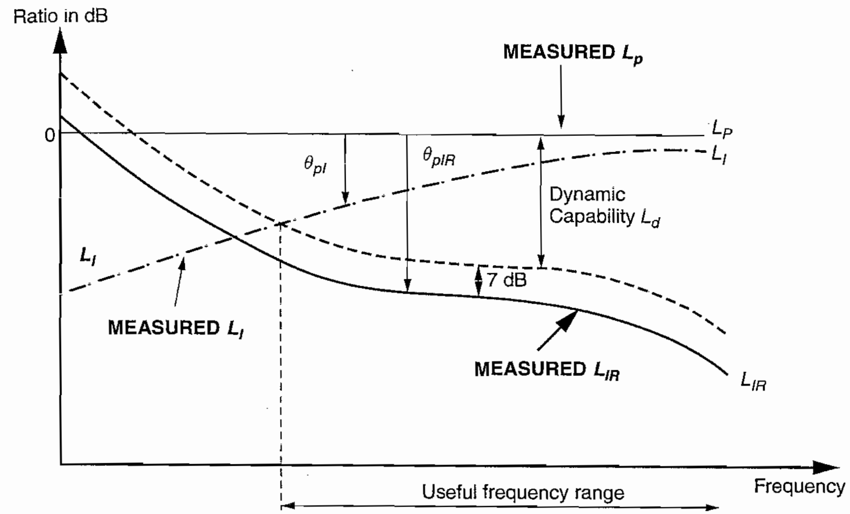

FIGURE 4.15 Dynamic capability of a sound intensity measurement system for 1-dB error as obtained from the pressure–intensity index. The values of L_p and L_I measured with the microphone in a small cavity are used to determine the residual pressure minus intensity index $\theta_{pIR} = L_p - L_{IR}$. The values of L_p and L_I on an actual noise source are used to determine the pressure minus intensity index, $\theta_{pI} = L_p - L_I$.

The pressure minus intensity index $L_{pI} = L_p - L_I$ obtained from the measurement of the actual noise source is an important quantity that characterizes at the measurement point the combination of the source properties and the sound field properties, particularly the effects of the wall reflections. The standards for the sound power measurements and other literature[21] provide essential details.

A typical machine (e.g., an engine) usually operates under conditions different from those under which it would be tested in a reverberant or anechoic room. Moreover, the radiation impedance "seen" by the source may be different from that in a controlled acoustical environment. Hence, its radiated power may be somewhat dependent on how it is mounted and on the proximity of surrounding surfaces.

The intensity technique permits, in most situations, measurement of the sound power of a source of any size operating in its natural environment or on a test stand. In many situations, the sound power radiated from parts of a source can be measured while the whole source is operating. In addition, the intensity technique has become an analytical tool to determine the sound power radiation from different regions of the surface of the source so that the areas of major power radiation can be found. These tasks require an extensive general knowledge of the characteristics of the sound fields, near and far, from the source, wave interference, reflected wave fields, and diffuse sound fields. The details of these important subjects can be found in the literature.[21,22]

Standards which use the direct measurement of sound intensity have been prepared by the ISO and are based on extensive research as well as practical experience gained from measurements. Part 1 of ISO 9614[23] is based on the sampling of sound intensity at discrete points. The intensity probe is moved from point to point and held at each point for a time sufficiently long to make the temporal averaging error small. Part 2 of the same standard uses a scanning technique. The intensity probe is moved over a prescribed path with a sufficiently low speed to satisfy the temporal averaging criterion. The measurement surface is subdivided into smaller sampling areas to secure the required uniformity in the motion of the hand-held probe. Part 3 of the same standard defines the conditions for using the scanning technique for more exact measurements than in Part 2. In practice, the intensity probe is held perpendicular to the measurement surface so that the scalar product converts into an algebraic product.

One of the principal advantages of using the intensity method in field situations is that the results are, in principle, independent of sources outside the measurement surface. The sound energy of external sources propagates through the measurement surface without contributing to the measured power of the sources within the surface—provided that no sound energy due to external sources is absorbed within the surface. Similarly, sound waves reflected from room boundaries or standing waves, unless they are too strong, do not affect the results of a sound power measurement. The standards are applicable to stationary sources located in a nonmoving medium. Because of instrumentation limitations, the frequency range is generally limited to the one-third-octave bands from 50 Hz to 6.3 kHz. A-frequency weighted data are calculated from one-third-octave-band data in this frequency range or from octave-band levels in the frequency range 63 Hz–4 kHz. The correction factors are given in Table 1.4.

Determination of the measurement uncertainty is an important component of the measurements. All standards define the methods and procedures for its determination. Before starting the measurement, the acoustical environment has to be examined for extraneous intensity, wind, gas flow, vibrations, and temperature. The next step consists of the calibration and field check of the instrumentation as specified in IEC 1043[19] or ANSI 1.9–1996.[20] The selection of the measurement surface is important. This is usually performed in two steps. First, an initial surface is selected and an initial measurement performed. The results are tested using a set of indicators that define the characteristics of both the pressure and intensity fields on the measurement surface.[23,24] If the values of these "field indicators" as specified in the standard are not satisfactory, the steps above have to be modified and the measurement repeated. Important field indicators are defined below.

The initial measurement surface is usually selected following the shape of the source at a distance greater than 0.5 m, unless that position is over an area that radiates an insignificant proportion of the sound power of the source under test. The selection of the number of measurement points depends on the shape, segments, and size of the measurement surface. A minimum of 10 points must be selected (greater number obviously leads to better precision, particularly at higher frequencies). If the source is large, one point per square meter of the measurement surface is usually selected, provided that the total number is not less than 50. If extraneous sound penetrates into the measurement area, the number of measurement points must be increased.

After both the sound pressure and the sound intensity are measured at all points, the results are tested by the field indicators in all frequency bands. Depending on the outcome from these indicators, the number and distribution of the measurement points and the distance of the measurement surface from the source may have to be changed. The standards provide tables and flow charts that define the actions to be taken.

The purpose of the indicators is to ensure a sufficient precision of the measurement. The statistical distributions of both the sound pressure and the sound intensity over the measurement surface depend on the source shape and its environment, primarily standing waves caused by sound reflections. Therefore, a general formula for the measurement error does not exist and the error must be determined experimentally. Figure 4.16 shows the flow diagram for the implementation of ISO 9614-1.

The field indicators as defined in ISO 9614 are as follows: F_1, temporal variability of the sound field; F_2, surface pressure–intensity; F_3, negative partial power; and F_4, field nonuniformity. The field indicators require measuring both the sound pressure and intensity. If the criteria for the indicators are not satisfied, the measurement arrangements must be modified. This concerns mainly the change of distance from the measurement surface and increase of the number of measurement points. The flow diagram indicates the actions to be taken. Table 4.8 provides detailed information on these actions.

Indicator F_1 checks the stationarity of the intensity field from several short time-average estimates of the sound intensity at one point of the measurement surface. Its value should be less than 0.6. This should assure that the source operation is steady and the environmental effects are not time variable.

Indicator F_2 is calculated from pressure square averages over the measurement area, converted into a pressure level L_p. Similarly, the intensity level L_I is determined from the arithmetic average of the sound intensities in individual points, all taken with positive sign, irrespective of the power flow out or the measurement surface at a particular point. Indicator F_2 must be smaller than the dynamic capability indicator L_d as defined by Eq. (4.25) and shown in Fig. 4.15 in order to keep the error caused by the instrumentation less than 1 dB for $K = 7$. This indicator is particularly important at low frequencies, as it is apparent in Fig. 4.15.

Indicator F_3 is similar to indicator F_2 except that the intensity level L_I is determined from intensity values with respect to its sign, which means that I is negative at the points where the sound power flows into the measurement surface. This can be caused by extraneous sources or strong reflections due to source environment. Thus $F_3 - F_2$, which is supposed to be less than 3 dB, is linked to the ratio of the sound power radiated out of the measurement surface to the sound power entering the measurement surface. Because both bias and

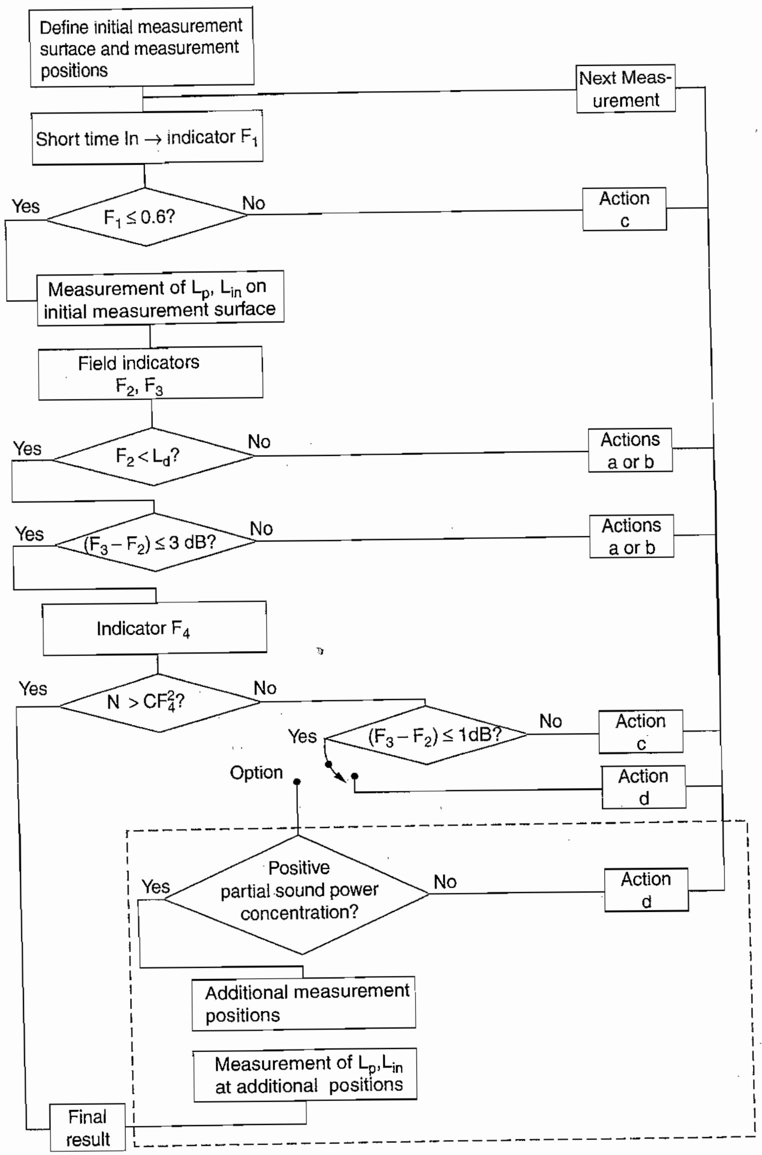

FIGURE 4.16 Flow diagram for the implementation of ISO 9614. The action codes defined in the center column of this figure are defined in Table 4.8. Calculation of the required number of measurement points requires a factor, C, which is defined in Table 4.9. The path enclosed in dashed lines represents an optimal procedure designed to minimize the number of additional measurement positions required on the initial measurement surface. (Courtesy of the International Organization for Standardization, Geneva, Switzerland.)

TABLE 4.8 Actions to Be Taken to Increase Grade of Accuracy of Determination

Criterion	Action Code[a]	Action
$F_1 > 0.6$	e	Take action to reduce the temporal variability of extraneous intensity, or measure during periods of less variability, or increase the measurement period at each position (if appropriate)
$F_2 > L_d$ or $(F_3 - F_2) > 3$ dB	a	In the presence of significant extraneous noise and/or strong reverberation, reduce the average distance of the measurement surface from the source to a minimum average value of 0.25 m; in the absence of significant extraneous noise and/or strong reverberation, increase the average measured distance to 1 m
	or b	Shield measurement surface from extraneous noise sources or take action to reduce sound reflections toward the source
Criterion 2 not satisfied and 1 dB $\leq (F_3 - F_2) \leq 3$ dB	c	Increase the density of measurement positions uniformly to satisfy criterion 2
Criterion 2 not satisfied and $(F_3 - F_2) \leq 1$ dB, and the procedure of ISO 9614 Section 8.3.2 either fails or is not selected	d	Increase average distance of measurement surface from source using the same number of measurement positions or increase the number of measurement positions on the same surface

[a]See Fig. 4.16.

random errors depend on $F_3 - F_2$, the 3-dB criterion satisfies the requirement to keep the bias errors low.

Indicator F_4 is the spatial variance of sound intensity measured at discrete points normalized to the average. The signs of intensity values are considered. This indicator reflects the variability of the power flow over the measurement surface. The higher is F_4, the more measurement points are needed. The number of the measurement points N is given by $N > C \times F_4^2$, where C is a factor which depends on frequency and required precision grade, as shown in Table 4.9.

Part 2 of ISO 9614 defines the measurement of both the sound pressure and intensity by scanning. The measurement area is subdivided into usually plane segments over which the probe is moved ("scanned") perpendicularly to the surface so that spatial averages of the measured quantities are obtained. The recommended moving pattern and speed are specified in the standard. Experimental evidence indicates that the results using the scanning technique are generally more precise than using point measurements.

TABLE 4.9 Values for Factor C

Octave Band Center Frequencies, Hz	One-Third-Octave-Band Center Frequencies, Hz	C: Precision (Grade 1)	C: Engineering (Grade 2)	C: Survey (Grade 3)
63–125	50–160	19	11	
250–500	200–630	29	19	
1000–4000	800–5000	57	29	
	6300	19	14	
A weighted[a]				8

[a] 63 Hz–4 kHz or 50 Hz–6.3 kHz.

Part 3 of ISO 9614 is also based on the scanning technique. The requirements for the measurements and the tolerances to be satisfied are more strict than in Part 2.

In addition to the cited international standards, the ANSI has developed a standard, ANSI S12.12-1992,[25] which mirrors, in its fundamental concept and measurement procedures, the ISO standards. This standard contains a greater number of field indicators and provides more details on the measurement procedures. The selection of any of these standards depends on the product to be measured, the purpose of the sound power determination, and commercial criteria.

ECMA International has also issued a standard for determining sound power from sound intensity using a scanning technique.[26] The standard is intended for use with computer and business equipment.

After substantial experience with the determination of sound power via sound intensity has been achieved, it is expected that these standards will be revised.

4.11 SOUND POWER DETERMINATION IN A DUCT

The most common application of in-duct measurements is to determine the sound power radiated by air-moving devices. The sound power level of a source in a duct can be determined according to ISO 5136[27] from sound-pressure-level measurements, provided that the sound field in the duct is essentially a plane progressive wave, using the equation

$$L_W = L_p + 10 \log \frac{S}{S_0} \tag{4.26}$$

where L_W = level of total sound power traveling down duct, dB re 10^{-12} W
L_p = sound pressure level measured just off centerline of duct, dB re 2×10^{-5} N/m^2
S = cross-sectional area of duct, m^2
S_0 = 1 m^2

The above relation assumes not only a nonreflecting termination for the end of the duct opposite the source but also a uniform sound intensity across the duct. At frequencies near and above the first cross resonance of the duct, the latter assumption is no longer satisfied. Also, when following the measurement procedures of ISO 5136, several correction factors are incorporated into Eq. (4.26) to account for microphone response and atmospheric conditions.

Equation (4.26) can still be used provided L_p is replaced by a suitable space average $\langle L_p \rangle$ obtained by averaging the mean-square sound pressures obtained at selected radial and circumferential positions in the duct or by using a traversing circumferential microphone. The number of measurement positions across the cross section used to determine $\langle L_p \rangle$ will depend on the accuracy desired and the frequency. (See ref. 27, Section 6.2.)

In practical situations, reflections occur at the open end of the duct, especially at low frequencies. The effect of branches and bends must be considered.[28] When there is flow in the duct, it is also necessary to surround the microphone by a suitable windscreen (see Chapter 14). This is necessary to reduce turbulent pressure fluctuations at the microphone, which can cause an error in the measured sound pressure level.

4.12 DETERMINATION OF SOURCE DIRECTIVITY[29,30]

Most sources of sound of practical interest are directional to some degree. If one measures the sound pressure level in a given frequency band a fixed distance away from the source, different levels will generally be found for different directions. A plot of these levels in polar fashion at the angles for which they were obtained is called the *directivity pattern* of the source. A directivity pattern forms a three-dimensional surface, a hypothetical example of which is sketched in Fig. 4.17. The particular pattern shown exhibits rotational symmetry about the direction of maximum radiation, which is typical of many noise sources. At low frequencies, many sources of noise are nondirectional—or nearly so. As the frequency increases, directivity also increases. The directivity pattern is usually determined in the far (free) field (see Fig. 4.4). In the absence of obstacles and reflecting surfaces other than those associated with the source itself, L_p decreases at the rate of 6 dB per doubling of distance.

Directivity Factor

A numerical measurement of the directivity of a sound source is the directivity factor Q, a dimensionless quantity. To understand the meaning of the directivity factor, we must first compare Figs. 4.17 and 4.18. We see in Fig. 4.18 the directivity pattern of a nondirectional source. It is a sphere with a radius equal in length to L_{pS}, the sound pressure level in decibels measured at distance r from a source radiating a total sound power W. The sources of Figs. 4.17 and 4.18 both radiate the same total sound power W, but because the source of Fig. 4.17

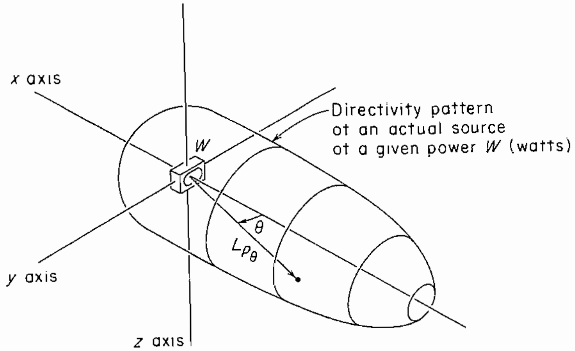

FIGURE 4.17 Directivity pattern of a noise source radiating sound power W into free space. A particular sound pressure level L_p is shown as the length of a vector terminating on the surface of the directivity pattern at angle θ. Sound pressure levels were measured at various angles θ and at a fixed distance r from the actual source in free space.

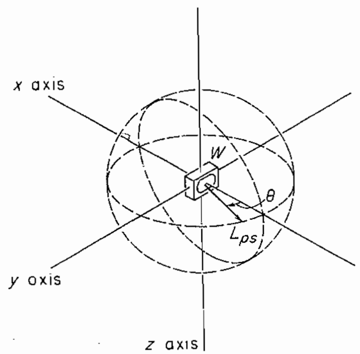

FIGURE 4.18 Spherical directivity pattern of a nondirectional source radiating acoustic power W into free space. At all angles θ and distance r, the sound pressure level equals L_{pS}, where $L_{pS} = 10\log(10^{12} \times W/4\pi r^2)$.

is directional, it radiates more sound than that of Fig. 4.18 in some directions and less in others.

To derive a directivity factor Q, we must assume that the directivity pattern does not change shape regardless of the radius r at which it is measured. For example, if L_p at a particular angle is 3 dB greater than at a second angle, the 3-dB difference should be the same whether r is 1, 2, 10, or 100 m. This can only be determined in the far field of a source located in anechoic space.

The directivity factor Q_θ is defined as the ratio of (1) the mean-square sound pressure p_θ^2 [(N/m^2)^2] at angle θ and distance r from an actual source radiating W watts to (2) the mean-square sound pressure p_s^2 at the same distance from a nondirectional source radiating the same acoustic power W. Alternatively, Q_θ

is defined as the ratio of the intensity in the direction of propagation (W/m^2) at angle θ and distance r from an actual source to the intensity at the same distance from a nondirectional source, both sources radiating the same sound power W. Thus

$$Q_\theta = \frac{p_\theta^2}{p_s^2} = \frac{I_\theta}{I_s} = \frac{10^{L_{p\theta}/10}}{10^{L_{pS}/10}} \quad \text{(dimensionless)} \tag{4.27}$$

or

$$Q_\theta = 10^{(L_{p\theta} - L_{pS})/10} \tag{4.28}$$

where $L_{p\theta}$ = sound pressure level measured a distance r and an angle θ from a source radiating power W into an anechoic space (see Fig. 4.17)
L_{pS} = sound pressure level measured at a distance r from a nondirectional source of power W radiating into anechoic space (see Fig. 4.18)

Note that Q_θ is for the angle θ at which $L_{p\theta}$ was measured and that L_{pS} and $L_{p\theta}$ are for the same distance r.

Directivity Index

The directivity index (DI) is simply defined as

$$\mathrm{DI}_\theta = 10\log Q_\theta \quad \mathrm{dB} \tag{4.29}$$

or

$$\mathrm{DI}_\theta = L_{p\theta} - L_{pS} \tag{4.30}$$

Obviously, a nondirectional source radiating into spherical space has $Q_\theta = 1$ and $\mathrm{DI} = 0$ at all angles θ.

Relations between $L_{p\theta}$, Directivity Factor, and Directivity Index

The sound pressure level for the nondirectional source of Fig. 4.18 is

$$L_{pS} = 10\log\frac{p^2 \text{ at distance } r}{4 \times 10^{-10}} \quad \mathrm{dB} \tag{4.31}$$

From Eqs. (4.5) and (4.11) and taking the quantity $D = \rho c W_0/p_{\text{ref}}^2$ to be small, L_{pS} is given by (see Fig. 4.18)

$$L_{pS} = 10\log\frac{W \times 10^{12}}{4\pi r^2} \quad \mathrm{dB} \tag{4.32}$$

From Eqs. (4.28) and (4.32), we find that

$$L_{p\theta} = 10 \log \frac{WQ_\theta \times 10^{12}}{4\pi r^2} \tag{4.33}$$

where W is in watts and r is in meters. In logarithmic form

$$L_{p\theta} = L_W + \mathrm{DI}_\theta - 20 \log r - 11 \text{ dB} \tag{4.34}$$

where r is the distance from the acoustical center of the source in meters.

Determination of Directivity Index in Spherical Space

The directivity index DI_θ of a sound source in free space at angle θ and for a given frequency band is computed from

$$\mathrm{DI}_\theta = L_{p\theta} - \langle L_p \rangle_S \tag{4.35}$$

where $L_{p\theta}$ = sound pressure level measured at distance r and angle θ from source, dB

$\langle L_p \rangle_S$ = sound pressure level averaged over test sphere of radius r (and area $4\pi r^2$) centered on and surrounding source

Determination of Directivity Index in Hemispherical Space

The directivity index DI_θ of a sound source on a rigid plane at angle θ and for a given frequency band is computed from

$$\mathrm{DI}_\theta = L_{p\theta} - \langle L_p \rangle_H + 3 \text{ dB} \tag{4.36}$$

where $L_{p\theta}$ = sound pressure level measured distance r and angle θ from source, dB

$\langle L_p \rangle_H$ = sound pressure level of space-averaged mean-square pressure averaged over a test hemisphere of radius r (and area $2\pi r^2$) centered on and surrounding source

The 3 dB in this equation is added to $\langle L_p \rangle_H$ because the measurement was made over a hemisphere instead of a full sphere, as defined in Eq. (4.37). The reason for this is that the intensity at radius r is twice as large if a source radiates into a hemisphere as compared to a sphere. That is, if a nondirectional source were to radiate uniformly into hemispherical space, $\mathrm{DI}_\theta = \mathrm{DI} = 3$ dB.

Determination of Directivity Index in Quarter-Spherical Space

Some pieces of equipment are normally associated with more than one reflecting surface, for example, an air conditioner standing on the floor against a wall. The power level of noise sources of this type may be measured with those surfaces in place. This is done best in a test room with anechoic walls but with one hard wall forming an "edge" with the hard floor. The general considerations of the

preceding paragraphs apply here as well. One determines the sound pressure level averaged over the quarter-sphere, $\langle L_p \rangle_H$, and also determines $L_{p\theta}$ as before. The directivity index is given by

$$\mathrm{DI}_\theta = Lp_\theta - \langle L_p \rangle_Q + 6 \text{ dB} \tag{4.37}$$

5.1 INTRODUCTION

This chapter deals with the description and prediction of sound due to sources in an outdoor environment. Specifically, it deals with the propagation path from source to receiver. Propagation is affected by geometrical spreading, ground effects including reflection and refraction due to temperature and wind speed vertical gradients, attenuation from intervening barriers, general reflections and reverberation, atmospheric absorption, and attenuation from intervening vegetation.

5.2 GENERAL DISCUSSION

The atmosphere is in constant motion due to wind and sun at amplitudes that are large compared to the amplitudes of sound–particle velocity. This constant motion results in considerable distortion of sound waves and considerable variability of propagation conditions. Ever since the careful observations and first scientific modeling of outdoor sound propagation by O. Reynolds, Lord Rayleigh, and Lord Kelvin in the nineteenth century,[1] numerous experimental and mathematical studies have provided detailed understanding of the effects of mechanical and thermal turbulence, humidity (including fog), boundary conditions at the ground surface, and obstacles such as trees, walls, and buildings in the propagation path.

Unfortunately, much of the vast amount of information published on outdoor sound propagation in scientific papers is not relevant to the practical control of noise from recreational and industrial facilities or from road, rail, and air

CHAPTER 5

Outdoor Sound Propagation

5.1 INTRODUCTION

This chapter deals with the description and prediction of sound due to sources in an outdoor environment. Specifically, it deals with the propagation path from source to receiver. Propagation is affected by geometrical spreading, ground effects including reflection and refraction due to temperature and wind speed vertical gradients, attenuation from intervening barriers, general reflections and reverberation, atmospheric absorption, and attenuation from intervening vegetation.

5.2 GENERAL DISCUSSION

The atmosphere is in constant motion due to wind and sun at amplitudes that are large compared to the amplitudes of sound–particle velocity. This constant motion results in considerable distortion of sound waves and considerable variability of propagation conditions. Ever since the careful observations and first scientific modeling of outdoor sound propagation by O. Reynolds, Lord Rayleigh, and Lord Kelvin in the nineteenth century,[1] numerous experimental and mathematical studies have provided detailed understanding of the effects of mechanical and thermal turbulence, humidity (including fog), boundary conditions at the ground surface, and obstacles such as trees, walls, and buildings in the propagation path.

Unfortunately, much of the vast amount of information published on outdoor sound propagation in scientific papers is not relevant to the practical control of noise from recreational and industrial facilities or from road, rail, and air traffic. Relevance is determined by the rating criteria required by governmental agencies for assessment of community environments, such as described in the ISO 1996 series and various governmental regulations. Relevant criteria most often are given in the form of two acoustical descriptors: the equivalent continuous and the average maximum A-weighted sound pressure level, L_{eq} (as defined in Chapter 2) and $L_{A,max}$ (e.g., during a single-vehicle pass-by).

For that purpose, mainly average favorable conditions for sound propagation (plus the frequency of such conditions) need to be considered. Unfavorable conditions, which result in a large and uncertain range of low sound pressure levels, play a minor role in Europe.

For example, when favorable conditions occur during 50% of the time and unfavorable conditions result in at least 5-dB lower levels, then the equivalent continuous level

$$\begin{aligned} L_{eq} &= 10 \lg \left(\frac{50}{100} 10^{L_{fav}/10} + \frac{50}{100} 10^{L_{unfav}/10} \right) \text{ dB} \\ &< L_{fav} - 3 \text{ dB} + 10 \lg(1 + 10^{-5/10}) \text{ dB} = L_{fav} - 1.8 \text{ dB} \qquad (5.1) \\ &> L_{fav} - 3 \text{ dB} \end{aligned}$$

lies some 2–3 dB below the average maximum level L_{fav} that occurs under favorable propagation conditions. It never lies outside that range, independent of the actual distribution of levels L_{unfav} for unfavorable propagation conditions.

The techniques in this chapter concentrate on such average favorable conditions for sound propagation to receiver positions about 4 m above the ground (first story above the ground story or higher). Additional techniques will be needed in governmental jurisdictions that require assessment of somewhat lower levels received 1.5 m above the ground—as is common within the United States and Canada.

In general, the level of outdoor sound decays with increasing distance between source and receiver. This geometrical divergence is most important for attenuation near the source, while meteorological conditions dominate attenuation further away.

Barriers, buildings, and hills that interrupt direct propagation from source to receiver are most important for excess attenuation. Of less importance are the effects of atmospheric absorption, porous ground (with receivers above 3–5 m), trees, single reflections from buildings, and reverberation in forests, valleys, and street canyons. Even though such effects are well understood, their computation requires input that is often not available in engineering practice—such as the spatial distribution of relative humidity or the effective flow resistivity of the ground between source and receiver. For planning purposes, engineering estimates or conventions have to be employed, rather than detailed models, to account for such effects.

In a homogeneous atmosphere at rest, geometrical divergence of sound from point sources is described by rigorous solutions of the wave equation in spherical

coordinates. In these solutions, sound travels on a straight course in all directions at the same speed.

In reality, however, sound paths are not straight, because sound speed varies with temperature and wind velocity, mainly as a function of height above the ground. Underwater sound propagation is similarly dependent on height, due to the variation of salt content with height. To account for refraction of sound under water, various specialized mathematical models have been developed: ray theory, the spectral method or fast-field program (FFP), the normal mode, and the parabolic equation (PE).[2] Except for the normal-mode model, which is based on essentially two-dimensional fields between the bottom and the surface of an ocean, all these models have been proposed for airborne sound as well.

In addition, for airborne sound propagation the particular effects of ground impedance can be computed with a boundary element model (BEM)—although that model is limited to a nonrefracting (homogeneous) atmosphere. Also in the acoustical literature is a Meteo-BEM (presently limited to linear sound speed profiles) and a generalized-terrain PE. The latter is limited to axis-symmetric cases, just like the PE, but is also applicable to terrain profiles with moderate slope.[3]

In spite of these advanced models, the much-simpler ray theory has now gained engineering importance, exclusively. In the past, ray theory was dominant because of excessive computation-time requirements for FFP- and PE-like models. At present, the comparison of results obtained with FFP (within the limits of reliable atmospheric input data involving the Monin-Obukhov boundary layer theory) has shown no particular advantage to FFP over ray theory. Instead, the two models show surprising consistency for downwind conditions up to a distance of 2000 m.[4,5]

At a reception point outdoors, only the A-weighted overall sound pressure level is considered in most practical cases. Further calculation of sound transmission into buildings, which requires information about the spectral distribution, is limited to special problems of building acoustics. Consequently, older engineering estimates neglect the frequency dependence of propagation losses. Instead, they assume a single frequency band that represents the attenuation of A-weighted overall sound pressure from sources with typical spectra. Due to increased computer capabilities, advanced engineering models now include calculations in frequency bands. Except for distant propagation to receiver heights of 1.5 m, full-octave bands are sufficient—both for the precision obtainable and the requirement for traceable details. One-third-octave bands are needed for special cases only.

Regulations that allow various calculation procedures with frequency bands of different widths have a great disadvantage. The simpler procedure is not always on the safe side, and so users quickly learn to choose the procedure that yields "better" results, from their point of view. To avoid ambiguous results of this type, one should follow well-established governmental regulations and conventions—such as ISO 9613-2[6] in Europe and the regulations of funding authorities in the United States and Canada.

5.3 SOURCES

Point Sources at Rest

Historically, acousticians distinguished between point, line, and area sources. Modern computer capabilities allow for the exclusive use of large numbers of point sources to approximate lines and areas. Such approximation is officially considered satisfactory in Europe, but not in the United States, where federal regulations generally require use of line source algorithms and computer programs. Such line source programs eliminate the possibility that gaps in noise barriers, for example, will be ignored by computations when the approximating point sources are not sufficiently dense along the roadway.

European computer programs automatically break up extended sources into sufficiently small elements, which can be described as point sources. For this purpose, it is generally sufficient that

- the largest dimension of a source element be less than half the distance between source and receiver,
- the sound power be about equally distributed over the source element, and
- about the same propagation conditions exist from all points on the source element to the receiver.

The last requirement pertains to effects of the ground and obstacles in the propagation path. If they are relevant, the permissible difference in height above the ground between two source elements is typically less than 0.3 m. Whether a particular computer program follows these rules needs to be carefully determined by test cases.

Point sources are described by

- the location (x,y,z) of the center,
- the sound power level L_W in frequency bands (relative to 1 pW), and
- the directivity index D_I in frequency bands (in one or two dimensions).

Preferred frequency bands are octave bands with center frequencies from 63 to 8000 Hz. Lower frequencies may be important—for example, in the vicinity of jet engine test cells. They need special consideration. Higher frequencies are subject to strong and variable atmospheric attenuation. They can be neglected outdoors.

When available, one should use measured sound spectra and directivity of specific noise sources. If these are not available but the A-weighted overall sound power level is known, Table 5.1 contains an estimate of the octave-band spectra applicable to a surprising number of sound sources—such as roadway, railway and aircraft traffic, rifle fire, muffled diesel engines, and many industrial noise sources. For comparatively large and slow sources or for substantial vibration damping, the spectrum may be shifted to lower frequencies by one octave. On the other hand, comparatively small and fast-moving sources with little vibration

TABLE 5.1 Typical Unweighted and A-Weighted Octave-Band Source Spectra Relative to A-Weighted Overall Sound Power

Octave-Band Center frequency, Hz	63	125	250	500	1000	2000	4000	8000
Unweighted: $L_{W,\text{oct}} - L_{WA}$, dB	−2	1	−1	−3	−5	−8	−12	−23
A weighted: $L_{WA,\text{oct}} - L_{WA}$, dB	−28	−15	−10	−6	−5	−7	−11	−24

damping may have a spectrum that is shifted to higher frequencies by one octave. When the frequency band around 500 Hz is taken as an equivalent for the attenuation of A-weighted overall sound, this simplifying assumption is relative to one octave band below the average maximum of A-weighted octave-band noise.

The directivity index is normalized so that the average value of $10^{D_I/10}$ in all directions is unity. In many cases of rotational symmetry, the directivity index is sufficiently described in one dimension. Examples are smoke stacks and gunfire. For receivers on level ground, the directivity index is often described in the horizontal plane only. A practical example is the directivity of sound from aircraft engines during ground run-up tests. For turbo-jet aircraft on the ground, a typical dependence of directivity on angle and frequency is plotted in Fig. 5.1. Highest values occur in the direction $\phi = 120°$ from the forward direction and in the 1000-Hz frequency band.

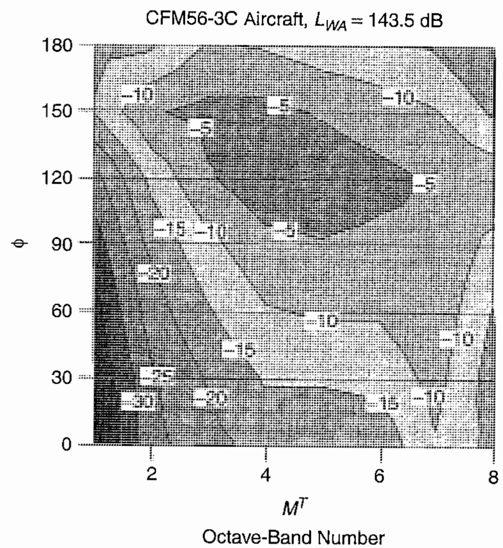

FIGURE 5.1 Combination of directivity and octave-band weighting for a turbojet engine with high bypass ratio at takeoff power setting. Octave-band number 2 is centered at 125 Hz and number 8 at 8000 Hz. Data are for a CFM-56-3C aircraft engine with $L_{WA} = 143.5$ dB.

The basic relation between the sound pressure level L_p at a distance d from a source and the sound power level L_W of the source is given by

$$L_p(d, \phi) = L_W + D_I(\phi) + D_\Omega - A(d, \phi) \tag{5.2}$$

where $A(d, \phi)$ = transfer function due to effect of all elements in propagation path; attenuating or enhancing effects are discussed in Section 5.4

$D_I(\phi)$ = directivity index

D_Ω = index that accounts for sound propagation into solid angles less than 4π steradians

When the sound power output of a source is determined from outdoor measurements of the sound pressure level $L_p(d, \phi)$ in various directions ϕ at a certain distance d from the source, it is important to apply the same transfer function $A(d, \phi)$ from the sound power level to the sound pressure level as is applied in the opposite direction.

The description of sound emission in terms of the sound power level generally includes the assumption that the source radiates into free space (solid angle $\Omega = 4\pi$). Instead, when the source is located on the ground, and therefore the solid angle of radiation is 2π, two equivalent assumptions can account for the ground: (1) an additional incoherent image source beneath the ground, with the same sound power, or (2) a correction of the sound power level L_W by D_Ω = 3 dB in Eq. (5.2). In general, when the source is located at a height h_S and the receiver at a height h_R above reflecting ground, the correcting index is

$$D_\Omega = 10 \lg \left[1 + \frac{d^2 + (h_S - h_R)^2}{d^2 + (h_S + h_R)^2}\right] \quad \text{dB} \tag{5.3}$$

from geometrical consideration of incoherent image sources.[6] Furthermore, in some cases the ground effect A_{gr} from source to receiver, which is part of $A(d)$ in Eq. (5.2), must be taken into account.

When the source is located close to a wall or in a corner formed by two walls, sound pressure at some distance would include reflections from these walls as well. Similar to Eq. (5.3), the effect of these reflections is a level difference of about D_Ω = 6 dB for a wall and about 9 dB for a corner. Alternatively—and necessarily for sound-absorbing walls—image sources may be considered separately.

Moving Sources

For traffic noise, it is common practice to consider the motion of sources along straight lines. Compared to continuous sources at rest, moving sources yield

- variable sound pressure levels at a stationary receiver,
- variable pitch of tonal components at a stationary receiver (Doppler effect), and
- different radiation due to different acoustical loading of the surrounding air.

The last of these effects is well described by theory, but in practice either included in the overall description of sound emission or neglected at low velocities.

The variation in pitch, from a higher pitch during vehicle approach to a lower pitch after passage, is determined by the factor $(1 + M)/(1 - M)$, in which $M = V/c$ is the Mach number resulting from the vehicle velocity V and the sound velocity c. For road traffic, this multiplicative factor roughly corresponds to one-third of an octave, but for high-speed maglev trains, it may reach a full octave. In addition, for maglev trains, the sinusoidal excitation of the track, which is due to the groove-passage frequency of magnets over the long-stator, results in a broadband maximum noise at receivers close to the track—when radiated frequencies shift upward from some parts of the track and downward from other parts (see Fig. 5.2). Pure tones from the vibration signal of the magnets are not audible during train passage.

For moving vehicles of any type, the variation in sound pressure level during approach and pass-by is generally not taken into account, except for its energy mean and, in some cases, its maximum value. An integrating sound-level meter is used to determine the total sound energy and then to report the pass-by's sound exposure level (SEL), which is the level of the integrated sound energy referred to a time interval of 1 s and is also called the single-event level. Since the direction of sound approach to a receiver from a long, straight track is equally distributed horizontally over 180°, Eq. (5.2) can be used without its directivity index to convert the SEL into a sound power level. Spreading this sound power over the distance the source travels in 1 h results in a sound power per unit length of track—the strength of a line source for one vehicle per hour. For further calculations, the line source is broken up into straight-line segments in the United States and Canada or into point sources in Europe.

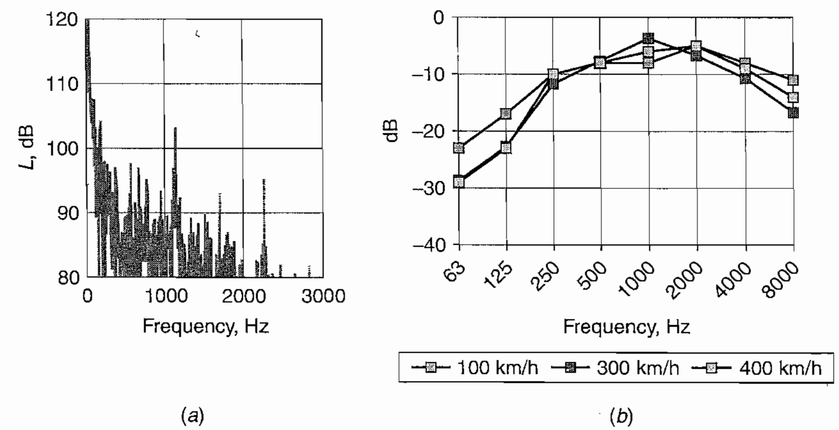

FIGURE 5.2 (*a*) Narrow-band spectrum of sound pressure level measured close to the magnets of a maglev train at 355 km/h. (*b*) A-weighted octave-band spectrum relative to A-weighted overall sound pressure level at some distance from a maglev train.

Although this procedure is normally applied to individual road and rail vehicles, the emission from the homogeneous section of a long train is usually evaluated differently. In such cases, the time integral of the squared sound pressure may be limited, without significant energy loss, to just when the center part of the homogeneous section passes by. This integral describes the sound emission from the homogeneous section in the same way as the SEL describes it for the entire train. Consequently, the same procedure can be used here (distribute the sound power over the distance the source travels in one hour) to determine the sound power per unit length of track for the train section selected. Sound power contributions from rolling noise of different vehicles are then added together. Contributions from sources at different heights need to be considered as separate line sources.

5.4 ELEMENTS IN PROPAGATION PATH

Overview

The transfer function of sound from a source to a receiver is determined by the sum of all attenuations along a particular ray path and by the contribution from all paths of direct and reflected sound. Attenuations account for spherical spreading A_{div}, ground effect A_{gr}, diffraction by barriers A_{bar}, partial reflections A_{refl}, atmospheric absorption A_{atm}, and miscellaneous others A_{misc}. They are described in the following.

Sound Propagation in Homogeneous Free Space over Ground

In the geometrical, high-frequency approximate solution of the Helmholtz equation for sound pressure p,

$$\Delta p + \left(\frac{2\pi f}{c}\right)^2 p = -\delta^2(\mathbf{r} - \mathbf{r}_S) \tag{5.4}$$

propagation of sound with frequency f from a point source at $\mathbf{r} = \mathbf{r}_S$ is described by ray theory. Rapid variations in phase are distinguished from slow variations in amplitude due to geometrical spreading and energy loss mechanisms. The ray trajectories are perpendicular to the surface of constant phase, which forms the wave front. The direction of average energy flux follows that of the trajectories. The amplitude of the field at any point can be obtained from the density of rays.

At short ranges, it is reasonable to assume straight rays. In free space, spherical spreading over a distance d results in an attenuation of

$$A_{\text{div}} = 10 \text{ lg } \frac{4\pi d^2}{d_0^2} \text{ dB} \tag{5.5}$$

where $d_0 = 1$ m. An observer above partially reflecting ground receives not only the direct ray but also a ground reflection, as sketched in Fig. 5.3. For simplicity,

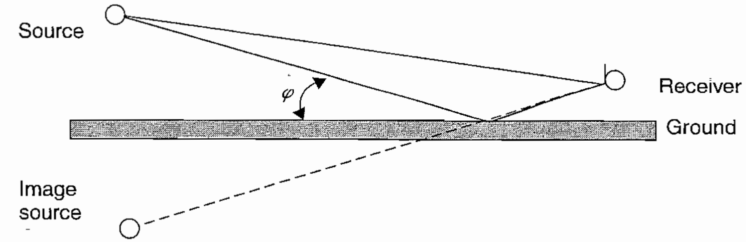

FIGURE 5.3 Ground reflection of a straight ray.

the plane-wave reflection coefficient

$$R_p = \frac{Z_s \sin\varphi - Z_0}{Z_s \sin\varphi + Z_0} \tag{5.6}$$

of a locally reacting surface of the ground, with impedance Z_s, may be used to determine the magnitude/phase effect of the reflection. The characteristic wave impedance of air, $Z_0 = \rho_0 c_0$, is generally very small compared to the magnitude of the ground impedance Z_s. Therefore, the reflection coefficient is usually about 1, except for very small angles φ—that is, when $|Z_s| \sin\varphi \ll Z_0$ and the reflection coefficient is about -1. Under the latter condition, the direct ray destructively interferes with the ground reflection and causes relatively low sound pressure close to the ground. In essence, the source and image source form a dipole, causing little radiation parallel to the ground. When the source is much closer to the ground than the receiver—e.g., for road traffic noise—the ground effect near the source can be attributed to a vertical radiation characteristic of the source. According to measurements over grassland near the shoulder of highways, the directivity index $D_I(\phi)$ of A-weighted road traffic noise drops from 0 dB at an elevation angle of 15° to about -5 dB at 0°. Generalized per reciprocity for arbitrary source and receiver heights, this relation converts to a reduction in overall A-weighted sound level[6]:

$$A_{\text{gr},D} = \left[4.8 - \frac{h_{\text{av}}}{d}\left(34 + \frac{600 \text{ m}}{d}\right)\right] \text{ dB} > 0, \tag{5.7}$$

where d is the source–receiver distance and

$$h_{\text{av}} = \tfrac{1}{2}(h_S + h_R) \tag{5.8}$$

is the average height of the sound ray from a source at height h_S to a receiver at height h_R.

Within a receiver distance of less than 200 m, this description is quite consistent with calculations of the Ontario noise regulation[7] from the equation

$$A_{\text{gr},O} = 10G \text{ lg}\frac{r}{15 \text{ m}} \text{ dB} > 0 \tag{5.9}$$

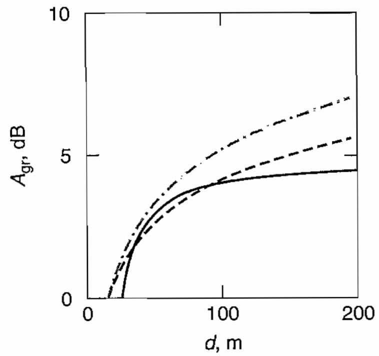

FIGURE 5.4 Excess attenuation A_{gr} over grassland as a function of distance d for an average height of 2 m: (—) according to Eq. (5.7); (- - -) according to Eq. (5.9) with $G = 0.5$; (-·-) according to Eqs. (5.9) and (5.10).

with

$$0 \leq G \equiv 0.75 \left(1 - \frac{h_{av}}{12.5 \text{ m}}\right) \leq 0.66 \tag{5.10}$$

for an average height of 2 m (or a receiver height of 4 m for a source close to the ground), as shown in Fig. 5.4.

More precise models have been developed to account for the curvature of wave fronts using a spherical reflection factor and possibly for an extended reaction of soft ground (e.g., fresh-fallen snow).[8] Such models explain a pronounced interference dip of sound pressure for sources and receivers within 2 m above the ground. This dip typically occurs in octave bands centered at 250 and 500 Hz. A dominant parameter of these more precise models is the effective flow resistivity of the ground. United States and Canadian agencies generally require the application of such models to properly account for this dip to receivers 1.5 m above the ground (the required receiver height). Note that this dip is caused by interference, not energy absorption at the ground.

However, near-complete destructive interference of two rays requires about equal amplitude and opposite phases. Diffuse rather than specular ground reflection, plus phase distortion due to thermal and wind turbulence in the propagation path, reduces or inhibits such near-complete interference, especially at large distances. Predicted ground attenuation A_{gr} of more than 20 dB for average lawn surface is unrealistic.

From an engineering point of view (especially in Europe), this interference effect is of little use. Some sound-level reduction may be experienced on a terrace surrounded by a lawn. But neighbors to industrial plants cannot be protected from sound impinging on their bedroom windows (4 m or more above the ground) by interfering reflections from a substantially lower ground. In Europe, planning of new roadways or commercial activities does not depend on the ground conditions of adjacent property, as it does in the United States and Canada.

Refraction of Sound in Inhomogeneous Atmosphere

Very important for outdoor sound propagation is the inhomogeneity of the atmosphere. The normal state of air is one of "convective equilibrium," in which the sound velocity c varies with temperature and wind velocity as a function of height above the ground. Higher temperature close to the ground results in higher sound velocity there and therefore in curvature of sound rays toward the sky. A component of wind in the direction of sound propagation causes refraction of sound rays toward the ground, because wind speed always increases with height. Linear wind and temperature profiles result in rays following a catenary curve that can be approximated by a circular arc with radius

$$R = \frac{1}{a \cos\phi} \tag{5.11}$$

as already described by Lord Rayleigh,[1] where a denotes the sound speed gradient due to vertical temperature and wind gradients. In the Nordic countries of Europe, measurements of wind and temperature are specified at heights of 0.5 and 10 m above level ground, expressly to determine a from the relation[9]

$$a = \frac{10^{-3}}{3.2 \text{ m}} \left(\frac{0.6\ \Delta T}{1°\text{C}} + \frac{\Delta u}{1 \text{ m/s}}\right) \tag{5.12}$$

where $\Delta T = T(10 \text{ m}) - T(0.5 \text{ m})$ is the difference in temperature and $\Delta u = u(10 \text{ m}) - u(0.5 \text{ m})$ is the difference in wind speed component at those two heights.

For negative values of a, causing upward refraction, there is a limiting arc between source and receiver at a distance

$$D = \sqrt{\frac{2}{|a|}} \left(\sqrt{h_S} + \sqrt{h_R}\right) \tag{5.13}$$

that just grazes the ground (see Fig. 5.5). Beyond this distance, sound can reach the receiver not along a ray but only by diffraction. The limiting arc determines the boundary of an acoustical shadow zone. For source and receiver height $h_S = 0$ m and $h_R = 4$ m, respectively, and a moderate gradient $a = -10^{-4}$ m^{-1}, this distance $D = 282$ m. Stronger gradients reduce the distance, but typically not below 100 m. Consequently, meteorological conditions are often neglected for sound propagation over less than 100 m. To ensure reliable measurements of industrial noise at a minimum height of 4 m, the Nordic countries specify a minimum value $a = -10^{-4}$ m^{-1} at distances from 50 to 200 m and $a > -10^{-4}$ m^{-1} at larger distances.

Most noticeable is the case of temperature inversion ($a > 0$), which happens on calm days during dawn and dusk when dampness covers the ground and sunshine is restricted to the upper layers of the atmosphere. With temperature inversion, traffic noise is trapped in the lowest layer by downward refraction

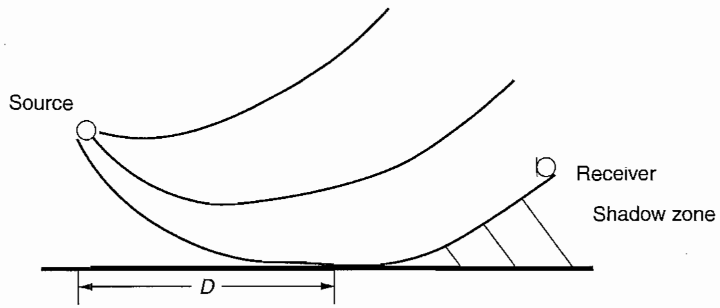

FIGURE 5.5 Sound rays and shadow formation for negative values of a.

and repeated reflections from the ground. As a result, sound can be heard over very large distances, due to divergence in only two (rather than three) dimensions—that is, no divergence upward. Even stronger effects can be observed for sound propagation over lakes and wide rivers.

Opposite effects occur from sound propagation over hot spots, as is well known from the poor quality of communication over an open fire. Ground surfaces warmed up by the sun or by industrial facilities may cause upward refraction and scattering of sound out of straight rays, both effects resulting in excess attenuation.

The combined effects of ground and micrometeorology have been studied in detail for the development of a heuristic model for outdoor sound propagation.[10] This model accounts for

- ray theory for the fastest path in air from source to receiver;
- one or more ground reflections during sound propagation downwind or for temperature inversion conditions, the number depending on the magnitude of the positive sound speed gradient;
- diffraction of sound into the shadow zone for a negative sound speed gradient;
- spherical reflection coefficient for refracted sound rays incident on the ground, depending on the effective flow resistivity of the ground; and
- reduced coherence of the various contributions to the sound pressure at the receiver, due to different travel times of these components and turbulence of the atmosphere.

Data calculated from this model have been compared to data measured over grassland at relatively low receiver positions with the following results:

- High excess attenuations calculated for negative gradients a at distances of more than 400 m have not been observed. Up to 1600 m, the average attenuation values were limited to approximately 20 dB in the frequency band centered at 630 Hz.

- For positive gradients a, average measured excess attenuations were limited to a few decibels and did not increase significantly with distance from 400 to 1600 m in the frequency bands below 200 Hz and above 630 Hz. Calculated values of excess attenuation came out higher.
- A pronounced excess attenuation in the frequency bands from 200 to 1000 Hz was both calculated and measured for low wind and a small positive gradient a.

A much simpler model for the ground effect on sound propagation outdoors has been adopted in ISO 9613-2[6]:

- Downwind (or a positive gradient a) is considered exclusively.
- The ground is either hard ($G = 0$) or porous ($G = 1$). If only a fraction of the ground is porous, G takes on a value between 0 and 1, the value being the fraction of the region that is porous.
- Three regions for ground reflection are distinguished: (1) the source region stretching $30h_S$ (maximum) toward the receiver, (2) the receiver region stretching $30h_R$ (maximum) toward the source, and (3) if the source and receiver regions do not overlap, a middle region in between.
- Similar to the angular parameter involved in Eq. (5.7), a parameter

$$q = \left(1 - 60\frac{h_{\text{eff}}}{d}\right) \text{dB} > 0 \tag{5.14}$$

is introduced to account for reflections in the middle region by a ground attenuation equal to $-3q$ in the octave band centered at 63 Hz and equal to $-3q(1 - G_m)$ in all the higher octave bands up to 8 kHz center frequency, where G_m is the value of G in the middle region. Together with the assumption that sound is radiated into a half-space with solid angle 2π, there is a 6-dB increase in sound pressure level due to correlated ground reflection at 63 Hz, independent of ground porosity, and at higher frequencies for hard ground. Over porous ground, a 3-dB increase at higher frequencies is due to uncorrelated reflections.
- For the source and the receiver region, $q = 0.5$ accounts for the splitting of regions and G_m is replaced by G_S or G_R, where the indices S and R refer to the source and receiver regions, respectively. In addition, the following attenuations are taken into account for both regions in four octave bands:

Midband Frequency, Hz	Attenuation Contribution, dB	
125	$3Ge^{-[(h-5\text{m})/2.9\text{m}]^2}\left(1 - e^{-d/50\text{m}}\right)$	
	$+5.7Ge^{-(h/3.3\text{m})^2}\left(1 - e^{-(d/600\text{m})^2}\right)$	(5.15)
250	$8.6Ge^{-(h/3.3\text{m})^2}\left(1 - e^{-d/50\text{m}}\right)$	
500	$14Ge^{-(h/1.5\text{m})^2}\left(1 - e^{-d/50\text{m}}\right)$	
1000	$5Ge^{-(h/1.05\text{m})^2}\left(1 - e^{-d/50\text{m}}\right)$	

Largest attenuation occurs over porous ground in the octave band with center frequency 500 Hz. Consequently, the simplifying assumption that this frequency band is representative for the attenuation of A-weighted overall sound may not be conservative. Instead, it could actually underestimate the sound pressure level at the receiver.

The attenuation linearly increases with distance d up to about $d = 50$ m and then approaches a limit, except for the low-frequency band around 125 Hz, where a further extending ground wave is assumed.

Equations (5.15) show an exponential decay of attenuation with the square of receiver height. For the octave band at 500 Hz, the normalizing height in that band's equation is 1.5 m, roughly two wavelengths of sound. At 1000 Hz, this normalizing height is 1.05 m. The ratio of height to wavelength is similar in the relevant octave bands around 250 and 1000 Hz, indicating that the model is based on physical considerations together with experimental findings.

Despite essential simplifications compared to the heuristic model, the procedure described in ISO 9613-2 for octave-band calculations of ground attenuation is often replaced in practice by the procedure of Eq. (5.7) for A-weighted overall sound, mainly because ground factors G are often ambiguous.

The application of Eq. (5.15) to road and rail traffic noise with low source height is questionable. Ground effects near the source are already included in measured data. Uneven surfaces due to ditches for drainage are not covered by the model. Ground effects near the receiver can be excluded by an appropriate minimum height. Consequently, it has been decided that German guidelines for prediction of rail traffic noise, presently under revision, shall not account for frequency-dependent ground effects.

In contrast, U.S. requirements for road traffic computations consist of a more detailed computer model based on acoustical theory—the U.S. Federal Highway Administration (FHWA) Traffic Noise Model (TNM).[11] Version 2.5 of this model has been compared with more than 100 h of measured sound levels (L_{eq}) at 17 highway sites, most with flat terrain, with and without noise barriers. Measurements ranged to 400 m from the roadway during daytime hours under varying wind conditions. Under these conditions, the average difference between results of computations and measurements was within approximately 1 dB.[12]

Barriers

Any large and dense object that causes an acoustical shadow zone in the path of a sound ray is considered as a sound barrier. Such objects include walls, roofs, buildings, or the ground itself if it forms an edge or a hill. Sound penetrates into such shadow zones by diffraction and thereby suffers barrier attenuation D_z. The amount of attenuation is primarily determined by the Fresnel number

$$N = \frac{2z}{\lambda} \tag{5.16}$$

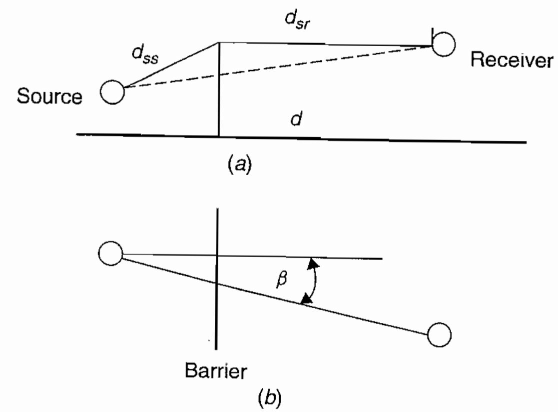

FIGURE 5.6 Barrier between source and receiver: (*a*) cross sectional view; (*b*) plan view.

where z is the increase in path length (the extension of a hypothetical rubber band between source and receiver) caused by one or more of the barrier edges and $\lambda = c/f$ is the wavelength of sound at frequency f. Note that z decreases with increasing angle of sound incidence β (see Fig. 5.6).

For $z = 0$ there is already a small barrier attenuation of about 5 dB plus an interference pattern at the edge of the shadow zone. Details of this interference pattern require a substantial computational effort that is not needed for engineering purposes. Therefore, preferred are simple approximations that are derived from extrapolations of the diffraction model and the ray-tracing model. When both models provide the same result for the line of sight over a hill or over undulating ground, the calculation of barrier insertion loss should be based on a limiting ($z = 0$) ground attenuation of about 5 dB independent of frequency, as described by Eq. (5.7). This consideration leads to the barrier insertion loss:

$$A_{\text{bar}} = \begin{cases} D_z - A_{\text{gr}} > 0 & \text{for diffraction over top edge of barrier} \\ D_z > 0 & \text{for diffraction around vertical edge of barrier} \end{cases} \tag{5.17}$$

where D_z is defined in Eq. (5.18).

Inclined barrier edges are considered to be top edges whenever the angle of inclination against the ground is less than 45°. Otherwise they are considered to be vertical edges.

Note in Eq. (5.17) that an intervening barrier causes the loss of all ground effects. At a height of 4 m or more over porous ground, this approximation is relatively accurate. Close to hard ground, however, it is not correct. Pressure doubling due to hard ground, which results in negative values of A_{gr}, persists even with intervening noise barriers and cannot result in larger values of A_{bar} than for porous ground.

The calculation of barrier attenuation is based on Huygens' model for wave fields, which takes all insonified points in a plane perpendicular to the ray from source to receiver as new sound sources. Points on a radius around the ray radiate with the same phase, varying between positive and negative values with increasing radius. Intervals between "phase zeros" in the hypothetical plane are called Fresnel zones. In free space, the contributions from neighboring Fresnel zones cancel each other, except for the center zone with the Fresnel radius $\sqrt{\lambda d_{so}}$, where d_{so} is the distance from the source to the plane. This center zone is the only uncanceled portion of the secondary wave front of Huygens' model and therefore is responsible for the entire sound field at the receiver. When this center zone is blocked by a barrier, the direct ray disappears.

In addition, a barrier partially blocks outer Fresnel zones and thereby inhibits the complete cancellation of their contributions. In the limit of many blocked Fresnel zones both above and on either side of the direct ray from the source to the receiver by a sufficiently high and long barrier, the intensity of the uncanceled portion decays with $1/N$; that is, the barrier attenuation increases with increasing path length difference over the top edge and with frequency.

Refined calculations of barrier attenuation include sound reflection at the barrier surface. When either the source or the receiver is close to a reflecting barrier surface, then the image source behind the barrier contributes almost as much to the sound field as does the actual source. This effect reduces the barrier attenuation but is often negligibly small.

Ground reflections can be important. When either the source or the receiver is high above the ground, ground-reflected contributions are relatively small due to relatively large path length differences z. But such high sources and receivers are generally not the case. Consequently, barrier attenuation over ground is computed 3 dB lower than the attenuation by a diffracting half-plane.

For outdoor sound propagation, the coherence of sound at different points in the sound field is reduced by wind and temperature fluctuations. This sets a limit for interference, depending upon the Fresnel radius and Fresnel number. Furthermore, one has to account for the curvature of rays due to gradients of wind and temperature. In the downwind direction, this curvature reduces the effective barrier height and the diffraction angle and, consequently, reduces the barrier attenuation—depending on the distance between the source, barrier, and receiver.

Theoretical and heuristic models have been developed to account for many or all of the effects just described. For prediction purposes, they suffer from the need for extremely detailed or unavailable input. In contrast, ISO 9613-2 requires less input—perhaps the upper limit of detail that can typically be obtained. In that standard, barrier attenuation is approximated by

$$D_z = 10 \lg (3 + 2NC_2C_3K_{\text{met}})\,\text{dB} < 20 \text{ dB for } C_3 = 1 (<25 \text{ dB for } C_3 > 1) \tag{5.18}$$

where $C_2 = 20$ and includes the effects of (1) sound rays from the source via the barrier edge to the receiver, (2) sound rays from the image source in the ground, and (3) sound rays to the image receiver in the ground (if ground reflections are taken into account separately in special cases, then $C_2 = 40$); $C_3 = 1$ for diffraction at a single edge but can increase to 3 for diffraction at two or more edges in series, according to

$$C_3 = \frac{1 + (5\,\lambda/e)^2}{1/3 + (5\,\lambda/e)^2} \tag{5.19}$$

with e as the path length from the first to the last diffracting edge; and K_{met} is a meteorological correction factor which accounts for down-wind ray curvature and is calculated from

$$K_{\text{met}} = \exp\left(-\frac{1}{2000\text{m}}\sqrt{\frac{d_{ss}d_{sr}d}{2z}}\right) \tag{5.20}$$

where d_{ss} is the path length from the source to the first diffracting edge, d_{sr} is the path length from the last diffracting edge to the receiver, and d is the path length without the barrier.

All of Eqs. (5.17)–(5.20) are conventions that are based on first-order approximations of theoretical relations, plus field experience, for sound propagation in a refracting atmosphere with curvature parameter $a > 0$. They can be applied for barriers of infinite or finite length on the ground, with one to three perpendicular diffracting edges. The barrier length must be large enough to meet the requirements for reflectors (see below). For example, this is true for typical railway barriers of 2 m height above the railhead. At a distance of 25 m and a height of 3.5 m above the railhead, the A-weighted sound pressure level of freight cars is reduced by about 11 dB.

Calculations of ISO 9613-2 do not include the case of barriers aloft, like shelter roofs at gas stations. If diffraction at a single edge is dominant for the received sound, the calculation should still be applicable, however. Contributions from more than one edge may be assumed as incoherent for sufficiently large barriers. Minimum dimensions must meet the requirements for reflectors.

Reflectors and Reverberation

Any large object—a wall, roof, building, or road sign, for example—that has plane surfaces in the path of a sound ray and that blocks an area with Fresnel radius at least $\sqrt{\lambda d_{so}}$ is considered to be a reflector. More specifically according to ISO 9613-2, the projection of the minimum dimension of the object in the direction of sound incidence shall meet the requirement

$$l_{\min} \cos\beta > \sqrt{\frac{2\lambda}{1/d_{so} + 1/d_{or}}} \tag{5.21}$$

where β is the angle of sound incidence on the reflecting plane and d_{so} and d_{or} are the path lengths from the reflection point to the source and to the receiver, respectively. Planes approximate nonplanar surfaces. Specular reflections are considered exclusively in terms of an image source (see Fig. 5.7).

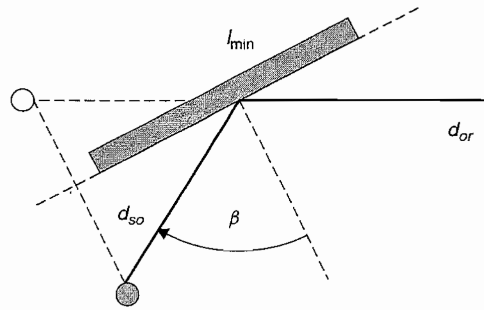

FIGURE 5.7 Specular reflection from a plane with minimum dimension l_{min}.

A reflection coefficient* $R < 1$ of the reflector reduces the sound power level of the image source by $-10\ \lg(R)$ dB. Diffuse reflections from rough building facades, which result in scattering of sound toward the sky, are generally taken into account with a reflection loss of 1 or 2 dB. The directivity of a source needs to be considered in the direction of a receiver image.

Atmospheric Absorption

The attenuation due to atmospheric absorption

$$A_{atm} = \alpha d \tag{5.22}$$

is theoretically well understood and fully described in ISO 9613-1.[13] For prediction purposes, one has to select the appropriate conditions of relative humidity, temperature, and ambient pressure. When low temperature and high humidity are assumed, the attenuation is relatively low around 500 Hz. In contrast, in the frequency bands at and above 4000 Hz, attenuation is high enough to reduce contributions to the A-weighted overall level to negligible values at distances of a few hundred meters. On the other hand, A_{atm} itself is mostly negligible in the frequency bands at and below 125 Hz. Table 5.2 contains selected values.

TABLE 5.2 Atmospheric Attenuation Coefficient α for Octave Bands of Noise at Selected Nominal Midband Frequencies[6]

		Atmospheric Attenuation Coefficient α, dB/km							
Temperature, °C	Relative Humidity, %	63 Hz	125 Hz	250 Hz	500 Hz	1000 Hz	2000 Hz	4000 Hz	8000 Hz
10	70	0.1	0.4	1.0	1.9	3.7	9.7	33	117
20	70	0.1	0.3	1.1	2.8	5.0	9.0	23	77
15	50	0.1	0.5	1.2	2.2	4.2	10.8	36	129
15	80	0.1	0.3	1.1	2.4	4.1	8.3	24	83

*ISO 9613-2 uses ρ instead of R.

Effects of Ground Cover and Trees

The consideration of ground cover and trees is often excluded from engineering prediction of excess attenuation in the propagation path of sound. The reason is twofold. The effect is small and unreliable. The situation is not only subject to seasonal variations but may change with different land use.

However, much money can be wasted building roadway noise barriers longer than truly needed if tree attenuation is ignored. This happens when barrier lengths are needlessly extended to reduce sound coming from far up and down the roadway—needlessly because trees adequately reduce that flanking sound by themselves. Note that sound arriving perpendicularly from the roadway might typically pass through only 50 m of trees, whereas sound arriving from far up and down the roadway passes through 500–1000 m of trees—for significant attenuation.

5.5 INTERACTION OF ELEMENTS AND CONTRIBUTIONS FROM VARIOUS PATHS

Standard Regulations for Consideration of Interactions

The attenuations discussed for individual elements in the propagation path of a sound ray are added to yield the total attenuation:

$$A = A_{div} + A_{gr} + A_{bar} + A_{atm} \tag{5.23}$$

where A_{div} = attenuation due to spherical spreading, predicted according to Eq. (5.5)
A_{gr} = attenuation due to ground effects, predicted according to Eqs. (5.7)–(5.10) and (5.14)–(5.15)
A_{bar} = attenuation due to diffraction at barrier edge, predicted according to Eqs. (5.16)–(5.20)
A_{atm} = attenuation due to atmospheric absorption, predicted according to Eq. (5.22)

The only interaction taken into account is that of barriers and ground, as described by Eq. (5.17). Reflections are assumed to result in incoherent contributions at the receiver.

Interaction of Barriers and Ground at Various Distances

Barriers on both sides of a roadway or railway provide at least two contributions to the total sound field at a receiver outside of the barriers—one by diffraction over the barrier at the receiver side and the second by reflection from the barrier on the other side—which may also suffer diffraction over the barrier on the receiver side (see Fig. 5.8). The second contribution is lower due to higher geometrical attenuation A_{div} but possibly higher due to lower barrier attenuation

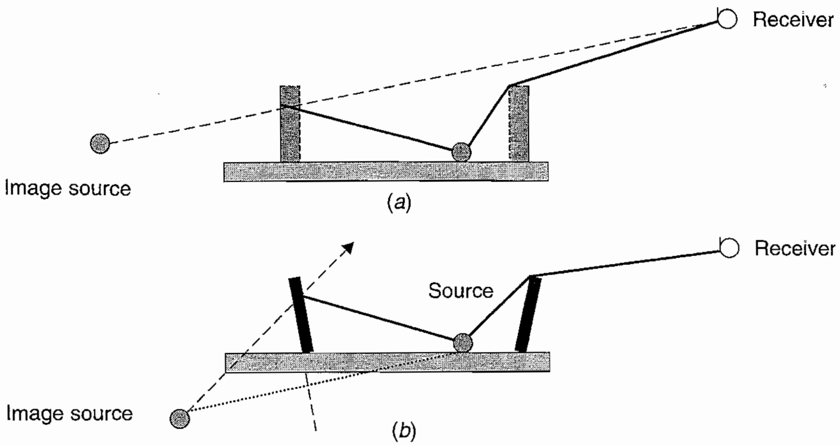

FIGURE 5.8 Sound rays from traffic lane shielded on both sides by (*a*) absorptive barriers and (*b*) inclined barriers.

A_{bar}. It generally needs to be reduced by absorptive or inclined barrier surfaces, which reduce the reflection toward the receiver.

Frequently discussed is the question of whether ground attenuation should be completely neglected for sound diffracted over the top of a barrier, as in Eq. (5.17). The reasoning to account for some ground attenuation in the barrier shadow zone is based on the assumption of an equivalent source at the diffracting edge. However, this assumption is not consistent with diffraction theory. There is no ray going out from the edge suffering attenuation just from divergence, but the diffracted field penetrates deeper and deeper into the shadow zone until it reaches the receiver. Since the ground effect on the receiver side is mostly determined by interference with a ground reflection close to the receiver, one has to consider two differently diffracted contributions, which are differently attenuated. Thus, the chance for considerable interference is reduced, particularly at high receiver positions. Of course, such an argument is valid only for meteorological conditions that provide no shadow formation. For greater accuracy at receiver positions near the ground, this interference is not neglected in the United States and Canada.

Barriers Close to Trees, with Gaps and Slots

The attenuation performance of barriers can be reduced by various influences. Past concern centered on trees or bushes that exceed the height of a nearby barrier. Experiments have shown that high-frequency components of noise are scattered by leaves into the barrier shadow zone.[14] However, this effect seems to be small compared to the better acceptability of "green" barriers.

Calculations with Eq. (5.18) assume that diffracted sound dominates in the barrier shadow zone. For this to be true, sound passing through the barrier must be negligible (down 5 dB or more) compared to the diffracted sound, which holds for a barrier relatively free of holes in its face and also free of a continuous gap between it and the ground. More sound energy gets through such holes/gaps than geometrically incident on the openings. Also required is a sufficiently large transmission loss through the surface material of the barrier. A mass per unit surface area (excluding framing) of 20 kg/m^2 is usually sufficient to provide a transmission loss of 25 dB or more at 500 Hz. Such weight is easily achievable with thickness and materials needed for mechanical stability of the barrier.

Procedures Applied by Computer Software

Engineering computer software for noise mapping is based on geometrical data provided by geographical information systems. The ground is often described by plane triangles; roads, railways, and barriers by sections of straight lines; and individual sources by points. Houses are modeled by rectangles. The handling of numerous data for larger areas requires a high degree of sophistication.

A sound ray may experience several reflections and may be diffracted on the path from source to receiver. Because of computer speed, current computer software can deal with many reflections with reasonable computation times. However, current software is not necessarily precise, due to approximate modeling of reflectors and reflection losses. Normally only three reflections are taken into account. Former consideration of reverberation in street canyons is excluded from current computations.

An essential part of the software is its validation by test cases[15]. This task does not aim for physical correctness but for consistency with the referenced calculation schemes. For this purpose, the program must be run in the same mode for test cases as for real applications—for example, the setting of software switches for accelerated computation.

5.6 ENGINEERING APPROACHES TO ACCOUNT FOR METEOROLOGY

Correction Terms C_{met} and C_0

The transfer function of Eq. (5.2), as specified by the attenuation in Eq. (5.23), leads from source properties to the equivalent continuous A-weighted sound pressure level L_{AT}(DW) for meteorological conditions that are favorable to sound propagation. This may be appropriate to meet specific restrictive requirements. A slightly better balance between interests of industry and neighborhood is the long-term A-weighted sound pressure level L_{AT}(LT), where the time interval T is several months or a year. Such a period will normally include a variety of sound propagation conditions, both favorable and unfavorable.

According to ISO 9613-2, a value L_{AT}(LT) may be obtained from the value of L_{AT}(DW) by subtraction of a meteorological correction term,

$$C_{\mathrm{met}} = \begin{cases} 0 & \text{if } d \leq 10(h_S + h_R) \\ C_0\left(1 - 10\dfrac{h_S + h_R}{d}\right) & \text{if } d > 10(h_S + h_R) \end{cases} \tag{5.24}$$

where C_0 (in decibels) depends on local meteorological statistics for wind speed and directions plus temperature gradients. Similar to Eq. (5.7), this subtracted term depends on the ratio of the effective height of the sound ray and distance, so that Fig. 5.4 gives a qualitative impression, except for distance. The correction term C_{met} is applied at somewhat larger distances. Experience indicates that values of C_0 are limited in practice between 0 and approximately 5 dB, with values in excess of 2 dB being exceptional.

Local Weather Statistics

Among the various procedures proposed for the calculation of C_0 from weather statistics is the following:

$$C_0(\alpha, g) = -10 \lg\left(\sum_{i=0}^{I-1} Q\frac{W_i(\theta_i)}{2}[1 + g - (1 - g)\cos(\theta_{\mathrm{rec}} - \theta_i)] + 1 - Q\right) \text{ dB} \tag{5.25}$$

where θ_{rec} = angle between North and the source-receiver line
g = parameter between 0.01 and 0.1 that accounts for attenuation in upwind direction
θ_i = angle between North and ith wind direction
W_i = probability for ith direction of wind
I = number of wind directions
$1 - Q$ = probability for no wind (calm)

Values of $g = 0.1$ and $g = 0.01$ correspond to a maximum upwind attenuation of 10 and 20 dB, respectively. Crosswind attenuation is less than 3 dB. Such values are effective for single point sources and wind always from the same direction. For extended sources (e.g., traffic lines or larger industrial areas), the appropriate averaging procedure typically results in values slightly smaller than 2 dB.

5.7 UNCERTAINTIES

General

The uncertainty of sound pressure levels calculated for a receiver position results from the uncertainty ΔL_W of the source level, determined, among other matters, by uncertain assumptions about the operating conditions of a sound source, the number of vehicles on a road, the roughness of rail heads, and the uncertainty

ΔA of the propagation losses. In the following, the uncertainty ΔA is discussed exclusively. However, note that uncertainties about source levels cannot always be neglected.

Elements

Uncertainty about spreading losses is generally small. Except for air traffic, distances between source and receiver can be determined very precisely. Effects of road traffic distribution on several parallel lanes are generally small if the most inner and outer lanes are modeled separately.

Uncertainty is significantly affected by effects of ground and meteorology. Very pronounced uncertainty has been obtained by Schomer[16] from long-term measurements with a loudspeaker centered at a height of 0.6 m above grassland and receivers at 1.2 m at distances up to 800 m. The standard deviation describing high portions of received octave-band levels is shown in Fig. 5.9.

At low frequencies up to 125 Hz and also at high frequencies above 2000 Hz, the standard deviation increases approximately continuously with distance and frequency, as one would expect. Anomalies can be seen in the intervening frequency bands. These anomalies can be attributed to variable ground interference. The low measurement height of 1.2 m may exaggerate the effect, though this receiver height is important to computations in the United States and Canada.

For special barrier-top design, a considerable uncertainty about barrier attenuation is found in the comparison of standard calculations with results calculated or measured in laboratories. However, in field tests such designs have hardly ever shown level differences of more than 1 dB at a distance of more than 25 m from a roadside or railway barrier. Source or receiver positions close to a barrier,

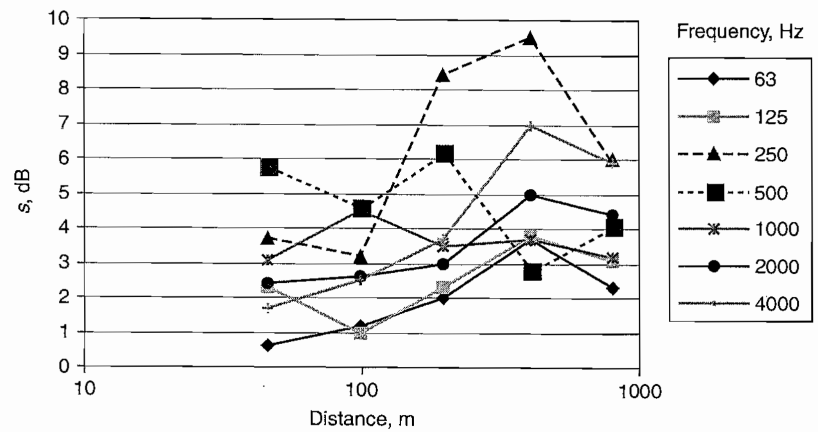

FIGURE 5.9 Standard deviation s of octave-band sound pressure levels for downwind condition at various distances from a loudspeaker centered at a height of 0.6 m and receiver height 1.2 m above grassland.

where reflections from the barrier surface or deep shadow zones play a role, are rarely met in practice, and therefore the laboratory effects are not observed in the field.

There is substantial uncertainty about the validity of the factor C_3 in Eq. (5.19). In many laboratory cases, multiple diffraction has shown an increase in barrier attenuation by more than 5 dB. But these cases are often related to barrier attenuations in excess of 20 dB. In practice, they depend significantly upon specific propagation paths from source to receiver.

Significant uncertainty exists for the meteorological correction factor of Eq. (5.20). It is matched to numerous data obtained for downwind situations at distances up to 1000 m over porous ground. Estimates for this uncertainty are about 2 dB, independent of distance, since the magnitude of barrier attenuation decreases with distance.

Uncertainty due to the roughness and absorption of reflecting surfaces is approximately 1 dB. In addition, limiting the number of reflections to three is sometimes not sufficient to let even a single computed sound ray enter through a passageway into a courtyard. It is obvious from such considerations that ray theory and specular reflections are limited to relatively open areas. Otherwise, standard deviations of more than 5 dB may occur. It is this consideration that partially argues for the U.S. and Canadian retention of line segment sources instead of point source approximations.

Uncertainty about atmospheric absorption may be calculated from the uncertainties of relative humidity, temperature, and ambient pressure. At low frequencies, that uncertainty is very small. At high frequencies, it is of little concern for engineering purposes. At frequencies around 500 Hz, the standard deviation is usually small compared to that of ground effects.

Overall A-Weighted Sound Pressure Level

The uncertainty for sound attenuation along the path of a ray in any frequency band increases with the square root of the sum of variances due to geometry, ground effects, barriers, reflectors, and atmospheric absorption. When several rays contribute to the sound pressure level at the receiver, the variances must be weighted according to their energy and the sum is divided by the total energy. This summation of uncorrelated partial uncertainties results in a reduction of the total uncertainty.

The uncertainty for the A-weighted overall sound pressure level may be calculated from the variances in octave bands, weighted according to their energy. When a number of n frequency bands equally contribute to the overall level, the uncertainty is reduced by a factor $1/\sqrt{n}$.

Approximately consistent with estimated accuracies in ISO 9613-2 is the standard deviation reported by Schomer[16] for the A-weighted overall sound pressure level received from a source of pink noise.[14] At distances from 100 to 800 m and an average height above grassland of 0.9 m, that standard deviation was about 3 dB. At an average height above 5 m, ISO 9613-2 estimates an accuracy of 1 dB. Advanced procedures for calculation of outdoor noise levels aim for an accuracy with a standard deviation of 1 dB up to a distance of 1000 m over flat terrain and of 2.5 dB over hilly terrain.[3]

6.1 INTRODUCTION

Only in an anechoic room may sound waves travel outwardly in any direction without encountering reflecting surfaces. In practice, one must deal with every shape and size of enclosure containing an infinite variety of sound-diffusing, sound-reflecting, and sound-absorbing objects and surfaces. However, in small rooms of fairly regular shape, with smooth walls, the sound is not statistically diffuse and will depend on the acoustical modal response in the room. Typical examples where this is the case are the passenger compartments of transportation vehicles, ductwork and small rooms in buildings, enclosures used to enhance the response of audio equipment, and enclosures designed for sound isolation. Because of the need to understand the modal nature of sound in such enclosures, this chapter will describe the governing equations, the modal theory, and its application for determining and controlling the interior acoustical response. While the modal theory for rectangular enclosures is described in most standard textbooks on acoustics,[1–5] the extended approach for irregular geometries and the use of advanced numerical techniques are more amenable to practical application and are also described here.

6.2 SOUND IN A VERY SMALL ENCLOSURE

Before considering the more general case, it will be instructive to consider the sound pressure response in a very small enclosure. Frequently, in noise control problems, a noise source is enclosed in a very small box to prevent it from radiating noise to the exterior, as conceptually represented in Fig. 6.1*a*. When the noise source has a frequency low enough so that the wavelength of the

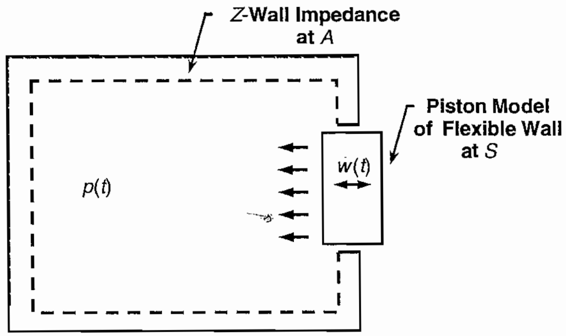
(*a*) Interior Noise Source



(*b*) Vibrating Flexible Wall

FIGURE 6.1 Sound in small enclosure with impedance boundaries generated by (*a*) interior noise source and (*b*) piston model of flexible-wall vibration. Symbols: $p(t)$, sound pressure; $Q(t)$, volume velocity; Z, wall impedance; A, impedance wall area; $\dot{w}(t)$, piston velocity; S, piston area.

sound is long compared to the largest distance of the box, the sound pressure produced by the source will be uniform throughout the entire cavity. A uniform sound pressure field will also be created in an enclosure when the walls of the enclosure are forced to vibrate at low frequency by the pressures of an external sound source, as conceptually represented by the vibrating piston in Fig. 6.1*b*. Frequently, the walls of the enclosure will be damped by applying panel-damping treatment or absorption material over the walls.

The uniform sound pressure $p(t)$ in such an enclosure will satisfy an extended form of Eq. (2.9) as $(1/P)dp/dt + (\gamma/V)d\tau/dt = (\gamma/V)Q(t)$, where $Q(t)$ is the *volume velocity* of the sound source (m^3/s), V is the enclosure volume, P is the ambient air pressure, and $\tau(t)$ is the volume variation. At the wall area A (m^2)

in Fig. 6.1*a* or *b*, the specific acoustical impedance is $Z = p/u$ and the particle velocity is $u(t)$, so $d\tau/dt = Au = Ap/Z$. Since $c^2 = \gamma P/\rho$ by Eq. (2.12), the uniform sound pressure in the enclosure satisfies

$$\frac{dp}{dt} + 2\delta p = \left(\frac{\rho c^2}{V}\right) Q(t) \qquad (6.1)$$

where $\delta = \rho c^2 A/(2VZ)$. For steady-state excitation, $Q(t) = \hat{Q}\cos(\omega t + \phi)$, which is the volume velocity of the source operating at the forcing frequency $f = \omega/2\pi$ (hertz) with the volume velocity amplitude $\hat{Q}$ and phase ϕ. The steady-state sound pressure in the enclosure is then $p(t) = p_0 \cos(\omega t + \theta_0)$, with the sound pressure amplitude and phase given by

$$p_0 = \frac{\rho c^2 \hat{Q}}{V[(\omega + 2\delta_i)^2 + (2\delta_r)^2]^{1/2}} \quad \text{N/m}^2$$
$$\theta_0 = \phi - \tan^{-1}\frac{\omega + 2\delta_i}{2\delta_r} \quad \text{rad} \qquad (6.2)$$

Here $\delta = \delta_r + i\delta_i$ is a complex damping factor ($i = \sqrt{-1}$) that accounts for the acoustical impedance $Z = R + iX$ of the wall area A, where

$$\delta_r = \frac{cA}{2V}\mathrm{Re}\frac{\rho c}{Z} \qquad \delta_i = \frac{cA}{2V}\mathrm{Im}\frac{\rho c}{Z} \quad \text{s}^{-1} \qquad (6.3)$$

For the interior noise source in Fig 6.1*a*, $Q(t)$ is taken as positive for outward volume flow, while for the flexible-wall vibration in Fig. 6.1*b*, $Q(t) = -S\dot{w}(t)$ is an *equivalent* volume velocity with outward piston velocity $\dot{w}(t)$ taken as positive.

From Eq. (6.2), we see that the amplitude p_0 of the sound pressure in the enclosure depends, not only on the noise source amplitude $\hat{Q}$ and forcing frequency $f = \omega/2\pi$, but also on the enclosure volume V and total wall impedance in δ. For a rigid-wall enclosure, $|Z| \to \infty$, so that $\delta_r, \delta_i = 0$, and

$$p_0 = \frac{\rho c^2 \hat{Q}}{\omega V} \quad \text{N/m}^2$$
$$\theta_0 = \phi - \tfrac{1}{2}\pi \quad \text{rad} \qquad (6.4)$$

In this case, the sound pressure depends only on the amplitude and frequency of the volume velocity of the source and on the enclosure volume. The sound pressure lags the volume velocity by exactly 90°, indicating that the source does not radiate any acoustical power.

Example 6.1. The piston of Fig. 6.1*b* has an area of 1 cm^2 and is driven harmonically with a peak-to-peak displacement of 4 mm at a frequency of 100 Hz.

The volume of the cavity is 0.0125 m^3 and it has rigid walls. What is the sound pressure level in the cavity?

Solution For harmonic displacement excitation $w = \hat{w} \sin \omega t$, and we obtain $\dot{w} = (\omega\hat{w}) \cos \omega t = \hat{\dot{w}} \cos \omega t$, so that $\hat{\dot{w}} = \omega\hat{w}$. Therefore, $\hat{Q} = S\hat{\dot{w}} = S\omega\hat{w}$ and from Eq. (6.4),

$$p_0 = \frac{\rho c^2 S\hat{w}}{V} = \rho c^2 \frac{\Delta\hat{V}}{V} \quad \text{N/m}^2 \tag{6.5}$$

where $\Delta\hat{V} = S\hat{w}$ is the volume change of the enclosure due to the piston displacement. Inserting the appropriate numerical values, we have $\Delta\hat{V} = 10^{-4} \times 2 \times 10^{-3} = 2 \times 10^{-7}$ m^3, so that

$$p_0 = 1.21 \times 343^2 \times \frac{2 \times 10^{-7}}{1.25 \times 10^{-2}} = 2.28 \text{ N/m}^2$$

The sound pressure level is then

$$L_p = 20 \log_{10} \frac{p_{\text{rms}}}{p_{\text{ref}}} = 20 \log_{10} \frac{0.707 \times 2.28}{2 \times 10^{-5}} = 98 \text{ dB}$$

Example 6.2. A noise source is enclosed in a very small box, as in Fig. 6.1*a*, that has flexible but very stiff walls. Determine the formula for the interior sound pressure.

Solution For a mass–spring–dashpot model of the box walls, the acoustical impedance is $Z = A^{-1}[C + i\omega(M - K/\omega^2)]$, where A is the wall surface area and C, M, K are overall values of wall damping, mass, and stiffness. For very stiff walls, $Z \approx -iK/A\omega$ so that, from Eq. (6.3),

$$\delta_r = 0 \qquad \delta_i = \frac{\omega}{2}\frac{\rho c^2 A^2/V}{K} = \frac{\omega}{2}\frac{K_{\text{air}}}{K} \quad \text{s}^{-1}$$

where $K_{\text{air}} = \rho c^2 A^2/V$ (N/m) is the *stiffness* of the air and K (N/m) is the wall stiffness. Substituting δ_r and δ_i into Eq. (6.2) then gives

$$p_0 = \frac{1}{1 + K_{\text{air}}/K}\frac{\rho c^2 \hat{Q}}{\omega V} \quad \text{N/m}^2 \tag{6.6}$$
$$\theta_0 = \phi - \tfrac{1}{2}\pi \quad \text{rad}$$

Note that the sound pressure in an enclosure with compliant walls is lower than the sound pressure in an equivalent rigid-wall enclosure given by Eq. (6.4), and the addition of damping to the walls can be shown to produce a similar effect.

Example 6.3. A *Helmholtz resonator* is a rigid-wall enclosure with a small aperture of cross-sectional area S that connects the enclosure to a column of air of length L that oscillates as the piston in Fig. 6.1*b*. Determine the natural frequency.

Solution The mass of the column of air is $M = \rho SL$ and the force on it is pS. Hence we must have $M\ddot{w} = pS$, where $\dot{w}$ is the velocity of the air column. Since $\hat{\dot{w}} = \omega\hat{w}$, we obtain $\hat{Q} = S\hat{\dot{w}} = S^2 p_0/\omega M$. Substituting this for $\hat{Q}$ in Eq. (6.4) gives $(1 - \rho c^2 S^2/\omega^2 MV)p_0 = 0$ or $(1 - K_{\text{air}}/\omega^2 M)p_0 = 0$, where $K_{\text{air}} = \rho c^2 S^2/V$ is the air stiffness. The natural frequency is then $\omega_0 = \sqrt{K_{\text{air}}/M} = c\sqrt{S/LV}$.

6.3 GOVERNING EQUATIONS FOR ACOUSTICAL MODAL RESPONSE

For larger enclosures or for higher frequencies, the sound pressure field in the enclosure is no longer uniform but depends on the acoustical modal response in the enclosure. More importantly, the sound pressure can be amplified considerably near discrete frequencies corresponding to the acoustical cavity resonances. This modal nature of sound in an enclosure results from the superposition of sound waves that propagate according to the well-known *acoustical wave equation* [Eq. (2.13)],

$$\nabla^2 p - \frac{\ddot{p}}{c^2} = 0 \quad \text{N/m}^4 \tag{6.7}$$

where $\ddot{p}$ denotes the second partial derivative with respect to time t.

Noise sources interior to an enclosed cavity can be included as forcing terms in the wave equation. For the example of a monopole source (e.g., a loudspeaker in a cabinet) as in Fig. 6.1*a*, the time-varying mass flow rate is $\dot{m}(x, y, z, t) = \rho Q(x, y, z, t)$ (kg/s), so that

$$\nabla^2 p - \frac{\ddot{p}}{c^2} = -\frac{\rho\dot{Q}}{V} \quad \text{N/m}^4 \tag{6.8}$$

where $\dot{Q} = \partial Q/\partial t$. Other interior sources can be represented as combinations of monopole sources or else can be included directly in the wave equation in a similar manner. For simple harmonic motion, $p(x, y, z, t) = \text{Re}[\hat{p}(x, y, z)\exp(i\omega t)]$ and $Q(x, y, z, t) = \text{Re}[\hat{Q}(x, y, z)\exp(i\omega t)]$, and we obtain the inhomogeneous *Helmholtz equation* for the steady-state sound pressure response,

$$\nabla^2\hat{p} + \left(\frac{\omega}{c}\right)^2 \hat{p} = -\frac{i\omega\rho\hat{Q}}{V} \quad \text{N/m}^4 \tag{6.9}$$

where $f = \omega/2\pi$ (Hz) is the forcing frequency of the vibration and $\lambda = c/f$ (m) is the wavelength of the sound produced by the source.

The boundary conditions for p determine the reflection, absorption, and transmission of the sound waves at the enclosure's surfaces and are derived from fluid mechanical considerations.[6] For small-amplitude motions, a momentum balance at the boundary requires that the air particle velocity u normal to the boundary surface be related to p through

$$\frac{1}{\rho}\frac{\partial p}{\partial n} = -\dot{u} \quad \text{m/s}^2 \tag{6.10}$$

where $\partial/\partial n$ is the outward surface-normal derivative. For an impervious wall surface, u is the normal-velocity component of the air into the pores of the surface. Table 6.1 lists the boundary conditions for different wall surfaces and air interfaces that are characterized by their acoustical impedance Z and surface-normal vibration velocity $\dot{w}$. In what follows, we will investigate the steady-state, random, and transient sound pressure response in enclosures with flexible, absorbent boundaries where Z and $\dot{w}$ are defined as in Table 6.1.

6.4 NATURAL FREQUENCIES AND MODE SHAPES

Acoustical resonances that result in high sound pressure occur at discrete natural frequencies in an enclosed cavity. The acoustical resonances are found from the free-vibration solution of the wave equation by substituting $p_n = p_{n0}\Psi_n(x, y, z)\exp(i\omega_n t)$, which gives

$$\nabla^2\Psi_n + \left(\frac{\omega_n}{c}\right)^2\Psi_n = 0 \quad \text{m}^{-2} \tag{6.11}$$

with free-vibration boundary conditions for the walls. The nondimensional pressure distributions $\Psi_n(x, y, z)$ for $n = 0, 1, 2, \ldots$ are the *mode shapes*, with $f_n = \omega_n/2\pi$ (Hz) being the corresponding *natural frequencies*. For absorbent boundaries, the mode shapes and natural frequencies are complex, and the acoustical modes are damped. However, for rigid boundaries ($|Z| \to \infty$) or for fully reflective open boundaries ($|Z| = 0$), one obtains real, undamped modes, or *standing waves*, that depend only on the geometrical shape of the cavity.

Table 6.2 gives formulas for the natural frequencies and mode shapes of the undamped acoustical modes of a few regular-shape enclosures with rigid walls as well as those of a tube with fully reflective and open boundaries. (A more complete list can be found in ref. 7.) One can show that the acoustical modes are orthogonal over the cavity volume such that

$$\int_V \Psi_m\Psi_n\,dV = \begin{cases} 0 & m \neq 0 \\ V_n & m = n \end{cases} \quad \text{m}^3 \tag{6.12}$$

and constitute *normal modes* of the enclosure. In Table 6.2, the number of indices used to identify each mode is based on the dimensionality of the enclosure, whereas we have used a single index to identify a mode, so the equivalence for a three-dimensional enclosure would be $f_n \equiv f_{ijk}$ and $\Psi_n \equiv \Psi_{ijk}$.

TABLE 6.1 Acoustical Boundary Conditions

Type	Boundary Condition	Air Particle Velocity
1. Rigid wall 	$\frac{\partial p}{\partial n} = 0$	$u = 0$

[a]From Ref. 6.

It is noteworthy that the first natural frequency of a cavity that is completely enclosed by rigid walls is zero, $f_0 = 0$, and is a *uniform pressure mode* (sometimes called a *Helmholtz mode*) with $\Psi_0 = 1$ and

$$V_0 = \int_V \Psi_0^2 \, dV = V \quad \text{m}^3 \tag{6.13}$$

where V is the volume of the enclosure. Also, the fundamental frequency of the first spatially varying mode in an enclosed cavity is approximately $f_1 = c/2L$ (Hz), where L is the maximum linear dimension of the cavity.

For a cavity with an open boundary, the $n = 0$ mode is absent because a (nonzero) uniform pressure cannot be sustained. Also, the natural frequencies and mode shapes in Table 6.2 for a tube with an open boundary are approximate because the boundary condition ($p \approx 0$) does not fully model the exact physics of the acoustical behavior at an open boundary. The accuracy of the formulas in Table 6.2 for an open tube increases with increasing slenderness of the tube. In general, the dimension of the open boundary must be small compared with the acoustical wavelength so that the sound is fully reflected from the open boundary.

Example 6.4. A closed rectangular cavity has dimensions $0.41 \times 0.51 \times 0.61$ m. From Table 6.2, frame 4, the formulas for the normal-mode frequencies and mode shapes are

$$\begin{aligned} f_{ijk} &= \frac{c}{2}\sqrt{\left(\frac{i}{L_x}\right)^2 + \left(\frac{j}{L_y}\right)^2 + \left(\frac{k}{L_z}\right)^2} \quad \text{Hz} \\ \Psi_{ijk} &= \cos\frac{i\pi x}{L_x}\cos\frac{i\pi y}{L_y}\cos\frac{i\pi z}{L_z} \end{aligned} \tag{6.14}$$

Let $L_x = 0.61$ m, $L_y = 0.51$ m, and $L_z = 0.41$m. (a) Find the natural frequencies of the $i = 2$, $j = 0$, $k = 0$; the $i = 1$, $j = 1$, $k = 0$; and the $i = 2$, $j = 1$, $k = 0$ normal modes of vibration. (b) Plot the sound pressure distribution for these three normal modes of vibration. The speed of sound, adjusted for temperature, is 347.3 m/s.

Solution

(a) From Eq. (6.13) we have

$$f_{2,0,0} = \frac{347.3}{2}\sqrt{\left(\frac{2}{0.61}\right)^2} = 569.3 \text{ Hz}$$

$$f_{1,1,0} = \frac{347.3}{2}\sqrt{\left(\frac{1}{0.61}\right)^2 + \left(\frac{1}{0.51}\right)^2} = 443.8 \text{ Hz}$$

$$f_{2,1,0} = \frac{347.3}{2}\sqrt{\left(\frac{2}{0.61}\right)^2 + \left(\frac{1}{0.51}\right)^2} = 663.4 \text{ Hz}$$

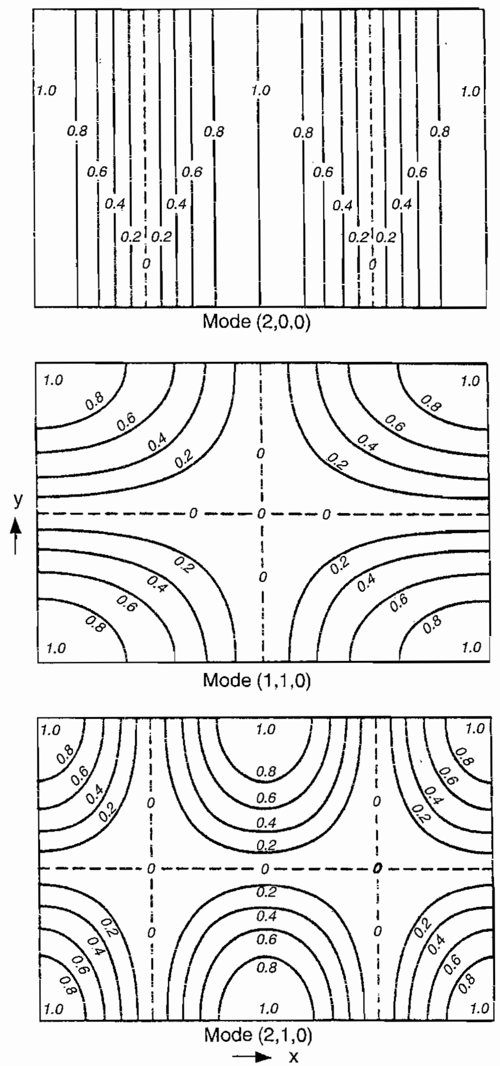

FIGURE 6.2 Sound pressure contour plots of a section through a rectangular enclosure for three different modes of vibration. The numbers on the plots indicate the relative sound pressure amplitude.

(b) The pressure distributions $|\Psi_{ijk}|$ of the modes are shown in Fig. 6.2, where the normalization is such that the maximum pressure at the corners is $|\Psi_{ijk}| = 1$. The minimum sound pressure occurs at the nodal surfaces for which $|\Psi_{ijk}| = 0$. Since $k = 0$ for all three modes, the pressure distributions are uniform in the z direction.

6.5 NUMERICAL METHODS FOR ACOUSTICAL ANALYSIS

For simple geometries and boundary conditions, the acoustical modes can be expressed analytically as in Table 6.2, but for more complicated geometries and boundary conditions numerical approaches such as the finite-element method or the boundary-element method are required.[8] The finite-element method is based upon the representation of the interior of the enclosure by a finite number of interconnected *volume* elements. The boundary-element method is based upon the representation of only the boundary surface of the enclosure by a finite number of interconnected *planar* elements. While both the finite-element method and the boundary-element method were originally developed for structural analysis, they are applicable to numerous nonstructural problems, and the acoustical cavity problem falls into this category. The major advantage of the boundary-element method is the reduction in modeling effort that is required because only the surface of the enclosure needs to be meshed. On the other hand, the finite-element method generally results in banded, frequency-independent, real matrices that require significantly less computational time when solving for the acoustical response.

To illustrate a numerical acoustical modal analysis of a complex-shaped enclosure, Fig. 6.3 shows the application of the acoustical finite-element method to an automobile passenger compartment. The acoustical finite-element model in Fig. 6.3*a* was developed from linear hexahedral and pentahedral elements, where only a half-model is required because of symmetry.[9] The model can be solved to obtain the acoustical modes by implementing a structural finite-element code and using the *structural–acoustical analogy*[10] outlined in Table 6.3. By specifying the structural material properties in terms of the acoustical material properties as shown in Table 6.3, the structural equations of motion reduce to the acoustical wave equation and the structural boundary conditions reduce to the required acoustical boundary conditions. The accuracy of the modal solution will be proportional to $(n/N)^2$ when using linear elements, where n is the mode number and N is the number of elements in a particular direction. Generally, accuracy to within 10% in frequency can be expected for the first four modes in a particular direction when there are about 10 linear elements in that direction.

The first acoustical mode predicted by the passenger compartment finite-element model in Fig. 6.3*a* is shown in Fig. 6.3*b*. It is a longitudinal mode with the nodal surface passing vertically through the passenger compartment. The nodal surface on which $|\Psi_n| = 0$ and the antinodal surfaces on which $|\Psi_n|$ is a local maximum are of practical importance because they indicate low- and high-noise regions, respectively, which result from excitation of the mode. For the example in Fig. 6.3*b*, excitation of the mode may go unnoticed by a front-seat occupant because of the proximity of the nodal surface, but it may be heard by a rear-seat occupant. The situation is just the opposite for the second mode illustrated in Fig. 6.3*c*. Because of the irregular geometrical shape of the compartment, these modes could not be predicted by simple formulas like those presented in Table 6.2. However, the numerical approach provides a method to predict the

FIGURE 6.3 Acoustical finite-element analysis of automobile passenger compartment to determine the acoustical mode shapes and natural frequencies. The mode shapes become increasingly more complex as the natural frequency increases and as the complexity of the enclosure geometry increases.

TABLE 6.3 Structural–Acoustical Analogy

Description	Structure	Analogy	Acoustical Cavity
Finite element	 $w_k = \sum_{I=1}^{N} (W_k)_I N_I^k \quad k = x, y, z$	$w_x = p$ $N_I^z = N_I$	 $p = \sum_{l=1}^{N} p_l N_l$
Constitutive equations	$\begin{pmatrix} \sigma_{xx} \\ \tau_{xy} \\ \tau_{xz} \end{pmatrix} = \begin{pmatrix} G_{11} & G_{14} & G_{16} \\ G_{14} & G_{44} & G_{46} \\ G_{16} & G_{46} & G_{66} \end{pmatrix} \begin{pmatrix} \varepsilon_{xx} \\ \gamma_{xy} \\ \gamma_{xz} \end{pmatrix}$	$\sigma_{xx} = u_x \quad \dfrac{\partial w_x}{\partial x} = \dfrac{\partial p}{\partial x}$ $\tau_{xy} = u_y \quad \dfrac{\partial w_x}{\partial y} = \dfrac{\partial p}{\partial y}$ $\tau_{xz} a = u_z \quad \dfrac{\partial w_x}{\partial z} = \dfrac{\partial p}{\partial z}$	$\begin{pmatrix} u_x \\ u_y \\ u_z \end{pmatrix} = \begin{pmatrix} -1/\rho & 0 & 0 \\ 0 & -1/\rho & 0 \\ 0 & 0 & -1/\rho \end{pmatrix} \begin{pmatrix} \partial p/\partial x \\ \partial p/\partial y \\ \partial p/\partial z \end{pmatrix}$
Equilibrium equations	$\dfrac{\partial \sigma_{xx}}{\partial x} + \dfrac{\partial \tau_{xy}}{\partial y} + \dfrac{\partial \tau_{xz}}{\partial z} = -\rho_s \ddot{w}_x$	Material properties $G_{11} = 1/\rho$ $G_{44} = 1/\rho$ $G_{66} = 1/\rho$ $G_{14} = 0$ $G_{16} = 0$ $G_{46} = 0$ $\rho_s = 1/\rho c^2$	$\dfrac{\partial u_x}{\partial x} + \dfrac{\partial u_y}{\partial y} + \dfrac{\partial u_z}{\partial z} = -\dfrac{1}{\rho c^2} \ddot{p}$
Finite-element equations	$([K] - \omega^2[M])\{w\} = \{0\}$ $K_{ij} = \int_V \{\nabla N_i^x\}^{\mathrm{T}} [G] \{\nabla N_i^x\}\, dV$ $M_{ij} = \int_V \rho_s N_i N_j \, dV$		$([K] - \omega^2[M])\{p\} = \{0\}$ $K_{ij} = \int_V \dfrac{1}{\rho} \{\nabla N_i\}^{\mathrm{T}} \{\nabla N_j\}\, dV$ $M_{ij} = \int_V \dfrac{1}{\rho c^2} N_i N_j \, dV$

acoustical modes, which can then be used to predict the forced sound pressure response by the methods of the following sections.

6.6 FORCED SOUND PRESSURE RESPONSE IN ENCLOSURE

Often the sound pressure response in an enclosure for known sound sources is of interest. The enclosure may be complicated in shape, and it may have walls that are both flexible and absorbent as well as multiple interior surfaces. If the undamped modes $\Psi_n(x, y, z)$ and natural frequencies $f_n = \omega_n / 2\pi$ for $n = 0, 1, 2, \ldots$ are known, the forced acoustical response in such an enclosure can be directly expressed using the *modal analysis* technique as the *normal-mode expansion*,[11,12]

$$p(x, y, z, t) = \sum_n P_n(t) \Psi_n(x, y, z) \quad \mathrm{N/m^2} \tag{6.15}$$

where the P_n are time-varying coefficients that must be determined to satisfy the acoustical wave equation, the boundary conditions, and the initial conditions.

For flexible and absorbent boundaries described by the boundary conditions in Table 6.1, the modal coefficients $P_n(t)$ are determined from

$$\ddot{P}_n + 2\delta_n \dot{P}_n + \omega_n^2 P_n = \frac{\rho c^2}{V_n} F_n(t) \quad \mathrm{N/m^2 \cdot s^{-2}} \tag{6.16}$$

where V_n is given by Eq. (6.12) and $F_n(t)$ is the *modal force*,

$$F_n(t) = \int_V \frac{\dot{Q}}{V} \Psi_n \, dV - \int_S \ddot{w} \Psi_n \, dS \quad \mathrm{m^3/s^2} \tag{6.17}$$

Q is the volume velocity of interior noise sources, and $\dot{w}$ is the vibration velocity of the wall panels at the boundary surface S. The integrations are carried out over the enclosure volume V and the wall panel surface S, respectively. In Eq. (6.16), δ_n is the *modal damping constant* or *modal damping decrement*, which as defined here is complex and given by

$$\delta_n = \delta_n^r + i\delta_n^i = \frac{\rho c^2}{2V_n} \int_A \frac{\Psi_n^2}{Z} \, dA \quad \mathrm{s^{-1}} \tag{6.18}$$

where $Z = R + iX$ is the complex wall impedance and the integration is carried out over the impedance wall area A. Table 6.1 determines the particular interpretation of $\dot{w}$ and Z in Eqs. (6.17) and (6.18) for different boundaries. The undamped modes Ψ_n are assumed to satisfy the rigid-wall boundary condition $(\partial \Psi_n / \partial n = 0)$ on both the wall panel surface S and the impedance boundary A.

From Eq. (6.18), the real and imaginary parts of δ_n can be expressed as [cf. Eq. (6.3)]

$$\delta_n^r = \frac{cA_n}{2V_n} \mathrm{Re} \frac{\rho c}{Z_n} \qquad \delta_n^i = \frac{cA_n}{2V_n} \mathrm{Im} \frac{\rho c}{Z_n} \quad \mathrm{s^{-1}} \tag{6.19}$$

where Z_n is an average impedance for the nth mode and

$$\frac{\rho c}{Z_n} = \frac{1}{A_n}\int_A \frac{\rho c}{Z}\Psi_n^2\, dA \qquad \text{where} \qquad A_n = \int_A \Psi_n^2 dA \tag{6.20}$$

When the wall impedance Z does not vary over the wall surface area A, Eq. (6.20) results in $\rho c/Z_n \equiv \rho c/Z$, as expected. Recalling the real and imaginary interpretation of the acoustical impedance in Eq. (6.19), we observe that δ_n^r relates to the wall resistivity ($\sim$ damping) and δ_n^i relates to the wall reactance ($\sim$ flexibility). In the above formulation, we have assumed that "light damping" exists such that $|\delta_n^r| \ll \omega_n$ and $|\delta_n^i| \ll \omega_n$. For more "heavily damped" enclosures that often occur in practice, the modal equations (6.16) are coupled through the boundary impedance and the wall flexibility, and they must be solved simultaneously. A complete discussion of the procedure is given in references 12 and 13.

Example 6.5. The acoustical modes Ψ_n and natural frequencies ω_n are given by the finite-element analysis in Table 6.3. Determine the normal-mode expansion for the forced sound pressure response.

Solution From the finite-element analysis, the acoustical modes are given as the $M \times N$ matrix

$$\{\Psi_1\Psi_2\cdots\Psi_n\cdots\Psi_N\} = \begin{bmatrix} \psi_{11} & \psi_{12} & \cdots & \psi_{1n} & \cdots & \psi_{1N} \\ \psi_{21} & \psi_{22} & \cdots & \psi_{2n} & \cdots & \psi_{2N} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \psi_{m1} & \psi_{m2} & \cdots & \psi_{mn} & \cdots & \psi_{mN} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \psi_{M1} & \psi_{M2} & \cdots & \psi_{Mn} & \cdots & \psi_{MN} \end{bmatrix} \tag{6.21}$$

where each row m corresponds to the response at a particular grid point of the finite-element model and each column n corresponds to the response of a particular mode. In matrix form, the normal-mode expansion in Eq. (6.15) for the forced sound pressure response then becomes

$$\begin{bmatrix} p_1(t) \\ p_2(t) \\ \vdots \\ p_m(t) \\ \vdots \\ p_M(t) \end{bmatrix} = \begin{bmatrix} \psi_{11} & \psi_{12} & \cdots & \psi_{1n} & \cdots & \psi_{1N} \\ \psi_{21} & \psi_{22} & \cdots & \psi_{2n} & \cdots & \psi_{2N} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \psi_{m1} & \psi_{m2} & \cdots & \psi_{mn} & \cdots & \psi_{mN} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ \psi_{M1} & \psi_{M2} & \cdots & \psi_{Mn} & \cdots & \psi_{MN} \end{bmatrix} \begin{bmatrix} P_1(t) \\ P_2(t) \\ \vdots \\ P_n(t) \\ \vdots \\ P_N(t) \end{bmatrix} \tag{6.22}$$

Each modal coefficient $P_n(t)$ is determined from Eq. (6.16) with ω_n known and $V_n = \{\Psi_n\}^{\mathrm{T}}[M]\{\Psi_n\}$, where superscript T indicates the transpose and $[M]$ is developed in the finite-element analysis as in Table 6.3. The modal forcing in Eq. (6.16) is

$$\{F_n(t)\} = [\Psi]^{\mathrm{T}}(\{\dot{Q}\} - [S]\{\ddot{w}\}) \tag{6.23}$$

where $\{\dot{Q}\}$ and $\{\ddot{w}\}$ are vectors of the grid point volume acceleration and wall panel acceleration and $[S]$ is a matrix of surface areas associated with each wall panel grid. Similarly, the damping constant in Eq. (6.16) is

$$\{\delta_n\} = \frac{\rho c^2}{2V_n}[\Psi]^{\mathrm{T}}\left[\frac{A}{Z}\right][\Psi] \tag{6.24}$$

where $[A/Z]$ is a matrix of grid point impedance values weighted by the surface area A_m associated with each grid point m. Most structural finite-element computer codes, when adapted for acoustical normal-mode analysis according to Table 6.3, also have capabilities for modal frequency response and modal transient response to give the forced sound pressure response in the form of Eq. (6.22).

6.7 STEADY-STATE SOUND PRESSURE RESPONSE

The steady-state sound pressure in an enclosure is often of interest where the noise emanates from a point source, as in Fig. 6.1*a*. For a point source located at (x_0, y_0, z_0) and having a steady-state volume velocity $\hat{Q}\cos(\omega t + \phi)$, the mass flow rate from the source can be mathematically represented using the Dirac delta function as $\dot{m}(x, y, z, t) = \rho\hat{Q}\delta(x - x_0)\delta(y - y_0)\delta(z - z_0)\cos(\omega t + \phi)$. At a particular forcing frequency $f = \omega/2\pi$, the sound pressure response in the enclosure can then be obtained from Eqs. (6.15)–(6.17) by using the *frequency response function* technique,

$$p(x, y, z, t) = \sum_n p_n(x, y, z, \omega)\cos(\omega t + \theta_n) \qquad \mathrm{N/m^2} \tag{6.25}$$

where

$$p_n(x, y, z, \omega) = \frac{\rho c^2\omega\hat{Q}\Psi_n(x, y, z)\Psi_n(x_0, y_0, z_0)}{V_n[(\omega^2 - \omega_n^2 + 2\delta_n^i\omega)^2 + (2\delta_n^r\omega)^2]^{1/2}} \qquad \mathrm{N/m^2} \tag{6.26}$$

and

$$\theta_n(\omega) = \phi - \tan^{-1}\frac{\omega^2 - \omega_n^2 + 2\delta_n^i\omega}{2\delta_n^r\omega} \qquad \mathrm{rad} \tag{6.27}$$

The amplitude of the modal sound pressure is $|p_n|$. When $\hat{Q} = 1$, $|p_n|$ is the amplitude of the modal frequency response function.

Equation (6.25) shows that the steady-state sound pressure at one point in the enclosure can be considered as the superposition of numerous components of the same frequency ω but with different amplitudes $|p_n|$ and phase angles θ_n. If the source location (x_0, y_0, z_0) or the observer location (x, y, z) in Eq. (6.26) is on the nodal surface of a particular mode n, then the minimum participation of that mode will be observed in the response. It is also noteworthy that the solution is symmetric in the coordinates (x_0, y_0, z_0) of the sound source and the point of observation (x, y, z). If we put the sound source at (x, y, z), we observe at point (x_0, y_0, z_0) the same sound pressure as we did at (x, y, z) when the source was at (x_0, y_0, z_0). This is the famous reciprocity theorem (see Chapter 10) that can sometimes be applied with advantage to measurements in room acoustics.

When only the uniform-pressure mode $(\omega_0 = 0)$ is excited, Eqs. (6.25)–(6.27) reduce to $p = p_0 \cos(\omega t + \theta_0)$, where

$$p_0(\omega) = \frac{\rho c^2 \hat{Q}}{V[(\omega + 2\delta_0^i)^2 + (2\delta_0^r)^2]^{1/2}} \quad \text{N/m}^2$$
$$\theta_0(\omega) = \phi - \tan^{-1}\frac{\omega + 2\delta_0^i}{2\delta_0^r} \quad \text{rad} \tag{6.28}$$

which are equivalent to Eqs. (6.2). The uniform-pressure mode applies to the case of sound sources operating at very low frequencies, well below the first $(n = 1)$ resonance of the enclosure. This requirement is generally met if $L < \lambda/10$, where L is the maximum linear dimension of the cavity and $\lambda = c/f$ is the wavelength of sound generated by the source operating at the forcing frequency $f = \omega/2\pi$.

Example 6.6. For the rectangular cavity of Example 6.4, determine the steady-state sound pressure response in the cavity for loudspeaker excitation when (a) the enclosure walls are rigid and there is no damping, (b) one wall is covered uniformly with absorption material of known impedance Z, and (c) the damping is expressed in terms of the *critical damping ratio* ζ_n. Assume the loudspeaker acts as a simple monopole source.

Solution

(a) For an undamped $(\delta_n^r = 0)$ and rigid-wall $(\delta_n^i = 0)$ enclosure, we obtain, from Eqs. (6.25)–(6.27),

$$p(x, y, z, t) = \rho c^2 \hat{Q} \sum_{i=0}^{I}\sum_{j=0}^{J}\sum_{k=0}^{K} \frac{\omega \Psi_{ijk}(x, y, z)\Psi_{ijk}(x_0, y_0, z_0)}{V_{ijk}|\omega^2 - \omega_{ijk}^2|}$$
$$\times \cos\left(\omega t + \phi - \frac{\pi}{2}\right) \quad \text{N/m}^2 \tag{6.29}$$

where Ψ_{ijk} and $f_{ijk} = \omega_{ijk}/2\pi$ are given in Eq. (6.14), V_{ijk} is determined from Eq. (6.12), and I, J, K are the number of modes we include to obtain a converged solution. For a closed rectangular enclosure,

$$\frac{V_{ijk}}{V} = \varepsilon_i \varepsilon_j \varepsilon_k \qquad \text{where} \qquad \varepsilon_n = \begin{cases} 1 & \text{for } n = 0 \\ \frac{1}{2} & \text{for } n \geq 1 \end{cases} \tag{6.30}$$

with $V = L_x L_y L_z$. Note from Eq. (6.14) that for every mode of vibration the sound pressure is a maximum at the corners of the rectangular enclosure. Also, for every mode of vibration for which one of the indexes i, j, or k is *odd*, the sound pressure is zero at the *center* of the enclosure; hence at the geometrical center of the enclosure only one-eighth of the modes of vibration produce a finite sound pressure. Extending this further, at the center of any one wall, the modes for which two of the indexes (i, j, k) are odd will have zero pressure, so that only one-fourth of them will participate. Finally, at the center of one edge of the enclosure, the modes for which one index is odd will have zero pressure, so that only one-half of them participate there.

(b) Assume the uniform absorption material is on the $z = 0$ wall. Then, from Eqs. (6.19) and (6.20),

$$\delta_{ijk}^r = \frac{cA_{ijk}}{2V_{ijk}} \operatorname{Re}\frac{\rho c}{Z_{ijk}} = \frac{c}{2L_z\varepsilon_k} \operatorname{Re}\frac{\rho c}{Z} \quad \text{s}^{-1}$$
$$\delta_{ijk}^i = \frac{cA_{ijk}}{2V_{ijk}} \operatorname{Im}\frac{\rho c}{Z_{ijk}} = \frac{c}{2L_z\varepsilon_k} \operatorname{Im}\frac{\rho c}{Z} \quad \text{s}^{-1} \tag{6.31}$$

where $\rho c/Z_{ijk} = \rho c/Z$ and $A_{ijk} = \varepsilon_i \varepsilon_j A_z$ with $A_z = L_x L_y$. Substituting Eq. (6.31) into Eqs. (6.25)–(6.27), one can evaluate the series solution for the sound pressure when Z is known.

(c) From the theory of vibration (Chapter 13), the critical damping ratio ζ_n is related to the damping constant through $\delta_n = \zeta_n \omega_n$. In complex form, $\zeta_n = \zeta_n^r + i\zeta_n^i$, so that $\delta_n^r = \zeta_n^r \omega_n$ and $\delta_n^i = \zeta_n^i \omega_n$, which can be substituted into Eqs. (6.25)–(6.27) to evaluate the sound pressure for given ζ_n.

Figure 6.4 shows the predicted versus measured sound pressure level in a rectangular enclosure for volume–velocity (loudspeaker) excitation. The response was predicted by using Eqs. (6.25)–(6.27) as developed in Example 6.6. Figure 6.4*a* is the response in the undamped, rigid-wall enclosure, where the resonance peaks resulting from the excitation of the rigid-wall cavity modes are identified. Theoretically, the response at these resonances in an undamped enclosure should be infinite. In practice, however, damping is present even in an enclosure with very rigid walls since viscous and thermal losses occur in the air and at the boundaries. Modal damping provides a convenient method of accounting for these losses, and it is easily included in the solution as described in Example 6.6(c). Since the losses are primarily resistive, a real value of modal damping is used. Figure 6.4*b* shows the sound pressure response when sound-absorptive material of known impedance covers the bottom wall of the enclosure. The predicted response is obtained using the complex "damping" formulas given

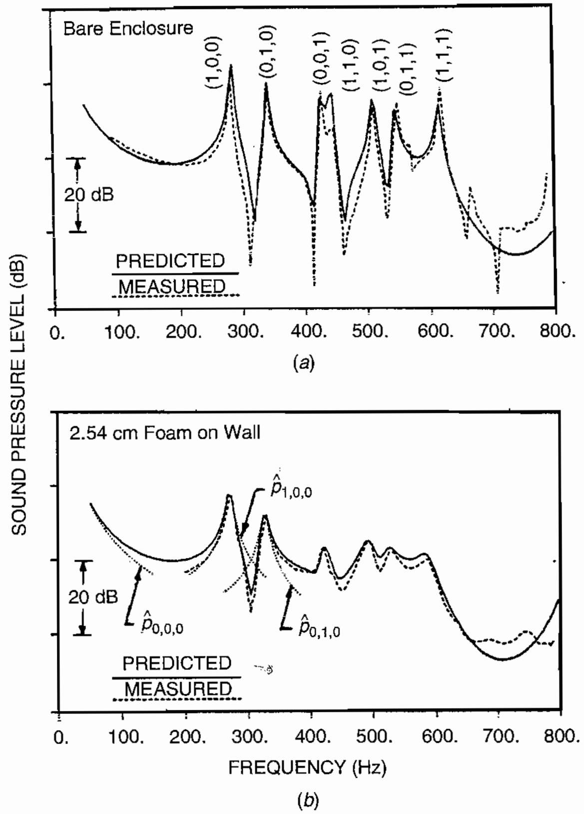

FIGURE 6.4 Comparisons of predicted versus measured of sound-pressure-level curves for a constant volume–velocity source in a rectangular enclosure of dimensions 0.61 × 0.51 × 0.41 m. The microphone was at (0.51 m, 0.10 m, 0.30 m) and the source was at (0.0 m, 0.10 m, 0.10 m). (*a*) Bare enclosure with 0.5% modal damping. (*b*) Acoustical foam 2.54 cm thick with measured impedance $\rho c/Z = (0.12 + 0.47i)(f/800)$ for $0 \le f < 800$ Hz covering the 0.61 × 0.51-m wall.

in Eq. (6.31) and by using the modes based on the reduced height of the enclosure due to the absorption material thickness. The resonant responses of the $|p_{0,0,0}|$, $|p_{1,0,0}|$, and $|p_{0,1,0}|$ terms in the series in Eq. (6.25) are also shown. The attenuation and frequency shift of the resonant peaks are evident by comparing Figs. 6.4*a* and 6.4*b*, and these are due to the resistive and reactive nature of the absorption material.

6.8 ENCLOSURE DRIVEN AT RESONANCE

If a point source of volume velocity Q is driven by a steady-state generator of frequency ω and if that frequency equals a normal-mode frequency ω_n, then the

modal sound pressure from Eq. (6.26) is

$$p_n(x, y, z, \omega_n) = \frac{\rho c^2 \hat{Q} \Psi_n(x, y, z) \Psi_n(x_0, y_0, z_0)}{V_n[(2\delta_n^i)^2 + (2\delta_n^r)^2]^{1/2}} \quad \text{N/m}^2 \tag{6.32}$$

From this we conclude that $|p_n| \to \infty$ when both $\delta_n^r = 0$ and $\delta_n^i = 0$, so that ω_n is the *resonance frequency* when we have an enclosure with undamped and rigid walls.

For an enclosure with reactive walls ($\delta_n^i \neq 0$, $\delta_n^r \equiv 0$), the frequency dependence in the denominator of Eq. (6.26) can be approximated by

$$\omega^2 - \omega_n^2 + 2\delta_n^i \omega \approx \omega^2 - \omega_n^2 \left(1 - \frac{2\delta_n^i}{\omega_n}\right) = \omega^2 - \omega_{n0}^2 \tag{6.33}$$

where

$$\omega_{n0} = \omega_n \sqrt{1 - \frac{2\delta_n^i}{\omega_n}} \quad \text{rad/s} \tag{6.34}$$

Since now $|p_n| \to \infty$ when $\omega \to \omega_{n0}$, we see that the new resonance frequency of an enclosure with undamped, reactive walls is ω_{n0}. The resonance frequency *shifts* from the rigid-wall resonance value ω_n due to the reactance δ_n^i of the walls, and ω_{n0} can be either higher or lower than the rigid-wall frequency ω_n, depending on whether $\delta_n^i < 0$ or $\delta_n^i > 0$, respectively. From Eq. (6.27), the phase angle between the modal pressure and the volume velocity source at resonance (i.e., when $\omega = \omega_{n0}$) is either 0° or 180°, and this provides a means of experimentally identifying the resonance frequency ω_{n0} and the enclosure reactance δ_n^i.

The enclosure dissipation δ_n^r controls the amplitude of the resonant peak when $\omega = \omega_{n0}$ since

$$p_n(x, y, z, \omega_{n0}) = \frac{\rho c^2 \, \hat{Q} \Psi_n(x, y, z) \Psi_n(x_0, y_0, z_0)}{2\delta_n^r V_n} \quad \text{N/m}^2 \tag{6.35}$$

The dissipation also shifts the resonance frequency an additional amount. The actual resonance frequency ω_{res} at which $|p_n|$ becomes a maximum can be shown to be

$$\omega_{\text{res}} = \sqrt{\omega_{n0}^2 - 2(\delta_n^r)^2} = \sqrt{\omega_n^2 - 2\delta_n^i \omega_n - 2(\delta_n^r)^2} \quad \text{rad/s} \tag{6.36}$$

The dissipative effect (δ_n^r) is always to reduce the resonance frequency, but this effect is of second order and generally less important than the reactive effect (δ_n^i), which is of first order, unless δ_n^r is large. In general, therefore, to first order, the resonance frequency of an enclosure is $\omega_{\text{res}} = \omega_{n0}$ with ω_{n0} given by Eq. (6.34). The *half-power bandwidth* of the resonant peak is the width of the resonance curve at 3 dB below the peak power (6 dB below the peak pressure) and is

$$\Delta\omega_{\text{res}} = 2\delta_n^r \quad \text{rad/s} \tag{6.37}$$

This provides a means of experimentally determining the enclosure dissipation δ_n^r.

Example 6.7. Determine the resonance frequency of the first mode in Fig. 6.4*b*. The measured wall impedance is $\rho c/Z = (0.12 + 0.47i)(f/800)$.

Solution For the (1, 0, 0) mode, we have $f_{1,0,0} = 284.8$ Hz from Eq. (6.14). For this frequency, $\rho c/Z = (0.12 + 0.47i)(284.8/800) = 0.043 + 0.167i$. Noting that the thickness of the absorption material is 2.54 cm, we have $L_z = 0.41 - 0.0254 = 0.3846$ m, and from Eq. (6.31),

$$\delta_{1,0,0}^r = \frac{347.3}{2 \times 0.3846 \times 1} \times 0.043 = 19.6$$

$$\delta_{1,0,0}^i = \frac{347.3}{2 \times 0.3846 \times 1} \times 0.167 = 76.2$$

Substituting these into Eq. (6.36) gives the resonance frequency

$$f_{\text{res}} = \frac{\omega_{\text{res}}}{2\pi} = f_n\sqrt{1 - \frac{2\delta_n^i}{\omega_n} - 2\left(\frac{\delta_n^r}{\omega_n}\right)^2}$$

$$= 284.8(1 - 0.085 - 0.00024)^{1/2} = 272.4 \text{ Hz}$$

Actually, the calculated frequency should be slightly greater than this because the impedance is frequency dependent and should be evaluated at f_{res}. An iterative calculation gives $f_{\text{res}} = 273$ Hz, while the measured resonance frequency in Fig. 6.4*b* is 274 Hz.

6.9 FLEXIBLE-WALL EFFECT ON SOUND PRESSURE

A flexible wall may exhibit structural resonances and affect the sound pressure in two ways: (a) by acting as a noise source when exterior structural or pressure loads excite vibrations of the wall and (b) by acting as a boundary impedance that can alter the cavity sound pressure. Both of these effects may occur simultaneously in a room with flexible walls, in which case a coupled *structural–acoustical analysis* is required to predict the sound pressure response. We shall first consider each of the two effects of a flexible wall separately and then consider the coupled structural–acoustical response.

Flexible Wall as Noise Source

When the vibration velocity $\dot{w}(x, y, z, t)$ of a flexible wall is known, the boundary condition in Table 6.1, frame 2 or 4, can be applied to Eqs. (6.16) and (6.17). The forcing is through the equivalent modal volume–velocity of the wall vibration,

$$Q_n = \hat{Q}_n \cos(\omega t + \phi_n) = -\int_S \dot{w}\Psi_n \, dS \quad \text{m}^3/\text{s} \qquad (6.38)$$

where the vibration velocity of the wall $\dot{w} = \hat{\dot{w}} \cos(\omega t + \phi_w)$ is assumed to have a known amplitude $\hat{\dot{w}}(x, y, z)$ and phase $\phi_w(x, y, z)$. The steady-state sound pressure response is then obtained as in Eqs. (6.26) and (6.27),

$$p_n(x, y, z, \omega) = \frac{\rho c^2 \omega \hat{Q}_n \Psi_n(x, y, z)}{V_n[(\omega^2 - \omega_n^2 + 2\delta_n^i\omega)^2 + (2\delta_n^r\omega)^2]^{1/2}} \quad \text{N/m}^2 \qquad (6.39)$$

$$\theta_n(\omega) = \phi - \tan^{-1}\frac{\omega^2 - \omega_n^2 + 2\delta_n^i\omega}{2\delta_n^r\omega} \quad \text{rad} \qquad (6.40)$$

where δ_n^r, δ_n^i relate to the layer of absorption material of acoustical impedance Z_a covering the flexible wall.

Figure 6.5*a* shows the calculation of the forced acoustical response in the automobile passenger compartment using the above method with measured panel acceleration amplitude and phase data to represent the wall vibration and with measured wall impedance data to represent the absorption materials. The solution is expressed in matrix form as in Eq. (6.22) with the acoustical modes obtained from a finite-element analysis (Fig. 6.3). Figure 6.5*a* shows that a large spatial variation in sound pressure level occurs in the passenger compartment because of the modal nature of the acoustical response. Figure 6.5*b* shows the sound pressure computed separately for the vibration of each individual wall panel. The individual sound pressures can be combined, by considering their magnitude and phase, to obtain the resultant sound pressure, which is shown in Fig. 6.5*b*. This provides a method to identify the major noise sources and the extent to which they must be controlled to yield a specified noise reduction. For example, Fig. 6.5*b* illustrates the large amplitude of the sound pressure due to the back-window vibration. Also note that the elimination of the roof vibration would increase the noise at the driver's ear.

Flexible Wall as Reactive Impedance

Wall panel vibration can generally be expressed in the normal-mode expansion form

$$w = \sum_m W_m(t)\Phi_m(x, y, z) \quad \text{m} \qquad (6.41)$$

where Φ_m are the structural vibration mode shapes and W_m are the modal amplitudes. If we consider the coupling between the wall panel and the cavity, for the mth structural mode and the nth acoustical mode, the modal acoustical impedance of the wall can be expressed as

$$Z_{mn} = (S_{mn})^{-1}\left[C_m + i\omega\left(M_m - \frac{K_m}{\omega^2}\right)\right] \quad \text{N/m}^3 \cdot \text{s}^{-1} \qquad (6.42)$$

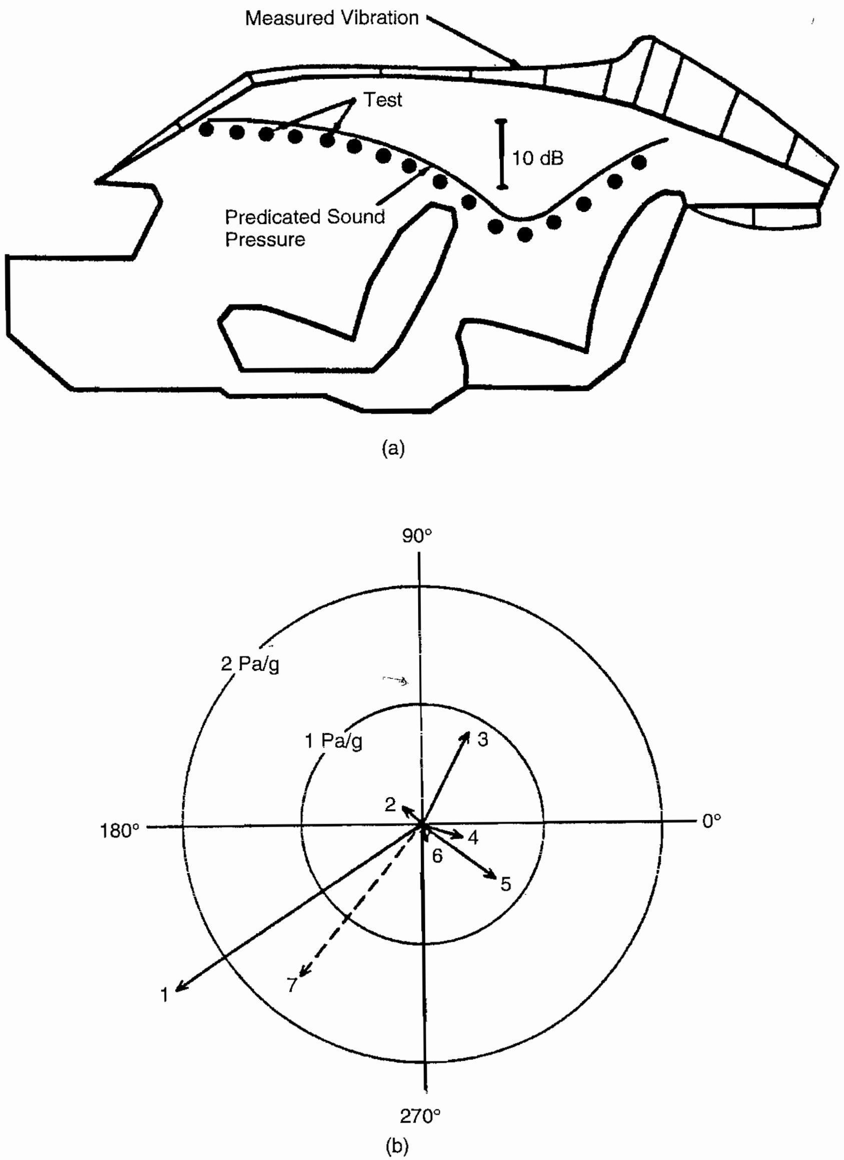

FIGURE 6.5 (*a*) Comparison of measured versus predicted sound-pressure-level spatial variation in automobile passenger compartment for 40-Hz structural excitation. (*b*) Polar amplitude–phase diagram indicating panel contributions to resultant sound pressure at driver's ear (1, back window; 2, rear floor; 3, roof; 4, windshield; 5, rear shelf; 6, front floor; 7, resultant).

where M_m, C_m, and K_m are the modal mass, damping, and stiffness of the mth wall mode, and

$$S_{mn} = \int_S \Phi_m \Psi_n \, dS \quad \text{m}^2 \tag{6.43}$$

where S_{mn} is the *structural–acoustical coupling*. [Note that when $S_{mn} = 0$, there is no coupling between the structural mode m and the acoustical mode n, and Eq. (6.42) does not apply. In practice, when S_{mn} is sufficiently small, the coupling can be neglected to simplify the solution.]

For an undamped enclosure, the structural–acoustical coupling modifies Eq. (6.26) to

$$p_n(x, y, z, \omega) = \frac{\rho c^2 \omega \hat{Q} \Psi_n(x, y, z) \Psi_n(x_0, y_0, z_0)}{V_n |\omega^2 - \omega_{n0}^2|} \left| \frac{\omega^2 - \Omega_m^2}{\omega^2 - \Omega_{m0}^2} \right| \quad \text{N/m}^2 \tag{6.44}$$

where $\Omega_m = \sqrt{K_m/M_m}$ (rad/s) is the natural frequency of the mth wall mode and ω_{n0}^2 and Ω_{n0}^2 are solutions of

$$(\omega^2 - \omega_n^2)(\omega^2 - \Omega_m^2) - D^2\omega^2 = 0 \tag{6.45}$$

where $D = \sqrt{K_{\text{air}}/M_m}$ with $K_{\text{air}} = \rho c^2 S_{mn}^2 / V_n$ (N/m) being the *stiffness* of the nth acoustical mode relative to the mth structural mode.

Equation (6.44) shows that the flexible wall introduces an additional resonance at $\omega = \Omega_{m0}$, which will appear as a resonance peak in the sound pressure response and corresponds to the wall resonance. It can be shown from Eq. (6.45) that, with wall modes at frequencies below the rigid-wall cavity resonance ($\Omega_m < \omega_n$, the case of *mass-controlled* boundaries), the cavity resonance is raised ($\omega_{n0} > \omega_n$) and the wall resonance is lowered ($\Omega_{m0} < \Omega_m$). With wall modes at frequencies above the rigid-wall cavity resonance ($\Omega_m > \omega_n$, the case of *stiffness-controlled* boundaries), the cavity resonance is lowered ($\omega_{n0} < \omega_n$) and the wall resonance is raised ($\Omega_{m0} > \Omega_m$). In addition, the wall acts as a vibration absorber when $\omega = \Omega_m$, so that the modal sound pressure $p_n = 0$. However, the total sound pressure p may not be zero because of the participation of other acoustical modes. A Helmholtz resonator used as a vibration absorber as described in Chapter 8 has impedance Z_R and performs in a similar manner.

Coupled Structural–Acoustical Response

Above we have considered the coupling of one acoustical mode n with one structural mode m, which is the case when a single coupling coefficient S_{mn} dominates for the mode pair (m, n). In practice, however, each acoustical mode n may couple with several structural modes, and the general case can be treated by substituting Eq. (6.41) into the second integral of Eq. (6.17) to obtain, from Eq. (6.16),

$$\ddot{P}_n + 2\delta_n \dot{P}_n + \omega_n^2 P_n + \frac{\rho c^2}{V_n} \sum_m S_{mn} \ddot{W}_m = \frac{\rho c^2}{V_n} F_n(t) \quad \text{N/m}^2 \cdot \text{s}^2 \tag{6.46}$$

where the summation is carried out over all coupled structural modes m. Similarly, each structural mode m may in general couple with several acoustical modes, and the corresponding equation for the structural modal amplitude $W_m(t)$ in Eq. (6.41) is

$$\ddot{W}_m + 2\Delta_m \dot{W}_m + \Omega_m^2 W_m - \frac{1}{M_m} \sum_n S_{mn} P_n = \frac{R_m(t)}{M_m} \quad \text{m/s}^2 \tag{6.47}$$

where the summation is carried out over all coupled acoustical modes n. In this latter equation for the structure, Δ_m is the modal damping constant, Ω_m is the natural frequency, M_m is the modal mass, and $R_m(t)$ is the modal force. The coupling between the acoustical and structural systems makes it necessary to solve Eqs. (6.46) and (6.47) simultaneously for all coupled P_n and W_m. A complete derivation of the equations and discussion of the procedure can be found in reference 12, and its finite-element implementation is described in references 14 and 15.

To illustrate a typical coupled structural–acoustical response, Fig. 6.6 shows an application to a small metallic box used to isolate instruments from an external noise field (cf. Fig. 6.1*b*). The analysis of such enclosures to predict their noise attenuation is discussed in detail in Chapter 11. The finite-element method can be used to model the box wall panels and the acoustical cavity (Figs. 6.6*b, c*) in order to compute the uncoupled structural and acoustical modes. Equations (6.46) and (6.47) are then solved for the coupled frequency response, where the exterior noise field in Fig. 6.6*a* is specified as an oscillating external pressure $\hat{p}_E \cos \omega t$ applied uniformly to the wall panels. The noise attenuation inside the enclosure is characterized by its *insertion loss*, defined in Chapter 11 as 20 $\log_{10}(\hat{p}_I/\hat{p}_E)$, where $\hat{p}_I$ is the interior sound pressure. The predicted versus measured insertion loss is shown in Fig. 6.6*d*. The structural–acoustical coupling effect is particularly evident in the rms panel vibration shown in Fig. 6.6*e*, which compares the coupled versus the uncoupled (i.e., in vacuo) panel response and illustrates the significant effect that the acoustical cavity modes have on the structural vibration response.

6.10 RANDOM SOUND PRESSURE RESPONSE

For steady-state, deterministic sound source excitation, the sound pressure response can be obtained by the frequency response function technique of Eqs. (6.25)–(6.27). However, for sound source excitation that is nondeterministic, it is generally necessary to utilize a random-analysis technique

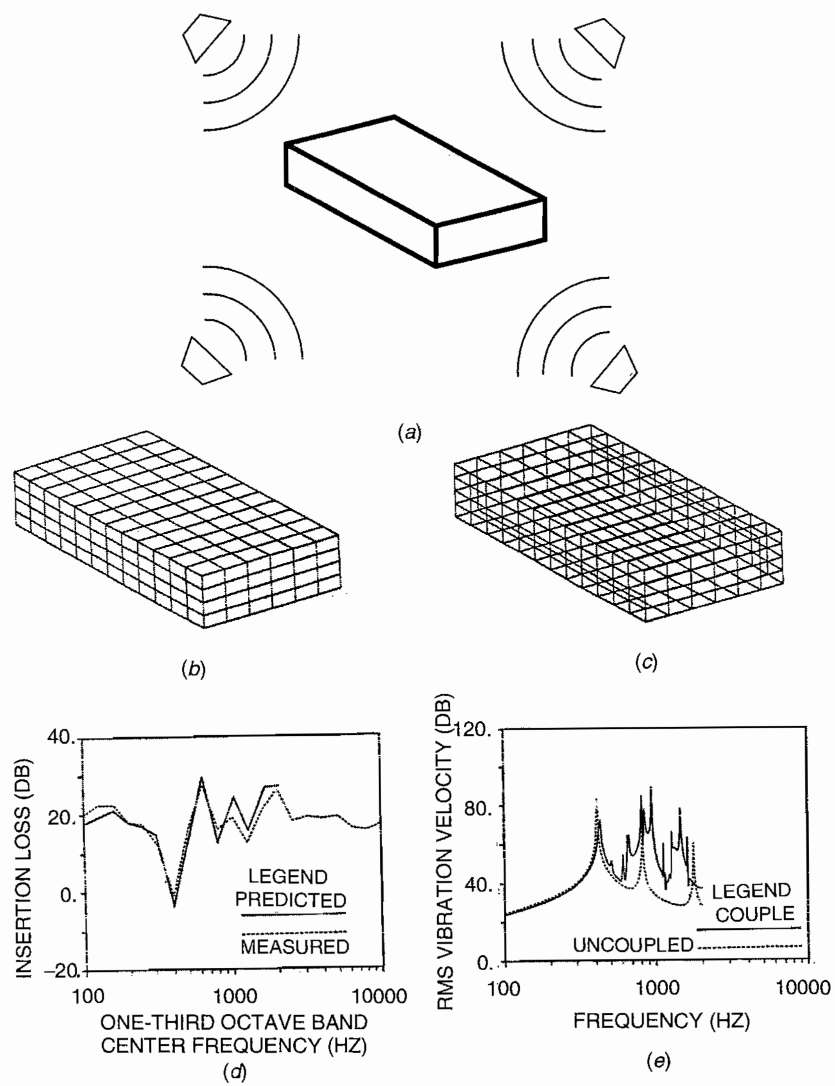

FIGURE 6.6 Structural–acoustical analysis to predict insertion loss of a 30 × 15 × 5-cm unlined aluminum box with 0.16-cm-thick walls: (*a*) box in uniform noise environment; (*b*) structural finite-element model of box wall panels; (*c*) acoustical finite-element model of box cavity; (*d*) predicted versus measured insertion loss at box center; (*e*) coupled versus uncoupled surface-averaged vibration of 30 × 15-cm wall panel. [Measured data in (*d*) from Chapter 11].

to obtain the sound pressure response. For example, irregular pressure fluctuations generated by turbulence can result in complicated sound sources that are more readily measured or defined as random excitations than as deterministic excitations. Also, interactions with irregular surfaces such as roads, runways, and pathways are more readily represented as random loads than as deterministic loads. Under certain conditions (stationarity) the average frequency content of these excitations may be represented by a spectral density function (Chapter 3). Then by using the spectral density representation of the input and the frequency response function technique to determine the sound pressure output, conventional random-analysis theory may be utilized to obtain the sound pressure spectral density response.

From random-analysis theory, nondeterministic stationary processes can be characterized by their auto- (power) spectral density function and their cross-spectral density function.[16] The power spectral density (PSD) function of a physical variable such as sound pressure $p(t)$ is defined as a real-magnitude function $S_p(\omega)$, where

$$S_p(\omega) = \lim_{T\to\infty} \frac{2}{T} \left| \int_0^T e^{-\iota\omega t} p(t)\, dt \right|^2 \quad (\text{N/m}^2)^2/\text{Hz} \tag{6.48}$$

Similarly, the PSD function $S_Q(\omega)$ for a volume–velocity point source $Q(t)$ is

$$S_Q(\omega) = \lim_{T\to\infty} \frac{2}{T} \left| \int_0^T e^{-\iota\omega t} Q(t)\, dt \right|^2 \quad (\text{m}^3/\text{s})^2/\text{Hz} \tag{6.49}$$

The PSD functions of the sound pressure response and sound source excitation are related via the frequency response function as

$$S_p(x,y,z,\omega) = \sum_n p_n^2(x,y,z,\omega) S_Q(\omega) \quad (\text{N/m}^2)^2/\text{Hz} \tag{6.50}$$

where $S_p(x,y,z,\omega)$ is the sound pressure PSD response and $p_n(x,y,z,\omega)$ is the modal frequency response function in Eq. (6.26) for unit sound source excitation $\hat{Q} = 1$. Equation (6.50) is the random-response equivalent of Eq. (6.25) for the steady-state response. However, for random response, only the amplitude of the modal frequency response function is required and not the phase information in $\theta_n(\omega)$ in Eq. (6.27).

Another useful result from random-analysis theory is that, if several sound sources $Q_1(t), Q_2(t), \ldots, Q_a(t), \ldots$ are statistically independent, then the cross-correlation between any pair of sources is zero, and the total sound pressure PSD response is equal to the sum of the PSD responses due to the individual sources. That is,

$$\begin{aligned} S_p(x,y,z,\omega) &= \sum_a S_{p_a}(x,y,z,\omega) \\ &= \sum_a \sum_n p_{an}^2(x,y,z,\omega) S_{Q_a}(\omega) \quad (\text{N/m}^2)^2/\text{Hz} \end{aligned} \tag{6.51}$$

Finally, when two sound sources $Q_a(t), Q_b(t)$ are statistically correlated, the degree of correlation is related by a cross-spectral density function $S_{Q_aQ_b}(\omega)$ given by

$$S_{Q_aQ_b}(\omega) = \lim_{T\to\infty} \frac{2}{T} \left[\left(\int_0^T e^{-\iota\omega t} Q_a(t)\, dt \right)^* \left(\int_0^T e^{-\iota\omega t} Q_b(t)\, dt \right) \right] \quad (\text{m}^3/\text{s})^2/\text{Hz} \tag{6.52}$$

where the asterisk denotes complex conjugate. Unlike the PSD function, the cross-spectral density function is generally a complex number that includes both amplitude and phase information. For correlated sound sources, the spectral density of the sound pressure response is then a complex number given by

$$S_p(x,y,z,\omega) = \sum_a \sum_b \sum_m \sum_n (p_{am}(x,y,z,\omega) e^{i\theta_m(\omega)})(p_{bn}(x,y,z,\omega) e^{i\theta_n(\omega)})^* \times S_{Q_aQ_b}(\omega) \quad (\text{N/m}^2)^2/\text{Hz} \tag{6.53}$$

where the phase relationships $\theta_m(\omega), \theta_n(\omega)$ are from Eq. (6.27) with $\phi = 0$. In the case where the sound sources are uncorrelated, Eq. (6.53) reduces to the previous real-magnitude sound pressure PSD functions in Eqs. (6.50) and (6.51).

Example 6.8. Determine the sound pressure PSD response in the very small enclosure in Fig. 6.1*a* with rigid walls when (a) there is a single sound source Q_a in the enclosure with PSD amplitude $S_{Q_a} = S(\omega)$; (b) there are two uncorrelated interior sound sources Q_a, Q_b in the enclosure with PSD amplitudes $S_{Q_a} = S(\omega)$, $S_{Q_b} = S(\omega)$; and (c) there are two interior sound sources with $S_{Q_a} = S(\omega)$, $S_{Q_b} = S(\omega)$ but perfectly correlated so that $S_{Q_aQ_b} = S(\omega)$.

Solution

(a) For a rigid-wall enclosure with a single sound source, substituting Eq. (6.4) into Eq. (6.50) gives

$$S_p(x,y,z,\omega) = p_0^2(x,y,z,\omega) S_{Q_a} = \left(\frac{\rho c^2}{\omega V}\right)^2 S_{Q_a} = \left(\frac{\rho c^2}{\omega V}\right)^2 S(\omega)$$

(b) For two uncorrelated sound sources in the enclosure, Eq. (6.51) gives

$$S_p(x,y,z,\omega) = \left(\frac{\rho c^2}{\omega V}\right)^2 (S_{Q_a} + S_{Q_b}) = 2\left(\frac{\rho c^2}{\omega V}\right)^2 S(\omega)$$

(c) For two correlated sound sources in the enclosure, Eq. (6.54) gives

$$S_p(x,y,z,\omega) = \left(\frac{\rho c^2}{\omega V}\right)^2 (S_{Q_a} + S_{Q_b} + 2S_{Q_aQ_b}) = 4\left(\frac{\rho c^2}{\omega V}\right)^2 S(\omega)$$

Thus, for uncorrelated sound sources, doubling the number of the sound sources in the enclosure *doubles* the sound pressure PSD response (3 dB increase), as in (b). On the other hand, for perfectly correlated sound sources, doubling the number of the sound sources *quadruples* the sound pressure PSD response (6 dB increase), as in (c).

The random-analysis formulas in Eqs. (6.50)–(6.53) are also applicable to structural analysis, by replacing the acoustical frequency response functions and sound source excitations with the corresponding structural frequency response functions and structural excitations.[16] Also, the coupled structural–acoustical analysis provided by Eqs. (6.46) and (6.47) can be applied to predict the sound pressure PSD response for random excitations.[17] As an example, Fig. 6.7 illustrates the predicted interior sound pressure PSD response in an automobile passenger compartment for the vehicle traveling at constant speed V over a randomly rough road. In this example, random road excitation occurs at the tire patch (Fig. 6.7*a*) and the sound pressure response in the passenger compartment results from the transmitted vibration to the vehicle body panels. Equations (6.46) and (6.47) can be used to obtain the sound pressure frequency response functions by employing the vehicle finite-element models in Figs. 6.7*b,c*. Equation (6.51) is then used to predict the sound pressure PSD response by applying the road profile PSD function in Fig. 6.7*d* as excitation at each tire patch at the vehicle speed V. Figure 6.7*e* shows the predicted sound pressure PSD response in the passenger compartment versus the 95% confidence band based on the measured responses in nominally identical vehicles. The relative participation of the sound sources and body panels to the sound pressure PSD response can also be identified by the methods in Chapter 3 and reference 17.

6.11 TRANSIENT SOUND PRESSURE RESPONSE

When the source of sound in a room is turned off, the sound dies out, or decays, at a rate that depends on the dissipation, or damping, in the room. The acoustical response that exists in the room can be found from the transient solution of Eq. (6.16), which is

$$P_n(t) = \frac{\rho c^2}{V\omega_{nD}} \int_0^t F_n(\tau) e^{-\delta_n^r(t-\tau)} \sin[\omega_{nD}(t-\tau)]\, d\tau \quad \text{N/m}^2 \qquad (6.54)$$

where $\omega_{nD} = \sqrt{\omega_n^2 - (\delta_n^r)^2 + (\delta_n^i)^2}$ is the "damped" modal frequency of the acoustical response in the enclosure. Equation (6.54) is the particular solution that satisfies zero initial conditions. For general initial conditions, the following free-vibration response must be added to the above equation:

$$P_n(t) = e^{-\delta_n^r t}\left[\frac{\dot{P}_n(0) + P_n(0)\delta_n^r}{\omega_{nD}} \sin \omega_{nD} t + P_n(0) \cos \omega_{nD} t\right] \quad \text{N/m}^2 \quad (6.55)$$

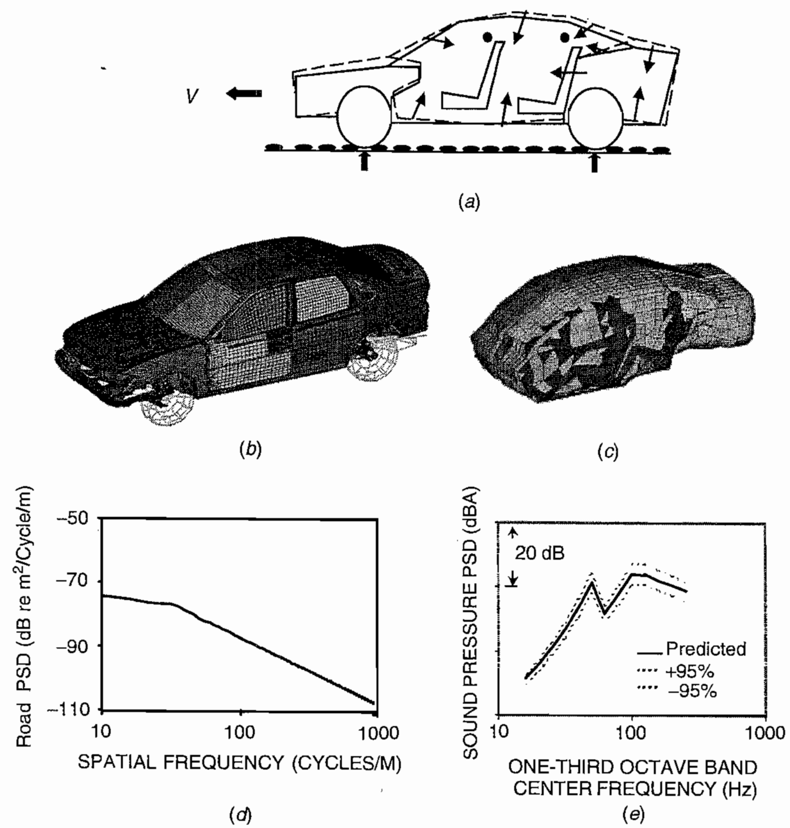

FIGURE 6.7 Structural–acoustical analysis to predict sound pressure PSD response in vehicle traveling at constant speed V on randomly rough road: (*a*) interior road noise generation; (*b*) structural finite-element model of vehicle; (*c*) acoustical finite-element model of passenger-trunk compartment; (*d*) road profile power spectral density; (*e*) predicted A-weighted sound pressure PSD response at front seat occupant ear location versus 95% confidence interval.

Equation (6.55) can be used to determine the decay of the modes after the sound source is turned off at $t = 0$, when the initial conditions $P_n(0)$ and $\dot{P}_n(0)$ are known. For light damping, each mode of vibration behaves independently of the others, and the total process of sound decay is the summation in Eq. (6.15) of the sound pressures associated with all of the individual modes of vibration that fall within the frequency band of interest. The long-time sound decay may be different than the short-time sound decay because of the different damping factors and initial conditions for the modes.

The *reverberation time* T is defined as the time in seconds required for the level of sound to drop by 60 dB or for the pressure to drop to $\frac{1}{1000}$ of its initial value (see Chapter 7). One can similarly define a *modal* reverberation time T_n as that for which the sound pressure decays in that mode by 60 dB or $\frac{1}{1000}$ of its initial value. Since the reverberation time is that associated with the decaying part $(-\delta_n^r t)$ of the solution in Eq. (6.55),

$$T_n = \frac{6.91}{\delta_n^r} = \frac{13.82 V_n}{cA_n \operatorname{Re}(\rho c/Z_n)} \quad \text{s} \tag{6.56}$$

where we have substituted for δ_n^r from Eq. (6.19). With $c = 343$ m/s (20°C) and expressed in terms of the random-incidence absorption coefficient, $\alpha_n = 8\operatorname{Re}(\rho c/Z_n)$, with V in cubic meters and A in square meters, one obtains the modal reverberation time $(n > 0)$

$$T_n = 0.322 \frac{V_n}{\alpha_n A_n} \quad \text{s} \tag{6.57}$$

which can be evaluated for a given Z by using the formulas in Eqs. (6.20) and (6.12). The uniform-pressure mode $(n = 0)$ must be treated separately. The general transient solution of Eq. (6.16) when $n = 0$ reduces to

$$P_0(t) = P_0(0)e^{-2\delta_0^r t} + \frac{\rho c^2}{V} \int_0^t \int_0^\tau F_0(\sigma)\, d\sigma \; e^{-2\delta_0^r (t-\tau)}\, d\tau \quad \text{N/m}^2 \tag{6.58}$$

and the reverberation time for the decay of a uniform sound pressure is $T_0 = 6.91/2\delta_0^r = 6.91V/cA\operatorname{Re}(\rho c/Z)$ so that, for V in cubic meters and A in square meters,

$$T_0 = 0.161 \frac{V}{\alpha A} \quad \text{s} \tag{6.59}$$

In this case, the formula for the reverberation time of a uniform sound pressure is identical to the formula of Sabine for the reverberation time of a diffuse sound field.

If the pressure–time history is dominated by a single mode, then the reverberation time is equal to the appropriate modal reverberation time. If the sound source is turned off at $t = 0$, the magnitude of the sound pressure associated with a particular mode at a response location (x, y, z) is given by Eq. (6.55). The decay of the response from its maximum amplitude $[\dot{P}_n(0) = 0]$ can then be written as

$$p_n(x, y, z, t) = P_n(0)\Psi_n(x, y, z)e^{-\delta_n^r t} \cos(\omega_n t + \theta_n) \quad \text{N/m}^2 \tag{6.60}$$

where $\theta_n = \tan^{-1}(\delta_n^r/\omega_{nD})$ is the modal phase. If we take the rms time average of $\cos(\omega_n t + \theta_n)$ and the rms spatial average of $\Psi_n\,(x, y, z)$ and we designate the resultant as $\overline{p}_n(t)$, then Eq. (6.60) indicates that on a plot of $\log \overline{p}_n$ versus

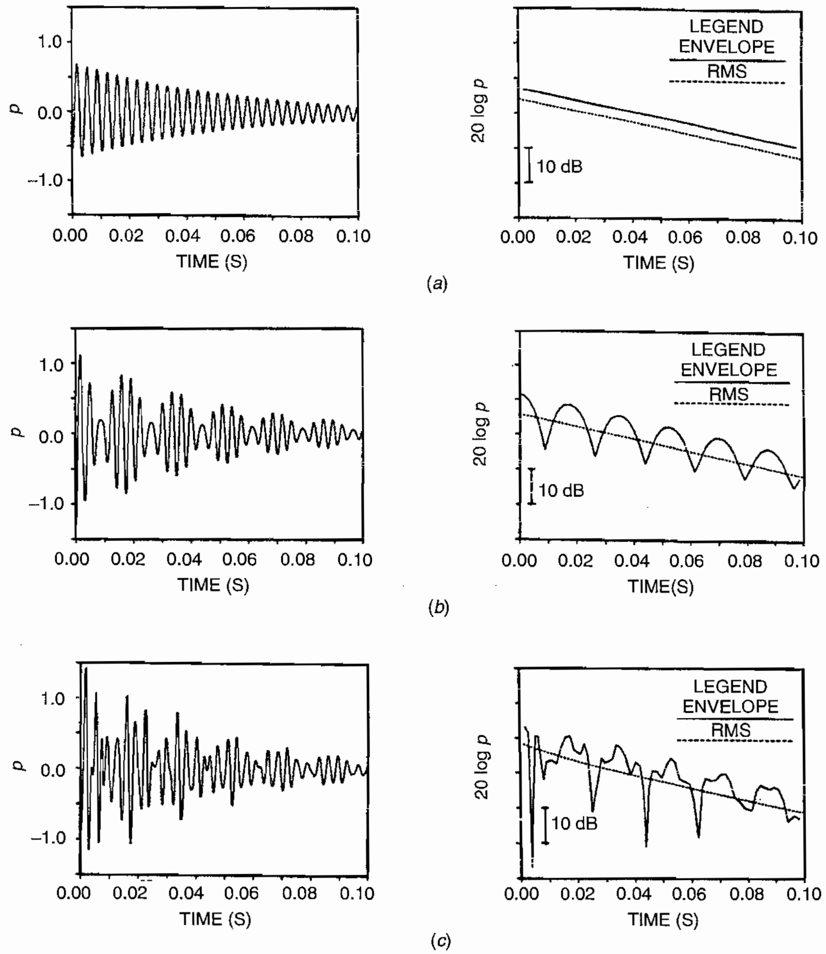

FIGURE 6.8 Sound pressure decay curves for rectangular enclosure of Fig. 6.6: (*a*) for the (1, 0, 0) mode of vibration; (*b*) for the (1, 0, 0) and (0, 1, 0) modes together; (*c*) for all modes up to 800 Hz. The graphs on the left show the course of the instantaneous sound pressure at the microphone location, and those on the right show the curve of the envelope of the left graphs and the rms pressure of Eq. (6.61) plotted on a log p-versus-t coordinate system.

time, as in Fig. 6.8*a*, both the envelope of the sound pressure and the rms sound pressure decay linearly with time and have the constant reverberation time T_n.

When many normal modes of vibration (each with its own amplitude, phase, resonance frequency, and damping constant) decay simultaneously, the total rms (spatial and temporal) sound pressure is obtained from Eq. (6.15) as

$$\overline{p}(t) = \sqrt{\overline{p}_I^2 + \overline{p}_{I+1}^2 + \cdots + \overline{p}_{I+N}^2} \quad \text{N/m}^2 \tag{6.61}$$

where I is the first mode in the frequency band considered and $I + N$ is the last mode in the decay. In this case, the decay envelope is generally not linear as above, even when the modal reverberation times do not vary greatly from one mode to another so that all modes in the frequency band have a similar damping constant. The decay envelope is irregular, as in Figs. 6.8*b,c*, because the modes of vibration have different frequencies and beat with each other during the decay. However, the rms decay from Eq. (6.61) will be nearly linear if the modal reverberation times are similar (Fig. 6.8*b*) or if the long-time decay is governed by a least-damped mode, which may occur when the modal reverberation times or initial conditions differ (Fig. 6.8*c*).

This brief description of sound decay in small rooms is applicable to rooms of any size and shape, and it can be extended to include the effects of structural–acoustical coupling. The fact that sound fields in large enclosures involve too many modes for the calculations to be practical does not mean that there are not distinct normal modes of vibration, each with its own natural frequency and damping constant. Alternate and more practical methods for handling large enclosures involving large numbers of modes are discussed in the next chapter.

CHAPTER 7

Sound in Rooms

MURRAY HODGSON

University of British Columbia
Vancouver, Canada

JOHN BRADLEY

National Research Council of Canada
Ottawa, Canada

Acoustical problems experienced by room users include difficult verbal communication in classrooms and conference rooms, impaired student learning and teacher voice problems in classrooms, hearing loss in industrial workshops, and inadequate speech privacy in open-plan offices. Room sound fields comprise both "signals" (useful sounds, such as speech) and detrimental "noise". To modify room sound fields and improve acoustical conditions, the acoustician must understand the relationship between the room user and activity, the sound sources, the room and its contents, and the characteristics of room sound fields. Models for predicting room sound fields are of primary importance. They allow the acoustical conditions to be optimized during design and permit sound control measures to be evaluated for cost effectiveness in new or existing rooms. In this chapter, we take an energy-based approach, ignoring phase, interference, and modal effects discussed in Chapter 6. This is justified, except perhaps at low frequencies, since we are interested in rooms which are large compared with the sound wavelength, which are of complex shape and may not be empty. Further, we are interested in wide-band (total A-weighted, octave- or third-octave band) results. In this chapter, the sound field is quantified by the time-averaged, mean-square sound pressure p^2 in $(\mathrm{N/m^2})^2$ or the associated sound pressure level L_p in decibels ($L_p = 10\ \log_{10}[p^2/p_0^2]$, $p_0 = 2 \times 10^{-5}$ N/m^2). In the case of multiple sources or sound reflections, the total energy is the sum of the individual energy contributions: $p_{\text{tot}}^2 = \sum p_i^2$, $L_{p,\text{tot}} = 10\ \log_{10}\left(\sum 10^{L_{pi}/10}\right)$.

Sound sources radiate energy over some frequency range and, at each frequency, with a certain intensity. The rate of emission of energy is described by the sound power W in watts or the associated sound power level L_w in decibels ($L_w = 10\ \log_{10}(W/W_0)$, $W_0 = 10^{-12}$ W), usually measured in octave- or third-octave frequency bands. As discussed in Section 7.8, the presence of surfaces near a source effectively increases its sound power output. Depending on its physical characteristics and frequency, a source may radiate uniformly in all directions (omnidirectional source) or more or less in certain directions (directional source). Source directivity is quantified by the directivity factor Q, which is the ratio of the mean-square sound pressure radiated in the receiver direction to the average of that radiated in all directions (see also Chapter 4). Small sources with three similar major dimensions can often be modeled as compact sources. Most real sources (large machines, conveyors, building walls) are more complex than a compact source, being extended in space in one or more dimensions. Readers wishing to do further reading on more fundamental aspects of room acoustics should consult reference 1. Throughout this chapter, references are provided for the benefit of readers who wish to do more in-depth reading on the topic under discussion.

7.1 ROOM SOUND FIELDS AND CONTROLLING FACTORS

Propagation of Sound

Sound waves propagate away from a source, being reflected (or scattered) by room boundaries, barriers, and furnishings. The resulting sound field at the receiver is composed of two parts. Sound which propagates directly from the source to the receiver is the direct sound. Its amplitude decreases with increasing distance from the source, as in a free field (discussed in Chapters 1 and 2). Sound which reaches the receiver after reflection from room surfaces or furnishings is the reverberant sound. Its amplitude decreases with increasing source distance at a rate which depends on the source geometry and on the acoustical properties of the room and its contents, as will be discussed below. To examine sound propagation in rooms, independent of the source sound power, to which it is directly related, we define the sound propagation function $\mathrm{SPF}(r) = L_p(r) - L_w$ in decibels as the variable characterizing the effect of the room alone on the sound field. Sound pressure levels may then be obtained using $L_p(r) = \mathrm{SPF}(r) + L_w$. Thus, from Eqs. (1.27)–(1.31), for a compact source with $Q = 1$ in a free field, $\mathrm{SPF}(r) = -20 \log_{10} r - 11$ dB. In the case of multiple sources, the individual source contributions are obtained from the source sound power levels and the room sound propagation function values at the relevant source/receiver distances. The total sound pressure level at the receiver position is obtained by summing the individual levels on a power (p^2) basis.

Sound Decay

Shortly after a steady-state sound source begins to radiate, an equilibrium (or steady state) is established between the rate of energy absorption in the room and the rate of energy emission by the source. If the source then ceases to radiate, the energy in the room decreases with time at a rate determined by the rate of energy absorption. This is the room sound decay. It is usually characterized by

the reverberation time T_{60}, which is the time in seconds required for the sound pressure level to decrease by 60 dB. Calculations of T_{60} are based on the average rate of decay over some part of the decay curve—usually the −5- to −35-dB part. Also of interest, since it quantifies perceived reverberance, is the early-decay time (EDT), based on the average rate of decay over the first 10 dB.

Air Absorption

Energy is absorbed continuously as sound propagates in air. This process follows an exponential law, $E(r) = E_0 e^{-2mr}$, where the constant $2m$ in the exponent is called the energy air absorption exponent, expressed in nepers per meter (1 Np = 8.69 dB), with $e = 2.7173$. Air absorption depends on air temperature, relative humidity, ambient pressure, and sound frequency. Table 7.1 presents some typical values calculated using reference 2.

Surface Absorption and Reflection

The ability of a surface to absorb incident sound energy is characterized by the energy absorption coefficient α. This is the fraction of the energy striking the surface that is not reflected, as discussed in more detail in Chapters 8 and 11. It is usually measured in octave- or third-octave bands. If E_i is the energy incident on a surface with absorption coefficient α, the reflected energy is $E_r = E_i(1 - \alpha)$. Ignoring transmission, acoustical energy not absorbed by a surface that it strikes is reflected. If the surface is flat, hard, and homogeneous, reflection is specular; that is, the angle of reflection is equal to the incident angle. In practice, because of finite absorber size, surface roughness, as well as physical or impedance discontinuities, the energy is scattered or diffused (reflected into a range of angles). Such diffuse reflections usually result in a more rapid decay of sound and lower reverberation times in the room.

TABLE 7.1 Energy Air Absorption Exponents ($2m$ in Terms of 10^{-3} Np/m) Predicted Using Reference 2 Assuming Ambient Pressure of 101.3 kPa

Temperature, °C	Relative Humidity, %	Air Absorption Exponents at Selected Frequencies						
		125 Hz	250 Hz	500 Hz	1000 Hz	2000 Hz	4000 Hz	8000 Hz
10	25	0.1	0.2	0.6	1.7	5.8	18.7	43.0

	75	0.0	0.2	0.6	1.7	3.3	5.8	13.4

Furnishings

Many rooms are not empty, containing furnishings (the various obstacles, such as desks in a classroom or machines in a workshop, also called fittings). Often furnishings occupy the lower region of a room and there are fewer objects at higher elevations. Of course, the density and horizontal distribution of room furnishings may vary considerably. Acoustical energy propagating in furnished regions is scattered as well as partially absorbed, significantly modifying the sound field. In particular, it increases the rate of sound decay, reducing reverberation times. It also causes a redistribution of steady-state sound energy toward sources, due to back scattering, resulting in higher sound pressure levels near sources and a higher rate of decrease of levels with distance from sources.

7.2 DIFFUSE-FIELD THEORY

By far the best known theoretical models for predicting room sound fields are based on diffuse-field theory. Diffuse-field theory is widely applied because of its simplicity. Often forgotten is the fact that it may be of limited applicability because of its restrictive assumption of a diffuse field. The sound field in a room is diffuse if it has the following attributes:

1. At any position in the room, energy is incident from all directions with equal intensities (and random phase, though we are ignoring phase in this chapter).
2. The reverberant sound does not vary with receiver position.

These conditions are approximated only in specially designed acoustical test rooms called reverberation chambers, discussed in Section 7.8.

Average Diffuse-Field Surface Absorption Coefficient

Diffuse-field theory uses the average rate of random-incidence surface sound absorption averaged over all of the room surfaces. Thus, we define the average diffuse-field surface absorption coefficient as

$$\overline{\alpha}_d = \frac{\sum S_i \overline{\alpha}_{di}}{\sum S_i} \qquad (7.1)$$

where S_i and α_d are the surface area and diffuse-field absorption coefficient of the ith surface. If α_d is to be useful, it is necessary that no part of the room be strongly absorbing, since in this case a diffuse sound field cannot exist. Absorbing objects such as seats, tables, and people must be included when calculating α_d, despite the fact that such objects have ill-defined surface areas. In such cases it is common practice to assign an absorption A_i in square meters to each object, where $A_i = \alpha_d S_i$, with S_i the surface area. The absorptions of all objects are

summed, and the total absorption is included in the calculation of α_d, with no modification made to the total area. In other words, the total area $\sum S_i$ in Eq. (7.1) is taken to be that of the room boundaries, excluding objects and people. In the case of closely spaced absorbers, such as auditorium seats or suspended ceiling baffles, caution is necessary, since the total absorption may depend on the total area covered and may not be the sum of the absorptions of the individual objects. Also, the absorption coefficients of small patches of absorbing material (e.g., as measured in a reverberation room) are higher than those of a large area of the material (e.g., covering all of a room surface), due to the effects of diffraction at the material's edges. In the former case, the absorption coefficients of highly absorptive materials can exceed 1.0 (see also Section 7.7).

Sabine and Eyring Approaches

Several diffuse-field approaches exist; two are considered here. Both are expressed by the following equations, where Eq. (7.3) is applicable only for a compact source:

$$T_{60} = \frac{55.3V}{cA} \quad \text{(sound decay)} \qquad (7.2)$$

$$L_p(r) = L_w + 10\log_{10}\left(\frac{Q}{4\pi r^2} + \frac{4}{R}\right) \quad \text{(steady-state conditions)} \qquad (7.3)$$

where T_{60} = reverberation time, s
L_w = source sound power level, dB re 10^{-12} W
L_p = sound pressure level, dB re 2×10^{-5} N/m^2
c = speed of sound in air, $\approx$344 m/s at standard temperature and pressure (STP), m/s
R = room constant, $= A/(1-\alpha_d)$, m^2
A = total room absorption, $= -S\ln(1-\alpha_d) + 4mV$ (Eyring) $\approx \alpha_d S + 4mV$ (Sabine), m^2
r = source/receiver distance, m
Q = directivity factor
$2m$ = energy air absorption coefficient, Np/m
V = room volume, m^3
α_d = average diffuse-field surface absorption coefficient
S = total room (surface and barrier) surface area, m^2

The Eyring approach is applicable to rooms with arbitrary average surface sound absorption coefficient. It should be used, for example, to determine absorption coefficients of room surfaces from measured reverberation times. If, however, the average surface absorption coefficient is sufficiently low (say, $\alpha_d < 0.30$), it is accurate to use the Sabine approach; that is, Eqs. (7.2) and (7.3) with $-\ln(1-\alpha_d)$ replaced by α_d. Thus, the Sabine approach can be used when determining the sound absorption coefficients of materials in reverberation rooms. Of course, the approach applied in a particular sound field prediction must be consistent with that used to obtain the sound absorption coefficient data used in the prediction. Refer to reference 1 for further discussion of the relative merits of the Sabine, Eyring, and other diffuse-field theories.

Diffuse-field theory predicts the following characteristics of the sound field:

1. *Sound Decay/Reverberation Time.* After a sound source ceases to radiate, the mean-square pressure at the receiver decays exponentially with time. The corresponding sound pressure level decreases linearly with time. To a first approximation, the reverberation time is directly proportional to V/S and inversely proportional to α_d.
2. *Steady State.* The total field is the sum of direct and reverberant components described, respectively, by the first and second terms in parentheses of Eq. (7.3). The direct field, which dominates near the source, is independent of the room's properties. Its sound pressure level decreases at 6 dB/dd (dd = distance doubling). The reverberant field, which dominates far from the source, does not vary with source/receiver distance. Its sound pressure level is, to a first approximation (when both α_d and m are small), inversely proportional to α_d and S. The sound propagation function is as shown in Fig. 7.1.

Note that diffuse-field theory accounts for only some of the relevant room acoustical parameters and for some of these in an approximate manner. In particular, room geometry and source directivity are modeled only approximately. Neither the distribution of the surface absorption nor the presence of barriers or furnishings is modeled. This and the related fact that the theory is based on restrictive hypotheses seriously limit its applicability. To give one concrete example, the constant

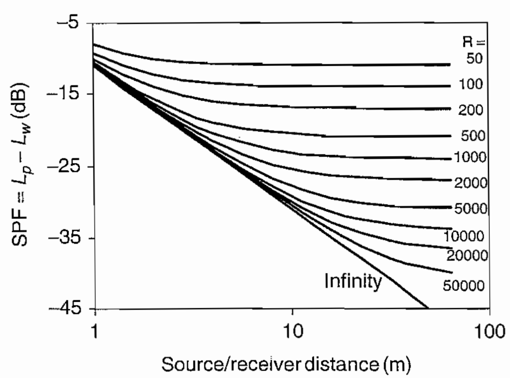

FIGURE 7.1 Sound propagation function curves predicted by diffuse-field theory for various values of the room constant R in m^2.

sound pressure level at sufficiently large distances from sources that is predicted by diffuse-field theory is only (approximately) found in practice in small rooms with low surface absorption (e.g., reverberation rooms, discussed in Section 7.8). Noise levels due to a single source in most rooms—especially large or absorptive ones—decrease monotonically with distance from the source (see, e.g., Fig. 7.4*b* below). Reference 3 discusses the applicability of diffuse-field theory more fully.

Diffuse-field theory, when applicable, can be used to estimate the reductions of reverberation time and noise level that occur when absorptive material is added to a room. Let A_b and A_a be the total room absorptions before and after treatment; $A_a = A_b + \Delta A$, where ΔA is the increase in room absorption. If A_b and ΔA are known, values of A_b and A_a can be used directly in Eqs. (7.2) and (7.3). Alternatively, if $T_{60,b}$ before treatment is known, $T_{60,a}$ after treatment can be determined from Eq. (7.2) as follows: since $T_{60,b} = 55.3V/(cA_b)$, then $A_b = 55.3V/(cT_{60,b})$. Now, $T_{60,a} = 55.3V/(cA_a) = 55.3V/[c(A_b + \Delta A)]$, and thus

$$T_{60,a} = \frac{55.3V}{c\left\{[55.3V/(cT_{60,b})] + \Delta A\right\}} \tag{7.4}$$

The steady-state sound pressure level $L_{p,a}$ after treatment can be calculated from that before treatment, $L_{p,b}$, as follows:

$$L_{p,a}(r) = L_{p,b}(r) + 10 \log_{10}\left[\frac{Q/(4\pi r^2) + 4/R_a}{Q/(4\pi r^2) + 4/R_b}\right] \tag{7.5}$$

At positions near sources, where the direct field dominates, the reduction in sound pressure level is small. At large distances from all sources, where the reverberant field dominates, the reduction approaches that of the reverberant sound pressure level alone. This, to a first approximation (when both α_d and m are small), is given by $10 \log_{10}(A_a/A_b)$. Doubling the room absorption reduces the sound pressure level of the reverberant field by 3 dB. Similarly, using Eq. (7.2), the reverberation time after treatment is $T_{60,a} = T_{60,b}(A_b/A_a)$. Doubling the sound absorption halves the reverberation time.

As an example, consider a room with dimensions 10 m × 5 m × 2.4 m (volume $V = 120$ m^3, surface area $S = 172$ m^2) and all concrete surfaces with $\alpha_b = 0.05$. Thus, ignoring air absorption and using the Sabine approach, we have $A_b = \alpha_b S = 0.05 \times 172 = 8.6$ m^2 and $T_{60,b} = 55.3V/(cA_b) = 55.3 \times 120/(344 \times 8.6) = 2.2$ s. A suspended acoustical ceiling with $\alpha_c = 0.9$ and surface area of 50 m^2 is installed to improve the acoustical environment. After treatment, $A_a = 8.6 + (0.9 - 0.05) \times 50 = 51.1$ m^2, so $T_{60,a} = 2.2 \times 8.6/51.1 = 0.4$ s.

7.3 OTHER PREDICTION APPROACHES

When diffuse-field theory cannot be applied, alternative approaches can be used to predict the steady-state sound pressure level, sound decay, and reverberation times in a room. These models apply only to compact sources. Extended sources must be approximated by an array of compact sources and the prediction model applied to each source. Two main approaches are available to accomplish this objective: computer algorithms (the method of image sources, ray or beam tracing, radiosity, hybrid models, etc.) and empirical models. The different approaches make assumptions which define and limit their applicabilities and accuracies. Furthermore, they take the various room acoustical parameters into account to a greater or lesser extent. To take advantage of the strengths of the different approaches and avoid their weaknesses, hybrid models combining several approaches into one model have been developed. Empirical prediction models are usually limited in application to specific building types.

Method of Image Sources

The method of image sources is based on the assumption that reflections from surfaces, assumed specular, can be replaced by the direct sound contributions of image sources. Figure 7.2 shows the simple example of a partial two-dimensional array of image rooms and sources. The simplest implementation of the method of image sources applies to empty, rectangular–parallelepiped rooms with no barriers.[4] In this case, the image sources corresponding to the infinite number of reflections are located on a three-dimensional grid. The total mean-square pressure is the sum of the contributions of all of the image sources, allowing for spherical divergence and energy losses due to absorption by the air and at each surface encountered by the ray from the image source. For decaying sound, the sound pressure at time t after the cessation of sound generation is calculated by summing over all image sources located at distances greater than ct from the receiver, where c is the speed of sound. The method of image sources can be extended to empty rooms of arbitrary shape bounded by planes; however, calculation times are greatly increased and become impracticable. The method of image sources can also account for the presence of furnishings, under the assumption that they are isotropically distributed in random fashion throughout

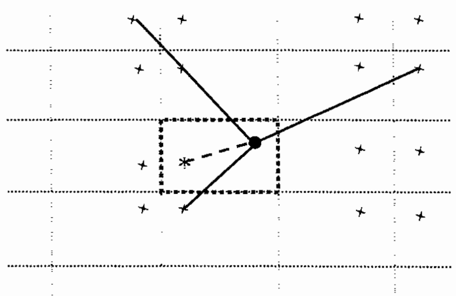

FIGURE 7.2 Image space of an empty two-dimensional room, showing the source (✱) and receiver (●), the image sources (⋆), the image surface planes (·········), the direct sound (- - - -), and the propagation paths of sound from three of the image sources (——).

the room.[5] In this case, the furnishings, as well as the sources, are mirrored in the room surfaces. The steady-state and decaying sound fields are formed as before. However, the contribution of each image source is modified due to scattering and absorption by the furnishings; absorption at surfaces is also increased due to scattering.

Ray and Beam Tracing

Ray-tracing techniques[6] can be used to predict sound fields in rooms of arbitrary shape with arbitrary surface absorption distributions, different surface reflection properties, and variable furnishing density. Source directivity can also be modeled. A computer program simulates the emission of a large number of rays (or beams) from each source in either random or deterministic fashion. Each ray is followed as it propagates in the room, being reflected and scattered by surfaces, barriers, and furnishings until it reaches a receiver position. The energy of a ray is attenuated according to spherical divergence as well as surface, furnishing, and air absorption. In principle, any surface reflection law (specular, diffuse, etc.) can be modeled. Ondet and Barbry[7] proposed an algorithm for accounting for quasi-arbitrary furnishing distributions in a ray-tracing model. Figure 7.3, taken from reference 8, illustrates the potential of ray-tracing techniques. It shows the contour map of the predicted reductions of total A-weighted noise levels over the floor of a furnished workshop containing eight machinery sources, which result from the introduction of an acoustical barrier around a noise-sensitive assembly bench and a partial ceiling absorption treatment suspended over the region of the sources. Of course, the program must be run for each frequency band (i.e.,

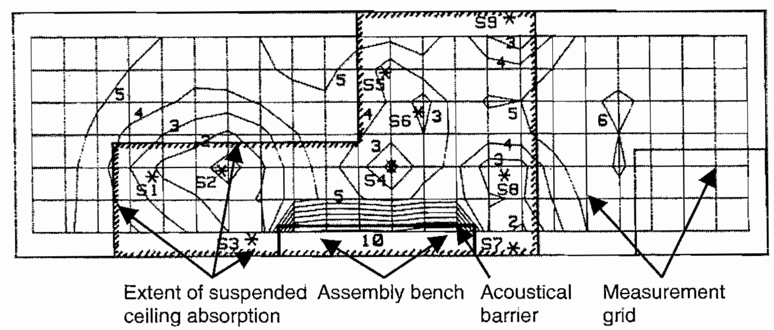

FIGURE 7.3 Floor layout of a furnished workshop (dimensions 46.0 × 15.0 × 7.2 m) showing a contour map of the predicted reductions of total A-weighted noise levels which result from the introduction of an acoustical barrier around a noise-sensitive assembly bench and of an absorptive treatment suspended below the ceiling over the region of the eight machinery sources (the shaded, L-shaped, enclosed area). The map was produced from noise levels predicted before and after treatment at positions on an imaginary 2 × 2-m grid, 1.5 m above the floor, as shown. Also shown are the noise sources (e.g., S4*) and the contour lines and their values (e.g., 5).

octave- or third-octave bands) to account for the frequency-dependent nature of the sound absorption coefficient of the room surfaces and that of the barrier insertion loss. This kind of detailed analysis is not possible using diffuse-field theory. It would only be possible to estimate noise reductions from the increase in absorption. These reductions could then be corrected as a function of the proximity of the receiver to the acoustical treatment and of the estimated insertion loss of the barrier.

Empirical Models

Empirical models are developed from experimental data. They usually focus on a particular category of room—models for offices, classrooms, and industrial workshops are discussed below. Measurements are made, in a number of rooms of some category, of the acoustical quantities to be predicted. Empirical algorithms or equations which predict the experimental results from appropriate predictor parameters describing the rooms are developed. This can, for example, involve multivariable regression modeling, whereby statistical modeling software is used to find the minimum set of mutually statistically independent predictors, each of which is highly correlated with the data to be predicted, that most accurately predicts the measured data. For further information on multivariable regression modeling, consult reference 9.

Auralization

Auralization is the process of rendering audible sounds "played" in a virtual room for which the acoustical response has been predicted. It allows subjective evaluation of the room. If done accurately, auralization allows full three-dimensional sound perception, with source externalization (i.e., the sound is perceived to be outside the head), spatial localization, and spatiousness. Auralization involves predicting the combined response of a virtual room and a virtual listener in it. The listener response is quantified by head-related transfer functions (HRTFs) quantifying how the acoustical response of the human external auditory system varies with frequency and angle. The room response is predicted using models, such as ray tracing, which predict the individual sound path contributions arriving at the receiver; since impulse responses involving phase effects are required, the room's phase response must also be considered. The result is the binaural impulse response (comprising the impulse responses at the left and right eardrums) of the room–listener combination. This is convolved with a sound signal for replay to a real listener. Readers interested in further details of this technique should consult reference 10.

7.4 DOMESTIC ROOMS AND CLOSED OFFICES

Schultz[11] investigated the prediction of sound pressure levels in domestic rooms and closed offices. He measured the variation of sound pressure level with distance from a source in a variety of small rooms, observing that levels never

become constant at larger distances as predicted by diffuse-field theory. In fact, he found that the curves always had a slope of about −3 dB/dd, though the absolute levels of the curves varied considerably. He further found that existing models developed for predicting sound propagation in, for example, workshops and corridors could not predict his experimental results. Schultz therefore proposed the following empirical formula:

$$L_p(r) = L_w - 10\log_{10} r - 5\log_{10} V - 3\log_{10} f + 12 \text{ dB} \qquad (7.6)$$

where r is the source–receiver distance in meters, V is the room volume in cubic meters, and f is the frequency in hertz. Note that this formula does not explicitly contain a room absorption term. Such behavior contrasts markedly with that predicted by diffuse-field theories and is an excellent example of their limitations.

7.5 CLASSROOMS

Relevance and Characteristics

Classrooms are acoustically critical spaces in which verbal communication is crucial for teaching and learning. Acoustically, conference rooms, gymnasiums, and other rooms for speech have much in common with classrooms. Many classrooms are built with little or no attention paid to the acoustical design. Studies have shown that nonoptimal acoustical conditions in classrooms result in impaired verbal communication between teachers and students, impaired student language development and learning, and teacher voice and other problems.[12,13] The problems are particularly acute for "acoustically challenged" listeners, including young and hearing-impaired people and those using a second language.

Classrooms vary from small seminar rooms for a few occupants to school classrooms for several tens of children to larger university lecture rooms and auditoria accommodating hundreds of listeners. Smaller classrooms are usually of rectangular shape. Larger lecture rooms can have, for example, fan plan shape, inclined seating, and nonflat ceiling profiles. In smaller classrooms, talkers and listeners can be anywhere in the classroom, and source–receiver distances can vary from less than a meter to several meters. In lecture rooms, the talker is usually at one end of the room, with the listeners spread out in front; source–receiver distances can vary from several meters to several tens of meters. For hygiene reasons, classrooms may have hard, nonabsorptive surfaces, though carpets and wall and ceiling absorption are not uncommon. Lecture and conference rooms can have nonabsorptive or padded, sound-absorptive seating. Of course, the occupants themselves contribute significant absorption to the classroom. This and the fact that classroom occupancy can vary considerably must be considered in the acoustical design. A detailed discussion of the physical and acoustical characteristics of (university) classrooms is found in reference 14. Of particular interest is the rate at which speech and noise levels decrease with distance from their sources, which is small in small, nonabsorptive classrooms. It increases with classroom size and absorption and can be large in large, absorptive (e.g., occupied) classrooms. One consequence of this is that speech levels in large classrooms may decrease by 10 or more decibels from the front to the back of the seating area.

Speech Intelligibility

In classrooms, as in other rooms for speech, quality and ease of verbal communication are prime concerns (see also Section 7.7). The quality can be quantified in human terms by speech intelligibility, the percentage of words correctly identified by the listener. Here, in general, we consider the effect of the room on the accurate transmission of speech signals from a talker to a listener and not, for example, the effects of individual talker and listener characteristics. Verbal communication is considered to be affected by two main factors—the classroom reverberation and the speech-signal-to-background-noise-level difference (often called the signal-to-noise ratio). The effect of reverberation can be quantified by the early-to-late energy ratio C_{50} (which is highly correlated with early decay time and reverberation time in many cases). This frequency-dependent ratio is usually measured in octave bands. The signal-to-noise level difference depends on the levels of speech and the levels of noise at the listener position. Total A-weighted or octave- or third-octave-band equivalent continuous levels are often considered. If the voice levels remain constant, the speech intelligibility decreases with increased reverberation and increases with increased signal-to-noise level difference. A number of physical metrics exist which combine these two quantities into a single speech intelligibility measure; these include the useful-to-detrimental energy ratio U_{50}, articulation index AI (discussed in Section 7.7), speech transmission index STI, and speech intelligibility index SII.

Numerous studies have found that many classrooms have nonoptimal acoustical conditions, with excessive noise levels and reverberation. A review of published data and of the many complex issues associated with speech intelligibility in classrooms is contained in reference 15. The classroom speech sources are the teachers' and the students' voices. Classroom noise sources include mechanical services (e.g., ventilation outlets), classroom equipment (projectors, computers), and the teachers' or students' voices when another person is generating the signal to be heard. Noise breaking into the classroom from outside can be significant when the classroom is located near transportation (such as highways and airports) or in cases when children are active in nearby corridors or play areas. Finally, classroom activity itself generates significant noise, including impact noise from furniture, toys, and so on. Data on the typical sound pressure levels generated by human talkers and classroom noise sources are available.[16] It is likely that a number of complex factors, including room acoustics, affect what these levels are at listener positions in a given classroom at a given time.

It is generally considered that, for excellent speech intelligibility, background noise levels should not exceed about 40 dBA for acoustically unchallenged listeners and 30 dBA for acoustically challenged listeners. The question of what is the optimal reverberation for speech intelligibility is a complex one. One body of opinion considers that reverberation should always be minimized. However, this is based on the results of speech intelligibility tests that were done under conditions that did not account for the acoustical behavior of classrooms. Investigations involving the useful-to-detrimental energy ratio speech intelligibility metric and realistic room acoustical modeling show that some reverberation can be beneficial (since it increases reverberant speech levels). The results indicate that the reverberation should be optimized as a function of the classroom volume and background noise. Optimal reverberation times vary from low values in small, quiet classrooms to over 1 s in large, noisy ones. For a full discussion of this issue, refer to reference 17. In any case, reverberation should be minimized in classrooms with high signal-to-noise level differences (e.g., resulting from voice amplification). Moreover, it is likely that less reverberation can be tolerated by acoustically challenged listeners. It has been shown that speech intelligibility is not very sensitive to variations in reverberation, and it has been suggested that a classroom reverberation time of about 0.5 s is usually appropriate.[18]

Standards and guidelines exist to help design professionals achieve high acoustical quality in classrooms and other educational spaces. They specify the acoustical conditions to be achieved in new and renovated rooms. They discuss reverberation times and background noise levels to be achieved in the unoccupied room. They also provide advice on how to achieve the design targets. Two recent examples of such standards are ANSI S12.60—2002 in the United States[19] and Building Bulletin 93 in the United Kingdom.[20]

Predicting Classroom Acoustics

Predicting acoustical quality in a classroom involves predicting room reverberation and steady-state sound pressure levels generated by the speech and noise sources, including student activity. Prediction should take into account the absorption contributed by the room occupants and furnishings (e.g., absorptive seating). This involves an appropriate prediction model and accurate input data. In the case of small, untreated classrooms, it is likely that diffuse-field theory is reasonably accurate. For treated and larger classrooms, comprehensive techniques such as ray tracing can be used. Empirical models are also available and inherently incorporate realistic data. Based on measurements of reverberation times and steady-state levels generated by a speech source in a wide variety of typical university classrooms and on published information, empirical models for predicting octave-band reverberation times and total A-weighted speech levels have been developed.[21] Approximate values of $T_{60,u}$ in the unoccupied classroom can be determined using Eq. (7.2), with the average surface absorption coefficient calculated as the sum of contributions (presented in Table 7.2) to the room average value, which are associated with the sound-absorbing features present in the classroom. An alternative empirical formula for predicting the 1-kHz octave-band $T_{60,u}$ is

$$T_{60,u} = 0.874 + 0.0021(LW) + 0.303\text{refl} + 0.412\text{basic} - 0.384\text{absorb} - 0.804\text{upseat} \qquad (7.7)$$

TABLE 7.2 Typical Octave-Band Contributions of Classroom Sound-Absorptive Features to Room-Average Surface Absorption Coefficient

Surface Feature	125 Hz	250 Hz	500 Hz	1000 Hz	2000 Hz	4000 Hz	8000 Hz
Basic	0.12	0.10	0.10	0.09	0.10	0.09	0.10
Carpeted floor	0.00	0.00	0.02	0.04	0.07	0.09	0.17
Wall/ceiling absorption	0.01	0.04	0.08	0.10	0.10	0.10	0.10
Upholstered seats	0.20	0.20	0.16	0.12	0.09	0.07	0.05

TABLE 7.3 Octave-Band Values of Average Absorption per Person

Band, Hz	125	250	500	1000	2000	4000	8000

where the parameters are defined following Eq. (7.10). The absorption of the classroom occupants can be included using the data in Table 7.3, and the number of occupants can be used to estimate the associated increase in classroom absorption. For an average talker speaking between a normal and a raised voice (total A-weighted sound power level $\approx$74 dBA), total A-weighted speech levels in the unoccupied classroom can be predicted from

$$\mathrm{SLA}_u(r) = I_u + s_u \frac{\log_{10}(r)}{\log_{10}(2)} \tag{7.8}$$

with

$$I_u = 65.8 - 0.0105(LW) + 1.52\mathrm{fwdist} - 1.41\mathrm{absorb} - 4.32\mathrm{upseat} \tag{7.9}$$

and

$$s_u = -1.21 - 0.088\ L + 1.14\mathrm{basic} \tag{7.10}$$

where $T_{60,u}$ = 1-kHz octave-band reverberation time, s
SLA_u = total A-weighted speech level, dBA
I_u = intercept of total A-weighted sound propagation curve, dBA
s_u = slope of total A-weighted sound propagation curve, dBA/dd
r = source–receiver distance, m
L = average classroom length, m
W = average classroom width, m
fwdist = distance from source to nearest wall, m
refl = 1 if classroom contains beneficial reflectors, = 0 if not

absorb = factor quantifying extent of sound-absorptive wall or ceiling treatment
absorb = 1 corresponds to full-coverage wall or ceiling treatment; in other cases, values should be scaled proportionately
upseat = 0 for nonabsorptive seating; = 1 for padded, sound-absorptive seating
basic = 1 if all classroom surfaces and seats are not sound absorptive; = 0 otherwise

As an example, consider a large classroom with average dimensions of $L = 20$ m long, $W = 10$ m wide, and 6 m high (volume $V = 1200$ m^3, surface area $S = 760$ m^2). The distance from the typical lecturing position to the nearest (front) wall is fwdist = 2.5 m. The classroom has a profiled ceiling directing sound to the back (i.e., beneficial reflectors, refl = 1). Consider the cases where N_p is 50 or 200 occupants. Before treatment, the classroom has no sound-absorptive surfaces (absorb = 0, basic = 1) and nonabsorptive seating (upseat = 0). Thus, the average surface absorption coefficient is that corresponding to the "basic" configuration in Table 7.2 ($\alpha = 0.09$). Equation (7.2) gives the corresponding $T_{60,u}$'s. Assuming air absorption exponents for a temperature of 20°C and a relative humidity of 50% ($m = 0.0012$ Np/m; see Table 7.1) and using the Eyring approach, the total absorption in the unoccupied room at 1 kHz is $A_u = -S\ \ln(1-\alpha) + 4mV = -760\ \ln(1 - 0.09) + 4 \times 0.0012 \times 1200 = 77.4$ m^2. From Eq. (7.2) the 1-kHz $T_{60,u} = 55.3V/(cA_u) = 55.3 \times 1200/(344 \times 77.4) = 2.49$ s. With 50 occupants, the total room absorption $A_o = A_u + N_pA_p = 77.4 + 50 \times 0.81 = 117.9$ m^2, and $T_{60,o} = 55.3V/(cA_o) = 55.3 \times 1200/(344 \times 117.9) = 1.64$ s. Similarly, with 200 occupants $T_{60,o} = 0.81$ s. Here, T_{60} is excessive with low occupancy and decreases sharply with the number of occupants. To control the reverberation, the classroom is treated with full-coverage wall absorption (absorb = 1) and padded, sound-absorptive seating (upseat = 1); thus, basic = 0. The average surface absorption coefficients are now the sum of the values for basic, wall/ceiling absorption, and upholstered seats given in Table 7.2 (e.g., $0.09 + 0.10 + 0.12 = 0.31$ at 1 kHz). The 1-kHz T_{60}'s in the classroom when unoccupied and with 50 or 200 occupants are 0.67, 0.63, and 0.52 s. The treatment significantly reduces T_{60}—in the unoccupied classroom by as much as 200 occupants do—and decreases the variation of T_{60} with the number of occupants.

As for speech levels, consider listeners seated at the front and back of the classroom at distances of 3 and 12 m from the talker. Before treatment, from Eq. (7.9), $I_{u,b} = 65.8 - 0.0105LW + 1.52\mathrm{fwdist} - 1.41\mathrm{absorb} - 4.32\mathrm{upseat} = 65.8 - 0.0105 \times 20 \times 10 + 1.52 \times 2.5 - 1.41 \times 0 - 4.32 \times 0 = 67.5$ dBA and, from Eq. (7.10), $s_{u,b} = -1.21 - 0.088L + 1.14\mathrm{basic} = -1.21 - 0.088 \times 20 + 1.14 \times 1 = -1.83$ dBA/dd. Using Eq. (7.8), the speech level at any position is $\mathrm{SLA}_{u,b}(r) = 67.5 - 1.83\ \log_{10}(r)/\log_{10}(2)$; thus, at 3 and 12 m speech levels are 64.6 and 61.0 dBA. Levels in the occupied classroom can be calculated using Eq. (7.5). Assuming $Q = 2$ to the front of a talker, at the front and back of the classroom speech levels are 63.1 and 59.2 dB with 50 occupants and 60.9 and 56.2 dBA with 200 occupants. After treatment, $I_{u,a} = 65.8 - 0.0105 \times 20 \times 10 + 1.52 \times 2.5 - 1.41 \times 0 - 4.32 \times 1 = 63.2$ dBA and $s_{u,a} = -1.21 - 0.088 \times 20 + 1.14 \times 0 = -3.0$ dBA/dd, giving speech levels of 57.1 and 51.1 dBA unoccupied at the front and back seats; occupants decrease levels by no more than 1 dB. Acoustical treatment causes speech levels at the front and back of the unoccupied classroom to decrease by 7.5 and 9.9 dBA for 50 occupants and with 200 occupants by 4.5 and 6.1 dB. These results must be interpreted with care, as they do not account for certain relevant nonacoustical factors. For example, they assume that the talker's vocal output is invariant, as would be the case for a loudspeaker. In fact, research suggests that a talker's vocal output varies with the prevailing classroom acoustical conditions; a preliminary empirical model for predicting this phenomenon is presented in reference 16.

Noise levels generated by classroom noise sources (e.g., projectors or ventilation outlets) can be estimated from their output power levels and receiver distances using the above empirical model after adjusting for the difference between the actual and the assumed output power levels. Student activity noise should also be considered; a preliminary empirical model for predicting this is presented in reference 16. Then signal-to-noise level differences can be determined. Classroom early-decay times and signal-to-noise level differences can then be used to determine values of speech intelligibility metrics.

Controlling Classroom Sound

Controlling and optimizing the acoustical conditions in a classroom or other rooms for speech involve three fundamental considerations:

1. *Promoting High Speech Levels.* Avoid excessive classroom cubic volume due, for example, to high and vaulted ceilings. Use room geometries which direct sound to the back of the room. In large lecture rooms, this can include angled reflectors around teaching areas and profiled ceilings. Keep at least the central part of the ceiling sound reflective to promote the reflection of speech sounds to the back of the classroom. Use approximately square floor plans to avoid long and wide rooms. Amplification by a speech reinforcement system or a sound field enhancement system may be an option; their design is beyond the scope of this chapter; see reference 22. One important issue to consider at the classroom design stage is that the optimal acoustical conditions for unaided speech may not be the same as with a speech reinforcement system.

2. *Controlling Background Noise.* Avoid open-plan design. Control the noise and vibration of mechanical services (see Chapter 16). Locating ventilation outlets toward the front of lecture rooms where speech levels are highest helps optimize signal-to-noise level differences throughout the room. Avoid high terminal velocities of supply air terminal devices and place air-volume control devices at distances of 0.5 m or more upstream to minimize noise generated by turbulent flow. Choose quiet equipment for use in the classroom. Impact noise due to student activity can be reduced by the use of carpets and cushioning materials (split tennis balls on desk, table, and chair legs are widely used). The partitions bounding the classroom must provide adequate sound isolation (see Chapter 10); in critical cases, this might require the use of nonopenable windows.

3. *Optimizing Reverberation.* Apply appropriate sound-absorptive materials to the room surfaces. Avoid applying sound absorption to the central part of the ceiling, which provides useful reflections between talkers and listeners. Using sound-absorptive seating allows the ceiling to be left reflective and reduces the sensitivity of the classroom's acoustical conditions to the number of occupants.

7.6 INDUSTRIAL WORKSHOPS

Relevance and Characteristics

Industrial workshops often have serious acoustical problems due to excessive noise and reverberation. Most jurisdictions have regulations aimed at limiting the risk of hearing damage by limiting the noise exposure of industrial workers. Excessive reverberation can also lead to poor verbal communication and a reduced ability to identify warning signals, and thus danger, as well as to stress and fatigue.

Industrial buildings come in every shape and size. However, many are rectangular in floorplan (with widely varying dimension ratios and floorplan sizes), with flat or nonflat (e.g., pitched or sawtooth) roofs. The floors of most workshops are made of concrete. The walls are often of brick or blockwork, sometimes of metal cladding. Workshop roofs are usually of suspended-panel construction, consisting of metal or other panels supported by metal trusswork or portal frames. A common modern construction is the steel deck, consisting of, for example, profiled metal as the internal surface, a vapor barrier, several centimeters of thermal insulation, tar paper, and gravel ballast as the external surface, again supported by metal trusswork. Acoustical steel decks exist; the inner metal layer is perforated, and its profiles are filled with sound-absorptive material, providing high sound absorption over a broad range of frequencies. Acoustical decks can support loads almost as great as normal decks, cost only about 10% more, and should always be considered at the design stage. The average surface absorption coefficients of untreated industrial buildings are 0.08–0.16 in the 125- and 250-Hz octave bands, varying with construction, and 0.06–0.08 in the 500–4000-Hz octave bands.

Figures 7.4*a* and *b* show the reverberation times and 1-kHz sound propagation function curves measured in an empty, untreated workshop with average dimensions of 45 m × 42.5 m and height of 4 m and a double-panel roof.[23] It is often the case that the sound propagation function—$L_p(r) - L_w$ as defined in Eq. (7.3)—at most source–receiver distances and the reverberation time are found to be highest at midfrequencies. The values of both quantities decrease at low and high frequencies due to increased panel and air absorption.

The effects of workshop furnishings are also illustrated in Figs. 7.4*a* and *b*, showing the reverberation times and sound propagation function curves after first 25 and then an additional 25 printing machines were introduced. These

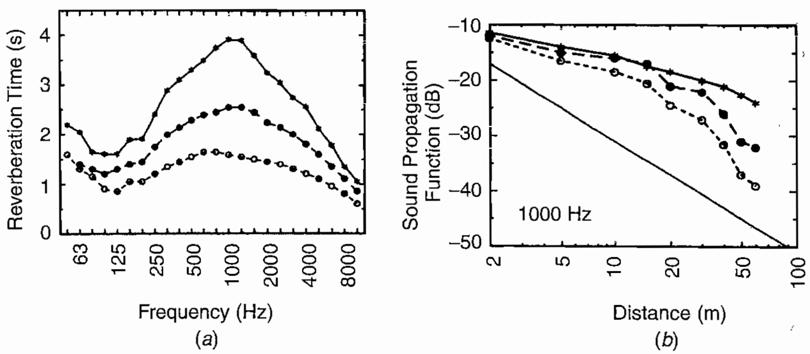

FIGURE 7.4 Measured (*a*) third-octave-band reverberation times and (*b*) 1-kHz sound propagation curves in an industrial workshop when empty (×——×) and containing 25 (•- - -•) and 50 (⊙····⊙) metal machines; (——) free-field sound.

metal machines had average dimensions of 3 m × 3 m and height of 2 m. Introduction of the furnishings significantly decreased reverberation times and sound propagation function values. According to diffuse-field theory, the decreases of reverberation time for this particular workshop correspond to the introduction of as much as 900 m^2 of acoustical absorption.[23] In fact, they are related to increased diffusion, not increased absorption. The percentage changes of reverberation time and the magnitudes of the changes of the sound propagation function with increasing furnishing density vary little with frequency. These results are supported by similar measurements in other workshops. They again illustrate the limitations of diffuse-field theory, which cannot accurately predict the effects of complex room geometry or furnishings.

Workshop Noise Prediction

Models developed for predicting noise levels and reverberation times in industrial workshops fall into two categories—*comprehensive* models, based on approaches such as ray tracing and the method of image sources, and *simplified*, based on simple theoretical or empirical approaches. Comprehensive models have been evaluated experimentally, concluding that the ray-tracing model of Ondet and Barbry[7] was most inherently accurate.[24] Ray tracing can account for complex room shape, barriers, and nonisotropic absorption and furnishing distributions. Simplified models have also been evaluated experimentally, concluding that a model developed by Kuttruff was inherently accurate in furnished workshops.[26]

Kuttruff[26] developed a simplified model for long and wide furnished workshops based on radiosity theory; the numerous furnishings on the floor and the ceiling were modeled as diffusely reflecting surfaces. According to this model, in a workshop of height h and with average absorption coefficient α, the sound pressure level $L_p(r)$ generated by an omnidirectional compact source of sound power level L_w at a distance r is given by

$$L_p(r) = L_w + 10\log_{10}\left\{\frac{1}{4\pi r^2} + \frac{1-\alpha}{\pi h^2}\left[\left(1+\frac{r^2}{h^2}\right)^{-1.5} + \frac{\beta(1-\alpha)}{\alpha}\left(\beta^2+\frac{r^2}{h^2}\right)^{-1.5}\right]\right\} \quad (7.11)$$

where $\beta \approx 1.5\alpha^{-0.306}$. Despite the assumption of infinite length and width, the model performed well in comparison with measurements made in workshops of a wide range of lengths and widths.[25] One disadvantage of the model is that it does not include a parameter that can be varied to account for variations in the number of furnishings. However, as can be seen from Fig. 7.4*b*, the variations are small at the smaller source–receiver distances that dominate noise levels in many practical cases. An alternative is empirical models for predicting workshop noise levels and reverberation times.[27]

When dealing with multiple sources in workshops, the effect of noise control measures may be determined to a first approximation by considering what happens at a distance corresponding to the average source–receiver distance. Changes in total noise levels due to noise control measures are approximated by changes in the sound propagation function at this distance. For machine operator positions, the average source–receiver distance is small—typically 1–2 m. For a room with a more or less square floorplan and with sound sources uniformly distributed over the floor, the average source–receiver distance is about one-half the average horizontal dimension.

As an example, let us use the Kuttruff model to calculate the 1-kHz noise level in the workshop illustrated in Fig. 7.3 (but without the acoustical screen and partial suspended ceiling shown) before and after introduction of full-coverage suspended ceiling absorption. Consider a position midway along the assembly bench and 1.5 m above the floor. The workshop dimensions are length 48.0 m, width 16.0 m, and height 7.2 m. Assume that the average midfrequency absorption coefficients of the workshop surfaces are 0.07 (untreated) and 0.4 (treated). The workshop contains nine noise sources located as shown in Fig. 7.3, with 1-kHz sound power levels and source–receiver distances as shown in Table 7.4. Table 7.4 shows the individual noise-level contributions of the sources before and after treatment. Total levels are determined by energy-based addition of the individual source contributions. The result is 82.4 dB before treatment and 78.7 dB after treatment. Introduction of the ceiling treatment is predicted to reduce the 1-kHz noise level at the assembly bench by 3.7 dB (confirming that the treatment illustrated in Fig. 7.3 is highly cost-effective).

Accurate prediction relies on an inherently accurate model and accurate input data. Workshop surface absorption coefficients were discussed above. Many workshop prediction models also include a parameter describing the workshop furnishing density. It is not known how to determine this quantity accurately. In theory, it can be estimated as the total surface area of the furnishings (or, more practically, of imaginary boxes that would fit around the individual objects)

TABLE 7.4 Details of Calculation of 1-kHz Noise Levels in Workshop before and after Acoustical Treatment Using Kuttruff Simplified Prediction Model[a]

Source Number	L_w, dB	Distance, r (m)	Before $L_{p,a}(r)$, dB	After $L_{p,b}(r)$, dB
1	94	13.5	70.7	65.3
2	101	9.8	79.1	74.8
3	92	7.6	71.1	67.5
4	94	3.9	75.6	73.5
5	86	9.5	64.2	60.0
6	90	7.6	69.1	65.5
7	91	8.7	69.6	65.6
8	89	8.5	67.6	63.8
9	93	15.5	69.0	63.2
Total noise level			82.4	78.7

[a] Reference 26.

divided by 4 times the volume of the furnished region.[24] However, there is some evidence that this procedure underestimates the correct value.[8] Research has shown that average workshop furnishing densities may attain 0.2 m^{-1} or higher, those of a workshop's furnished regions 0.5 m^{-1} or higher.[28] In any case, no simplified model will ever predict noise levels in workshops of complex shape or furnishing distributions or that contain, for example, barriers with high accuracy. In such cases, ray tracing may be the only viable option. Finally, a problem shared by all prediction models is the accurate estimation of the sound power levels of the noise sources. This problem is discussed in Chapter 4.

Workshop Noise Control

To achieve the reduction of workshop noise levels (as required by modern occupational noise regulations) in a cost-effective manner, the application of noise control principles should be incorporated into new designs and renovation in the following order of priority:

1. *Control at Source.* Reduce the sound power outputs of the equipment by design or by retrofit acoustical treatment.
2. *Control of Direct Field.* Isolate receiver positions from noisy sources by increasing the distance between them, by the use of source enclosures (see Chapter 12), and by surrounding the receiver by a cabin or screen. Barriers and screens are often not practical or cost-effective alternatives in workshops. Often separation can be achieved by appropriate planning of the workshop layout, taking full advantage of the building geometry, natural barriers such as stockpiles, and furnishings at the design stage.
3. *Control of Reverberant Field.* Apply sound-absorptive materials to the room surfaces. Such treatments should be accorded lower priority since they tend to be expensive and not very effective near noise sources, such as at operator positions. In practice, reductions of 0–6 dBA are possible. The best surfaces to treat are those closest to noise sources and/or receiver positions. In low-height industrial workshops, this usually implies the ceiling. Consider an acoustical steel deck at the design stage or acoustical treatments consisting of sound-absorptive materials applied to or suspended from the ceiling—for example, acoustical baffles (rectangular pieces of absorptive material) hung in appropriate patterns at appropriate densities. A particularly cost-effective treatment consists of suspending sound absorbers directly above noise sources. Difficulties may arise due to interference with overhead cranes and lighting and sprinkler systems and with respect to fire regulations and hygiene requirements. The treatment of walls may be warranted in more regularly shaped enclosures and where noise sources are located close to walls when it is important to absorb the strong wall reflections. Note that in workshops of any shape surface absorption, even when it has little effect on the total noise levels, may significantly reduce reverberation, reducing the perceived "noisiness" of the work environment and improving verbal communication.

Readers interested in the low-noise design of industrial workshops should be aware of relevant ISO standards available to help in the task. ISO 11688[29,30] provides advice on the design of low-noise machinery and equipment. Part 1 discusses planning, and Part 2 discusses the principles of low-noise design. ISO 14257[31] defines criteria for evaluating the acoustical quality of workshops with respect to noise control and describes how to perform the measurements to evaluate an existing workshop.

7.7 OPEN-PLAN OFFICES

Open-plan offices are one of the most common modern work environments. In these large spaces, many seated workers are separated by low barriers that provide partial visual and acoustical separation between workstations. The barriers may be free-standing but today are usually in the form of integrated furniture or cubicles. The ceiling and the carpeted floor form two large, extended sound-absorbing planes; their horizontal dimensions are much greater than the height of the ceiling. The space between these surfaces is filled with office furniture and barriers that are usually sound absorbing. Diffuse-field theory certainly does not apply in such a space; the sound pressure level decreases continuously with distance from sources (an example is shown in reference 3). The principal problem in an open-plan office is not propagation to large distances but the provision of privacy between neighboring workstations. The important sound paths are, therefore, the short-range ones. Sound from one work position reflects from extended surfaces (ceiling, walls, and windows) and diffracts over or around the edges of barriers, as illustrated in Fig. 7.5. These sound paths must be controlled to provide acoustical privacy for workers.

Open-plan offices can provide a reasonable degree of acoustical privacy if they are carefully designed as a complete system and if adjacent work functions are

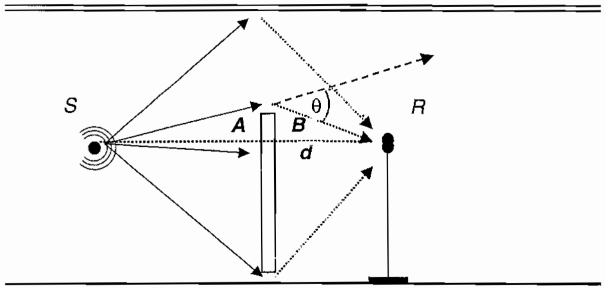

FIGURE 7.5 Possible sound paths between workstations in an open-plan office cross section. Reflection from the ceiling is reduced by using highly absorptive ceiling materials, transmission through the barrier by selecting a sufficiently heavy panel with adequate sound transmission loss, and diffraction over the barrier by increasing the barrier height.

compatible and not too close together. If any aspect of the system is neglected, then adequate acoustical privacy will not be achieved. Obtaining adequate acoustical privacy is first a question of attenuating unwanted speech sounds from adjacent work spaces, because speech sounds are much more distracting than most other types of noises. It is usually also necessary to include masking sound to render intruding speech sounds less intelligible while not being a source of annoyance. Special protection should be provided against noisy devices such as printers and copiers—for example, by locating them in a shielded area. Conference rooms with full-height partitions, providing good sound insulation, should be available for activities which require low background noise levels and particularly high privacy.

Open-Plan Office Barriers

Barriers (also called screens, partial-height partitions, workstation panels, or office dividers) provide sound attenuation and visual privacy between workstations for seated persons. They are the basic component of systems furniture (usually forming cubicles) that combines the functions of a barrier and supporting amenities such as storage compartments, lighting, power, communications, and work surfaces into a single unit. A barrier should attenuate sound that passes through it so that the transmitted sound is negligible.

Sound diffracts over the top of the barrier to reach the next workstation. For an infinitely wide barrier between a source and a receiver position, the insertion loss IL relative to the level at the receiver in the absence of the barrier can be approximated by[32]

$$\mathrm{IL} = 13.9 + 7\log_{10} N + 1.4(\log_{10} N)^2 \quad \mathrm{dB} \qquad \text{for } N \geq 0.001 \tag{7.12}$$

where the Fresnel number $N = 2f(A + B - d)/c$, d is the straight-line distance from the source to the receiver in meters, A is the distance from the source to the top of barrier in meters, B is the distance from the top of the barrier to the receiver in meters, and c is the sound speed (Fig. 7.5 shows A, B, and d). The greater the angle that sound has to bend to reach the receiver position on the other side of the barrier (θ in Fig. 7.5), the greater is the insertion loss of the barrier. Thus, higher barriers are more effective than lower ones, and barriers placed close to the talker or listener are more effective than those equidistant from both.

The effects of diffraction around and transmission through a barrier can be combined to determine the total insertion loss of a barrier. Sound transmitted through the screen should be negligible relative to the sound diffracted around it, especially at those frequencies important for speech intelligibility. Specifying that, at 1000 Hz, the normal-incidence sound transmission loss should be 6 dB greater than the theoretical insertion loss due to diffraction is a satisfactory criterion. This criterion leads to the requirement that the minimum mass per unit area of the barrier, ρ_s in kilograms per square meter, should be $\rho_s \geq 2.7(A + B - d)$. For an isolated screen, the total effect of the barrier can be calculated by applying Eq. (7.12) to each edge in turn and then summing the acoustical energies.

Maximum barrier dimensions are usually limited by physical convenience, possible interference with airflow, and preservation of the open look. Recommended minimum dimensions are height 1.7 m and width 1.8 m. Of course, a complete cubicle is equivalent to a long barrier, for which there is negligible propagation around the ends. If the attenuation of a high barrier is desired but visual openness must be maintained, a plate of glass or transparent plastic panel can be fitted to the top of a low barrier to increase its "acoustical height." The gap between the bottom edge of the barrier and the floor should be small; otherwise sound can reflect under the barrier to the opposite side. This is not critical, because sound following this path tends to be diffused or absorbed by furniture and carpets; a gap of up to 100 mm can be left when the floor is carpeted.

Measures for Rating Acoustical Privacy

Acoustical privacy is usually referred to as speech privacy because it is speech sounds that are usually the most disturbing (see also Section 7.5). Speech privacy is essentially the opposite of speech intelligibility. That is, the lower the intelligibility of the speech, the greater the speech privacy. Speech privacy (and speech intelligibility) is related to the level of the intruding speech sounds relative to the less meaningful ambient noise. Hence, speech privacy is related to measures involving the signal-to-noise level difference, where speech is the signal and the general ambient noise is the noise component.

Articulation index (AI) is a frequency-weighted signal-to-noise level difference measure which indicates the expected speech intelligibility in particular conditions. The signal-to-noise level differences in each frequency band are weighted according to their relative importance to the intelligibility of speech. These weighted signal-to-noise level differences are summed to obtain the AI value, between 0 and 1. An AI of 1 is intended to indicate conditions in which near-perfect intelligibility is expected. An AI close to 0 is expected to indicate conditions of near-perfect speech privacy. The AI has been widely used as a measure of speech privacy; AI $\leq$ 0.15 is considered to provide *normal* or *acceptable* speech privacy in open-plan office situations. The AI has now been replaced by the SII. It is similar to the AI but has slightly larger values, so the criterion for acceptable speech privacy becomes SII $\leq$ 0.20. Both have been described in ANSI standards.[33,34]

Figure 7.6 illustrates the suitability of this criterion. In this figure, median speech intelligibility scores are plotted versus SII for situations simulating conditions in open-plan offices. It is seen that SII = 0.2 represents the point below which privacy increases rapidly with decreasing SII. One can think of it as the point at which improvements to the acoustical design start to improve speech privacy. In practice, it is also a practically achievable goal if all aspects of the acoustical design are carefully considered.

Acoustical Design of Complete Workstations

Sound propagation between workstations in an open-plan office with modular workstations (cubicles) involves many different sound paths, not just propagation over a simple screen as described above. There are reflections from the ceiling and the other panels of the workstation as well as from nearby walls. These consist of not only simple first-order reflections but also paths with multiple reflections, such as those involving the floor and the ceiling or the vertical surfaces of the workstation. The problem of sound propagation between workstations has been addressed using the method of image sources (see Section 7.3) and implemented as a computer algorithm. Diffraction over the screen was modeled using Maekawa's results described in Eq. (7.12). The method of image sources assumes that all reflections are specular, so the angle of incidence equals the angle of reflection. However, the model includes an empirical correction to the

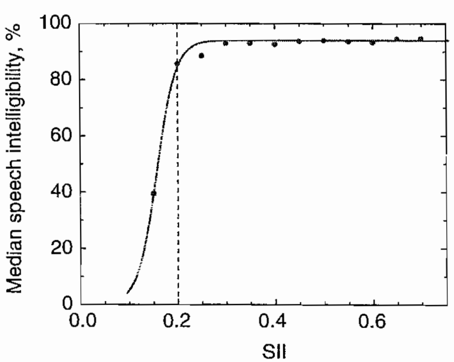

FIGURE 7.6 Variation of median speech intelligibility score with SII for situations simulating a range of conditions in open-plan offices.[35]

absorption coefficients of ceiling materials (obtained from standard reverberation room tests) to account for the limited range of angles of incidence for sound propagation between workstations, compared to that in a diffuse reverberant test room. The model has been validated with respect to a wide range of measurement conditions and is used here to illustrate the effects of various design parameters. See references 36–39 for details of the model.

Speech and Noise Levels

Two factors that have very large effects on speech privacy are the speech levels of the talkers in the open offices and the general ambient noise levels. These cannot be ignored when striving for acceptable speech privacy. Fortunately, people do not usually talk with *normal* vocal effort in open-plan offices. Measurements of talkers in open-plan offices have found mean voice levels close to those described as *casual* vocal effort. Using normal voice levels to calculate expected speech privacy greatly exaggerates the lack of speech privacy. The intermediate office speech level (IOSL) shown in Fig. 7.7 is recommended as the speech source level for calculating speech privacy in open-plan offices. It was obtained by averaging the mean speech levels measured in open-plan offices and the casual voice data and then adding 3 dB, corresponding to one standard deviation above the average talker level. The IOSL spectrum is therefore representative of louder talkers in open-office situations and corresponds to a speech source level at a distance of 1 m in a free field of 53.1 dBA. References 40–42 provide more details of speech levels.

One important aspect of achieving speech privacy is to encourage the use of lower voice levels as a form of open-plan office etiquette. Extended discussions should not be held in open-office areas but should be moved to closed meeting rooms.

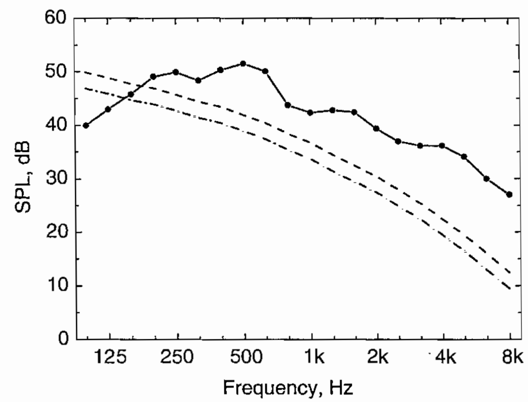

FIGURE 7.7 The IOSL spectrum and noise-masking spectra for open-office design calculations: (—●—) IOSL; (-·-·-·-) optimum masking; (- - - - -) maximum masking.

It is difficult to obtain acceptable speech privacy if the general ambient noise level is low. On the other hand, if ambient noise levels are high, they can become annoying and cause people to talk louder. There is a narrow range of ambient noise levels that are expected to be acceptable and that can also partially mask intruding speech sounds from adjacent workstations. (The masking of speech by noise is a well-researched field, and ANSI S3.5[34] includes many references on this topic.) For this reason, electronic sound-masking systems are often included in successful open-office designs. They can be designed to provide nearly ideal noise levels to mask speech sounds and enhance privacy without being unduly disturbing. The masking noise should be adjusted to sound like natural ventilation system noise and to be evenly distributed throughout the office. Figure 7.7 includes an example of a noise-masking spectrum that was judged to be at an optimal level, corresponding to 45 dBA. It has been found that the maximum acceptable level for masking sound is approximately 48 dBA. Hence, the maximum masking spectrum in Fig. 7.7 represents an example of such a maximum noise-masking spectrum. These two noise spectra are indicative of the narrow range of masking noises that provides *acceptable* speech privacy. Spatial variations of masking noise should be less than 3 dBA.

Conventional sound-masking systems have included those with centrally located electronics and others with distributed units. Distributed systems, with many small independent units, have the advantage of avoiding correlated sources, which can lead to annoying spatial variations in the masking sound. Manufacturers of both types claim various practical advantages. Although propagation into the ceiling void may aid the homogeneity of the masking sound in the office below, the masking sound will be modified by propagation through the ceiling tiles, and transmission through lighting fixtures can lead to localized areas of higher sound levels below. More recently, sound-masking systems with loudspeakers mounted in the ceiling tiles and on the panels of workstations have been introduced to provide better control over the resulting masking sound. The installation of noise-masking systems is best left to experienced professionals.

Important Design Parameters

In the design of an open-plan office, it is first assumed that the transmission loss of the workstation panels is sufficient to attenuate, to an insignificant level, the sound propagating directly through the panels. The requirement for surface density given by Eq. (7.12) usually leads to a minimum value corresponding to STC $\geq$ 20 (STC is the sound transmission class, obtained from a standard sound transmission loss test[43]; see also Chapter 10). After this, the two most important parameters are the sound absorption of the ceiling and the height of the separating barriers or panels. If these are not adequate, it will not be possible to achieve acceptable speech privacy.

The shaded area of Fig. 7.8 indicates combinations of ceiling absorption and panel height that can provide SII $\leq$ 0.20 if the other details considered below are also acceptable. Ceiling absorption is described in terms of the sound absorption

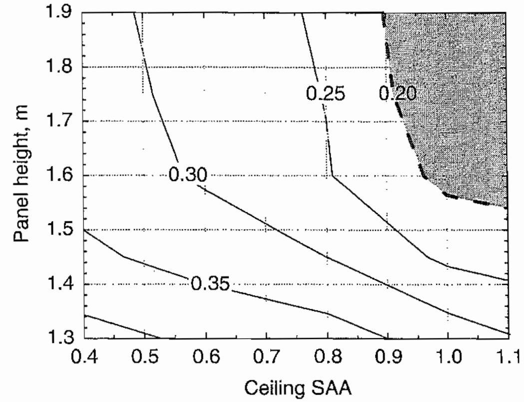

FIGURE 7.8 Shaded area shows combinations of workstation panel height and ceiling absorption that lead to *acceptable* speech privacy corresponding to SII $\leq$ 0.20.[44] Contours in unshaded part indicate degrees of unacceptable speech privacy. SAA is the average of the absorption coefficients in the third-octave bands from 250 Hz to 2.5 Hz.

average (SAA), which is the average of the absorption coefficients in the third-octave frequency bands from 250 Hz to 2.5 kHz. It replaces the older noise reduction coefficient (NRC) and has very similar values. Values of SAA greater than 1.0 are included in Fig. 7.8 because such values can result from the standard test procedure, due to the effects of edge diffraction (as mentioned in Section 7.2). It is seen that the sound absorption of the ceiling should correspond to SAA $\geq$ 0.90 and the separating panels should be $\geq$1.7 m high. Since the results in Fig. 7.8 were calculated with other details set to nearly ideal values, combinations of ceiling absorption and screen height outside of the shaded area make it impossible to achieve acceptable speech privacy.

A third key design parameter is the size of the workstation plan. The results in Fig. 7.8 are for a workstation with dimensions of 3 m $\times$ 3 m. If the workstation length and width each decrease by 1 m, then the resulting SII increases by 0.05. That is, for a 2 m $\times$ 2 m workstation plan, meeting the SII $\leq$ 0.20 criterion would require very high screens and the most absorptive ceiling materials.

Other Design Parameters

The sound-absorptive properties of the workstation panels and the floor have smaller effects on speech privacy. The height of the ceiling and the presence of lighting fixtures in the ceiling can also influence speech privacy.

The results shown in Fig. 7.8 were calculated for workstation panels with SAA = 0.9. If this were reduced to 0.75, the corresponding SII values would decrease by 0.01. If the panel absorption were decreased to 0.6, SII values would decrease by 0.02. These seem to be small degradations in the overall performance, but one must always remember that most designs will at best be on the edge of just providing acceptable speech privacy; even these small improvements may help to meet the SII ≤ 0.20 criterion. Of course, if the panels were not highly absorptive (i.e., SAA < 0.60), there would be a more significant increase in the resulting SII values. For example, if the workstation panels were nonabsorptive in an otherwise ideal workstation design, SII would increase from 0.2 to 0.3.

Varying floor absorption and varying ceiling height generally have very small effects on the resulting SII values. In most cases, varying these parameters changes SII by no more than about 0.01. On the other hand, lighting fixtures in the ceiling can degrade the speech privacy of the open-office design. The effect of a lighting fixture depends on the type of lighting unit and its location. Lights with a flat plastic or glass surface produce the strongest unwanted reflections and are most troublesome when located over the separating panel between two workstations. They will change SII values most when installed in a highly absorptive ceiling. Evaluation of the effects of several types and locations of lighting fixtures has shown that, for a ceiling with SAA $= 0.90$, SII values could increase by up to 0.08. Open-grill lighting fixtures have smaller effects but still reduce the effectiveness of a highly absorptive ceiling.

Practical Issues and Other Problems

Sound propagating in the horizontal plane can bypass barriers by reflection from vertical surfaces and hence reduce the sound attenuation between work positions. To minimize these effects, surfaces such as walls, office barriers, square columns, backs of cabinets, and systems furniture, as well as bookcases, should be covered with sound-absorptive material having SAA values of 0.7 or higher. A thickness of 2.5 cm or more of glass fiber with a porous fabric cover will satisfy this requirement. The application of carpets directly to hard surfaces is not an effective solution, since typical carpets have low sound absorption coefficients. Round columns with diameters of 0.5 m or less may be left uncovered. A simple way to avoid wall reflections is to avoid gaps between the wall and barriers. To prevent reflections from their surfaces, office barriers should be covered with sound-absorptive material on both faces.

Where workstations are adjacent to windows, there are often large gaps between the workstation panels and the window. To provide adequate acoustical privacy between these workstations, this gap must be filled with additions to the workstation panels. This problem cannot easily be solved using drapes, which would need to be heavy and closed; furthermore, most slatted blinds do not reduce reflections. Using the area next to the windows as a corridor is another solution to this problem.

Standard procedures exist for the evaluation of the degree of speech privacy in an existing office, in a mock-up of a proposed office,[45] or for the evaluation of open-plan noise-masking systems.[46] It is very important to evaluate the speech and noise in the office to completely determine the existing degree of speech privacy.

7.8 REVERBERATION ROOMS

Reverberation rooms are designed and equipped to give a close approximation to a diffuse sound field. Measurements in these rooms are used to characterize the sound-absorptive properties of materials, the sound power of sources, and the sound transmission through building elements, among other things, under standard diffuse-field conditions according to various standards.[43,47–52] A typical reverberation room has a volume of about 200 m^3; some are constructed with nonparallel walls. The walls and surfaces of the room are made highly reflective so that reverberation times are high and the region dominated by the direct field of a source is as small as possible.

At low frequencies, the frequency response to wide-band noise shows peaks corresponding to individual room modes. As frequency increases, the spacing between modes becomes less, the modes begin to overlap, and the individual modes are less obvious. At some transition frequency the room response for bands of noise becomes approximately constant, the properties of the sound field become more uniform, and the room response may be described in statistical terms. This transition point is usually defined by the Schroeder frequency[53] $f_S = 2000(T_{60}/V)^{1/2}$ hertz. For a $V = 250$ m^3 room with $T_{60} = 5$ s, $f_S =$ 282 Hz.

To make the response of the room more uniform at low frequencies, it is usually advisable to add low-frequency sound-absorbing elements. Even in rooms of approximately 200 m^3 volume, correctly chosen dimensions, and the recommended amount of sound absorption, the spatial variations of pressure and the sound decay rate are often too large to satisfy the precision requirements of standards. It is therefore common to add fixed panels suspended at random positions and orientations throughout the room to perturb the room modes and to create more diffuse conditions. In many cases rotating diffusers are also used for this purpose.

Fixed diffusers are most important in rectangularly shaped rooms used for sound absorption measurements. They may not be necessary in rooms that are sufficiently nonrectangular in shape. They help to create a more diffuse sound field during the measurement of sound decays by ensuring that, throughout the sound decay, a portion of the decaying sound energy is redirected toward the sound-absorbing sample. When commissioning a new reverberation room for sound absorption measurements, it is necessary to systematically increase the number of diffusers until measured absorption coefficients just reach maximum values due to the increasingly diffuse conditions in the chamber. Of course, adding too many diffusers can limit the number of valid positions for microphones, which must always be located more than a half wavelength (at the lowest frequency of interest) from reflecting surfaces such as walls and diffusing panels.

Rotating diffusers are particularly useful in reverberation rooms used for measuring the sound power levels of devices with strong tonal components. These types of sound sources lead to large spatial variations in sound levels that can be effectively reduced using a rotating diffuser. By continuously changing the geometry of the room, they shift the modal patterns and hence average out some of the spatial variations of the sound levels. Making the rotating diffuser in the form of panels of revolution can reduce the required drive power and aerodynamic noise.

In addition to such measures, it is still necessary to sample the room volume in order to measure mean-squared sound pressures and decay rates accurately. To provide statistically independent samples of the sound field, microphone positions must be more than one-half wavelength apart (at the lowest frequency of interest) as well as be located more than one-half wavelength away from reflecting objects to avoid nonrepresentative measures of the room average sound level.

It has been shown that close to one, two, or three infinite reflecting planes the sound pressure and energy increase. The mean-squared pressure p^2 can be expressed as

$$p^2 = 1 + \sum_{n=1}^{N_{\text{im}}} \frac{\sin(kr_n)}{kr_n} \quad (\text{N/m}^2)^2 \tag{7.13}$$

where $k = 2\pi/\lambda (\lambda = \text{wavelength})$
p^2 = mean-square pressure normalized to unity in absence of images or far from reflecting surfaces
r_n = distances from images of measurement point to measurement point
N_{im} = number of images: 1 for measurement near a plane surface, 3 near an edge, and 7 near a corner

Closer than $\lambda/2$ to highly reflecting surfaces, sound pressure increases significantly because of these positive interference effects. To account for the increase in sound energy close to surfaces, an adjustment term $(1 + S\lambda/8V)$ is included in the calculation of the sound power W from the space-averaged mean-square sound pressure. Thus, the relationship used to determine the sound power W of a source from the space-averaged mean-square sound pressure p^2 that it creates in the room is[54]

$$W = \frac{55.3 p^2 V}{4\rho c^2 T_{60}} (1 + S\lambda/8V) \qquad \text{N}\cdot\text{m/s} \tag{7.14}$$

where ρ = density of air, kg/m^2
c = speed of sound in air, m/s
V = room volume, m^3
T_{60} = reverberation time, s

It is assumed that sampling of the sound field in the room is confined to the central regions away from room surfaces. The Sabine formula, Eq. (7.2), relating reverberation time to room absorption is assumed to hold and is the basis for determinations of sound absorption in reverberation rooms.[47,48]

The planning and qualification of reverberation rooms are complex and best done by experienced professional acousticians.

7.9 ANECHOIC AND HEMI-ANECHOIC CHAMBERS

An anechoic chamber is a room with all of its interior surfaces highly absorptive such that a source in the room radiates in essentially free-field conditions. The resulting sound field has only a direct component. Hemi-anechoic chambers have a hard floor with all other interior surfaces highly sound absorptive. They are used for measuring the sound power level and radiation pattern of equipment (such as road vehicles, appliances, etc.) that are operated over a hard surface. The acoustical performance of an anechoic or hemi-anechoic room can be evaluated by determining how closely conditions in the room approximate those in a free field. This is usually done by measuring the variation of sound levels with distance from an approximately omnidirectional source; it should ideally be −6 dB per doubling of distance; see Eq. (7.3) and Fig. 7.1.

Tests are made in an anechoic room when it is necessary to accurately measure the unperturbed sound radiated by a source—for example, when measuring its radiation pattern (directivity) or sound power. The surfaces of anechoic chambers are made highly absorptive by lining them with deep, sound-absorptive materials. The lining typically consists of wedges of mineral wool or glass fiber.[55] All anechoic chambers are more anechoic at high than at low frequencies. The lowest frequency at which an anechoic chamber can be used depends primarily on the chamber volume and the depth of the wedges. This cutoff frequency, at which the wedges absorb 99% of the incident sound energy, is usually achievable with a wedge depth (including any air space between the base of the wedge and the hard wall) of approximately one-quarter wavelength. A large chamber with 1-m-deep wedges may be effective down to 80–100 Hz. To provide a walking surface to facilitate setting up experiments in an anechoic chamber, an open-metal-floor grid that is removed after the setup or a permanent wire-mesh floor can be provided. The perimeter frame of such a wire-mesh floor and to a lesser extent the wire mesh itself may degrade the high-frequency performance of the chamber.

8.1 INTRODUCTION

One of the most frequent problems faced by noise control engineers is how to design sound absorbers that provide the desirable sound absorption coefficient as a function of frequency in a manner that minimizes the size and cost, does not introduce any environmental hazards, and stands up to hostile environments such as high temperatures, high-speed turbulent flow, or contamination. The designer of sound absorbers must know how to choose the proper sound-absorbing material, the geometry of the absorber, and the protective facing. The theory of sound-absorbing materials and sound absorbers has progressed considerably during the last 10 years. Much of this progress is documented in K. U. Ingard's *Notes on Sound Absorption Technology*[1] and in F. P. Mechel's *Schall Absorber* (*Sound Absorbers*)[2] and the separately sold computer program on CD-ROM.[3] Ingard's book is a paperback edition of modest length and price and comes with a CD-ROM that allows the reader to make easy numerical predictions from almost all of the equations used in the book. The underlying physical processes are explained with great clarity and the mathematical treatment is kept simple. Derivations and difficult explanation are presented in appendices. The books cover all aspects of sound absorption in great detail. To derive full benefit, it helps if the reader has a reasonably strong mathematical background. However, even those with no such background will find the figures, which give the

*The authors acknowledge the contributions of Dr. Fridolin P. Mechel to the several parts of this chapter retained from the 1992 edition.

difficult mathematical results in graphical form, useful and practical. Mechel's book consists of three hard-covered volumes totaling 2866 pages. The associated computer program is available in MAC and Window versions but is expensive. The classical book of H. Kutruff, *Room Acoustics*,[4] deals predominantly with the room acoustics aspects of sound absorption and should be studied by acousticians designing buildings for the performing arts. Beranek's recently updated classic book *Acoustic Measurements*[5] describes the methods and experimental hardware for measuring all acoustical descriptors of sound-absorbing materials and sound absorbers. The reader with serious interest in sound absorption technology is advised to study all of these texts.

How Sound Is Absorbed

Sound is the organized superposition of particle motion on the random thermal motion of the molecules. The speed of the organized particle motion in air is typically six orders of magnitude smaller than that of the thermal motion. All sound absorbers facilitate the conversion of the energy carried by the organized particle motion into random motion. All forces, other than those that compress and accelerate the fluid, caused by the oscillatory particle flow in the presence of solid material result in loss of acoustical energy. The most important contribution to the conversion is associated with the drag forces caused by friction between the interface of a rigid or flexible wall or the skeleton of the porous or fibrous sound absorber material and the fluid in the thin acoustical boundary layer. For porous and fibrous sound-absorbing materials the acoustical flow speed is low and the flow remains laminar, and the drag force is proportional to the acoustical particle velocity. At high velocities, which occur at the mouth of resonators, the flow separates, turbulence is created, and the friction force becomes proportional to the square of the velocity. Other loss mechanisms, discussed in more detail elsewhere,[1,2] include the isothermal compression of air at low frequencies, direct conversion of acoustical energy into heat owing to a time lag between compression, and heat flow that takes place in closed cell foams. In the case of plate and foil (very thin plate) absorbers the acoustical energy is converted into heat in the vibrating flexible plate and radiated as sound from the rear of the plate or is transmitted in the form of vibration energy into connected structures.

A sound absorber can absorb only that part of the incident sound energy not reflected at its surface. Consequently, it is important to keep the reflection at the surface as low as possible. Essentially, the part of the incident acoustical energy that enters the absorber should be dissipated before it returns to the surface after traversing the absorber and reflecting from a rigid backing. Otherwise, the absorber gives back acoustical energy to the fluid on the receiver side that is in addition to the initial reflection. This requires a sufficient thickness. The challenge in sound absorber design is to keep the absorber thickness to a minimum.

Sound Absorption Coefficients

The acoustical performance of flat sound absorbers is characterized by their sound absorption coefficient α, defined as the ratio of the sound power, W_{nr}, that is not

reflected (i.e., dissipated in the absorber, transmitted through the absorber into a room to its rear, or conducted, in the form of vibration energy, to a connected structure) and the sound power incident on the face of the absorber, W_{inc}:

$$\alpha \equiv \frac{W_{nr}}{W_{inc}} \tag{8.1}$$

For convenience in analyses, the absorption coefficient is defined in terms of sound pressure reflection factor R of the absorber interface, namely

$$\alpha = 1 - |R|^2 \tag{8.2}$$

The vertical lines bracketing R indicate the absolute value. The reflection factor R is usually a function of the angle of sound incidence, the frequency, the material, and the geometry of the absorber. The absorber is characterized by its wall impedance (otherwise known as surface impedance) Z_w, defined as

$$Z_w = \frac{p}{v_n} \quad \text{N} \cdot \text{s/m}^3 \tag{8.3}$$

where p is the sound pressure and v_n is the normal component of the particle velocity, both evaluated at the interface. A substantial part of this chapter concerns the prediction of the wall impedance offered by a large variety of sound absorbers. The sound absorption coefficient as defined in Eqs. (8.1) and (8.2) is further differentiated according to the angular composition of the incident sound field, such as *normal incidence, oblique incidence, and random incidence*, and whether the absorber is *locally reacting* (sound cannot propagate in it parallel to the interface) or *non–locally reacting* (where sound can propagate in it parallel to the interface). At normal incidence there is no difference between locally and non–locally reacting materials.

Measurement of Normal-Incidence Sound Absorption Coefficient α_0. The normal incidence sound absorption coefficient α_0 can be measured in an impedance tube according to the American Society for Testing and Materials (ASTM) standard C384-98 as $\alpha_0 = 4\zeta/(\zeta+1)^2$, where $\zeta = p_{max}/p_{min}$ is the ratio of the maximum and minimum standing-wave sound pressure pattern in the tube upstream of the sample. Normal-incidence sound absorption coefficients, measured in an impedance tube, never exceed unity.

Measurement of Random-Incidence Sound Absorption Coefficient α_R(rev) in Reverberation Room. The random-incidence sound absorption coefficient α_R(rev), which is also referred to as the *Sabine absorption coefficient*, can be measured directly in a reverberation room according to ASTM C423-02. It is defined as $\alpha_R(\text{rev}) \equiv (55.3V/S)[(1/T_S) - (1/T_0)]$, where V is the volume of the reverberation chamber in m^3, $S = 6.7$ m^2 is the standardized surface area of the test sample, and T_S and T_0 are the reverberation times in seconds (see

Chapter 7) measured with and without the sample, respectively. It is important to distinguish between the two random-incidence sound absorption coefficients α_R(rev) and α_R. The coefficient α_R(rev), measured in the reverberation room, can yield values which exceed unity (measured values up to 1.2, as can be seen in Fig. 8.10). Such values obviously violate the theoretical definition of α given in Eq. (8.36) implying that the panel absorbs more energy than is incident on it. This fact that measured values of $\alpha_R(\text{rev}) > 1$ results from the finite size of the test sample, which means that there is diffraction at the edges of the sample. In design calculations, it is customary to replace all values of $\alpha_R(\text{rev}) > 1$ with unity. The random-incidence sound absorption coefficient α_R is computed from the wall impedance and never yields absorption coefficients that exceed unity. Based on the analyses of α_R(rev) measured according ASTM C423-02 for a large variety of thicknesses and flow resistivity of Owens Corning series 700 fiberglass boards, Godfrey[6] has proposed an empirical prediction scheme to relate α_R(rev) of a standard size (6.7 m^2) sample to α_R predicted theoretically from the computed wall impedance of the samples as

$$\alpha'_R(\text{rev}) = \left(\frac{21.3}{f^{0.5}} + 0.73\right)\alpha_R$$

where α'_R(rev) is the empirically predicted Sabine absorption coefficient of a standard size sample and f is the frequency in hertz. This formula provides reasonably accurate predictions for low-flow resistivities (in the range of 9000 N · m/s^4 = 0.56 $\rho_0 c_0$/in. to 17,000 N · m/s^4 = 1.1 $\rho_0 c_0$/in.) and small layer thicknesses from 1 to 3 in. (2.5–7.5 cm). For flow resistivities greater than 32,000 N · m/s^4 = 2 $\rho_0 c_0$/in. and layer thicknesses ≥76 mm = 3 in., the analytical method[7] yields the best prediction.

8.2 SOUND ABSORPTION BY NON–SOUND ABSORBERS

Although inefficiently, all rigid and flexible structures absorb sound. If efficient sound absorbers are present in the room, the contribution of these marginal sound absorbers may be neglected. However, if they represent the only sound-absorbing mechanism (such as is in the case of reverberation rooms without low-frequency absorbers), they, and at high frequencies the air absorption, account for the total sound absorption and set an upper limit for the maximum achievable reverberation time and for the buildup of reverberant sound pressure in these special rooms.

Sound Absorption of Rigid Nonporous Wall

The general assumption that a rigid, nonporous wall, however massive, gives rise to total reflection of the incident sound is not valid. In the immediate vicinity of the interface there are two phenomena that cause small but finite dissipation of sound energy. The first is that the wall-parallel component of the particle velocity of the incident sound results in shear forces in the acoustical boundary

layer. The acoustical boundary layer is identical to that which would develop at the interface between a stationary fluid and a plane, rigid wall oscillating with the frequency and velocity amplitude of the wall-parallel component of the sound-induced particle motion. The second component of the unavoidable dissipation results from the large thermal capacity of the wall, which makes it impossible to fully recover the heat energy in the rarefaction phase that was built up in the compression phase. According to reference 4, for randomly incident sound, the combined effect of these two dissipation processes results in a lower limit of the sound absorption coefficient of

$$\alpha_{\min} = 1.8 \times 10^{-4}(f)^{1/2} \tag{8.4}$$

where f is the frequency in hertz. For frequencies of 1 and 10 kHz, Eq. (8.4) yields values of $\alpha_{\min}$ of 0.006 and 0.018, respectively.

Sound Absorption of Flexible Nonporous Wall

Building partitions such as walls, windows, and doors absorb low-frequency sound. The sound power lost, W^{Loss}, when the incident sound interacts with a nonporous, flexible, homogeneous, and isotropic single partition that has another room or the outdoors on the receiver side is made up of three components:

$$W^{\text{Loss}} = W^{\text{ForcedTrans}} + W^{\text{ResTrans}} + W^{\text{ResDiss}} \quad \text{N} \cdot \text{m/s} \tag{8.5}$$

where $W^{\text{ForcedTrans}}$ is the sound power transmitted by the forced bending waves (i.e., mass law portion radiated from the receiver side by the forced bending waves), W^{ResTrans} is the sound power transmitted by the free resonant bending waves, and W^{ResDiss} is the sound power dissipated in the partition by the free resonant bending waves. The first two terms in Eq. (8.5) can be expressed in the form of sound transmission loss, TL, of the partition and the third term as a function of the space–time mean-square value of the sound-induced resonant vibration velocity $\langle v^2 \rangle$ of the plate, yielding

$$W^{\text{Loss}} = W^{\text{inc}}\, 10^{-\text{TL}/10} + \langle v^2 \rangle \rho_S \omega \eta S \quad \text{N} \cdot \text{m/s} \tag{8.6}$$

where η is the composite loss factor of the plate accounting for energy loss through dissipation in the plate as well as for that lost through structural coupling to neighboring structures at the plate boundaries and S is the surface area of the plate in square meters. The sound absorption coefficient is defined as

$$\alpha = \frac{W^{\text{Loss}}}{W^{\text{inc}}} \tag{8.7}$$

where W^{inc} is the sound power incident on the source side of the partition. As shown in Chapter 10, for random incidence, where the sound energy has equal probability of angle of incidence, the incident sound power is

$$W^{\text{inc}} = S\left(\frac{\langle p^2 \rangle}{4\rho_0 c_0}\right) \quad \text{N} \cdot \text{m/s} \tag{8.8}$$

where S is the surface area of the partition (one side) in square meters, $\langle p^2 \rangle$ (N^2/m^4) is the mean-square space–time average sound pressure in the source room, ρ_0 is the density of air in kilograms per cubic meter, and c_0 is the speed of sound of the gas at design temperature in meters per second. Using the results of the analyses in Chapter 10, for the power dissipated in the partition by the free bending waves, one obtains the following approximate formula for the random-incidence sound absorption coefficient α^{rand} of a single, flexible, homogeneous, isotropic, nonporous partition:

$$\alpha^{\text{rand}} \approx 10^{(-\text{TL}_{\text{rand}}/10)} + \frac{2\pi\sqrt{12}\rho_0 c_0^3 \sigma_{\text{rad}}}{\rho_M h^2 c_L \omega^2} \tag{8.9}$$

where TL_{rand} = random-incidence sound transmission loss of panel (measured or predicted according to Chapter 10)
ω = angular frequency, $= 2\pi f$
f = frequency, Hz
σ_{rad} = radiation efficiency of free bending waves (see Chapter 10)
ρ_M = density of plate material, kg/m^3
h = plate thickness, m
c_L = speed sound in plate material, in m/s

The second term on the right side of Eq. (8.9) is strictly valid only if the ratio of the power loss through dissipation and sound radiation by the free bending waves exceeds unity, $(h\rho_M\omega\eta_C/\rho_0 c_0 \sigma_{\text{rad}}) > 1$, which is almost always the case because σ_{rad} strongly decreases with decreasing frequency below the coincidence frequency of the plate. In Eq. (8.9) the first term represents the loss of energy by the transmission of sound into the receiver space as defined in Chapter 10. The second term represents the combined contribution of the dissipation of the free resonant bending waves in the plate and energy loss in the form of vibration energy transmission to neighboring structures at the boundaries. It is interesting to note that this second term does not depend of the composite loss factor η_C of the plate (the TL of the plate of course depends on η_C in the frequency range at and above the critical frequency where the free bending waves control the sound radiation). The physical reason for this is that in the case of a small loss factor the plate vibrates more vigorously and the combination of the increased vibration and decreased loss factor results in the same dissipation as happens in the case of a larger loss factor and less vigorous vibration response.

While the first term in Eq. (8.9) is valid for any type of partition (including, e.g., double walls and inhomogeneous and non isotropic plates), the second term is valid only for single, homogeneous, isotropic, platelike partitions. In case of

double walls or double windows the first term will exhibit a peak at the double-wall resonance frequency where the TL has a sharp minimum. In the case of double partitions made of two isotropic, homogeneous plates with air space in between, the second term in Eq. (8.9) can be crudely approximated by entering the parameters of the source-side plate into the second term.

8.3 SOUND ABSORBERS USING THIN LAYERS

For the purposes of this chapter, we call those constructions "sound absorbers" which have been designed on purpose to yield high sound absorption in a narrow or wide frequency band. The rest of this chapter deals with the design of such absorbers. We start with those absorber configurations which can be described by a few directly measurable parameters, such as a thin, flow-resistive layer in front of an air space backed by a rigid wall that can be fully characterized by its flow resistance and mass per unit surface area, and will proceed to configurations utilizing thick porous layers and to tuned absorbers.

Thin, Flow-Resistive Layer in Front of Rigid Wall

A sound absorber that consists of a thin, flow-resistive material in front of a rigid wall with an air space in between, such as shown in Fig. 8.1, is the configuration for which it is the easiest to predict acoustical performance. Accordingly, it is logical to treat it first. The flow-resistive layer might be rigid or flexible.

The sketch on the left in Fig. 8.1 depicts a configuration where the air space between the rigid porous layer and the rigid wall is partitioned in a honeycomb pattern to prohibit propagation of sound parallel to the plane of the porous layer. This absorber configuration is called *locally reacting* because the sound field in the absorber depends only on the sound pressure on the interface at the location of the particular honeycomb cell. The sound in the absorber can propagate only perpendicular to the plane of the interface. The sketch on the right in Fig. 8.1 has no partitioning of the air space and the sound can propagate within the absorber parallel to the plane of the interface. The sound pressure at any particular location in the air space depends on the sound pressure on all the locations on the sound-exposed face of the absorber. This configuration is called a *non–locally reacting* sound absorber.

Rigid Porous Layer

A thin, rigid, flow-resistive layer can be fully characterized by a single parameter, namely its flow resistance R_f or its normalized impedance $z' = R_f/(\rho_0 c_0)$, where ρ_0 is the density and c_0 is the speed of sound of the fluid. The normalized impedance of the partitioned air space is $z'' = j\cot(kt)$, where $k = 2\pi/\lambda$ is the wavenumber, λ is the wavelength of the sound, and t is the depth of the air space.

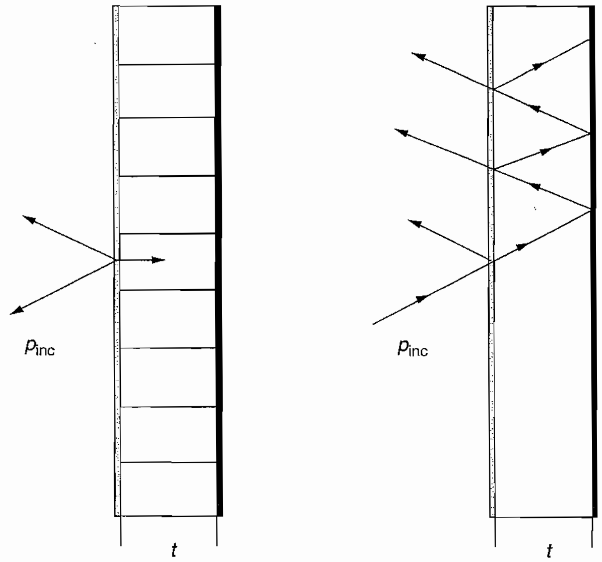

FIGURE 8.1 Thin porous sound-absorbing layer in front of an air space backed by a rigid wall. Left: Partitioned, locally reacting air space. Right: Not partitioned, non–locally reacting air space.

The normalized wall impedance for normal incidence, $\theta = 0$, is then given by

$$z_{w0} = z' + jz'' = \frac{R_f}{\rho c} + j\ \cot(kt) \tag{8.10}$$

The impedance of the air space is zero when $\cot(kt) = 0$, which is the case at those frequencies where the depth of the air space is an odd number of quarter wavelengths. The maximum value of the normal-incidence sound absorption coefficient is

$$\alpha_{0,\max} = \frac{4z'}{(1+z')^2} \tag{8.11}$$

indicating that total absorption occurs for $z' = 1$. According to reference 4, the normal-incidence sound absorption coefficient is given by

$$\alpha_0(f) = \left\{\left[\left(\frac{R_f}{\rho_0 c_0}\right)^{0.5} + \left(\frac{\rho_0 c_0}{R_f}\right)^{0.5}\right]^2 + \frac{\rho_0 c_0}{R_f}\cot^2\left(\frac{2\pi f t}{c_0}\right)\right\}^{-1} \tag{8.12}$$

Ingard[1] has computed the sound absorption coefficient of a rigid, flow-resistive layer in front of a locally reacting (partitioned) and non–locally reacting (unpartitioned) air space backed by a rigid wall for both normal and random incidence, as shown in Fig. 8.2.

Figure 8.2 shows that for a locally reacting air space the maximum normal-incidence sound absorption coefficient occurs at those frequencies where the depth of the air space corresponds to an odd multiple of quarter wavelengths [$t = (n+1)\lambda/4$, where $n = 0, 1, 2, \ldots$]. The physical reason for this is that the sound pressure in the partitioned air space just behind the porous layer is zero at these frequencies (the sound that is fully reflected from the hard wall is 180° out of phase with the incident sound). Consequently, the sound pressure gradient across the porous layer, Δp, reaches its maximum value that is numerically equal to the sound pressure on the incident side of the layer, namely $\Delta p = p_{\text{inc}}(1+R)$, where p_{inc} is the amplitude of the incident sound and R is the reflection factor:

$$R = \frac{R_f - \rho_0 c_0}{R_f + \rho_0 c_0}$$

This pressure gradient produces a particle velocity $v = \Delta p / R_f$ through the porous layer and the sound power dissipated per unit surface area of the absorber,

$$W^{\text{diss}} = v\,\Delta p = \frac{(p_{\text{inc}})^2(1+R)^2}{R_f}$$

In the case of $R_f = \rho_0 c_0$, $R = 0$ and $W^{\text{diss}} = (p_{\text{inc}})^2/(\rho_0 c_0) = W^{\text{inc}}$, indicating that all of the incident sound energy is dissipated in the porous layer. For values of $R_f \neq \rho_0 c_0$, the sound absorption coefficient still is a maximum but less than unity. The more R_f differs from $\rho_0 c_0$, the smaller is the sound absorption coefficient.

The maxima of the random-incidence sound absorption coefficient for a partitioned air space occur at the same frequencies as those at normal incidence. However, there is no value of R_f that would yield total absorption.

Another significant feature to be noted from Fig. 8.2 is that for a partitioned, locally reacting air space curves for both the normal and random-incidence sound absorption coefficients versus frequency have notches (zero absorption) at frequencies that correspond to an even multiple of half wavelengths. This occurs because at the corresponding frequencies the sound reflected from the hard wall combines at the rear of the porous layer with the incident sound in such a manner that there is no sound pressure gradient across the porous layer and consequently no sound is absorbed at these frequencies. This does not affect the random-incidence sound absorption coefficient obtained for the not partitioned (non–locally reacting) air space, as shown in the curves marked c. The advantage of not having notches in curves of the random-incidence sound absorption coefficient versus frequency must be "paid for" by having substantially lower sound absorption at low frequencies. The most important observation from Fig. 8.2 is that it is not possible to achieve a high sound absorption coefficient with a rigid porous layer in front of an air space backed by a rigid wall unless the thickness

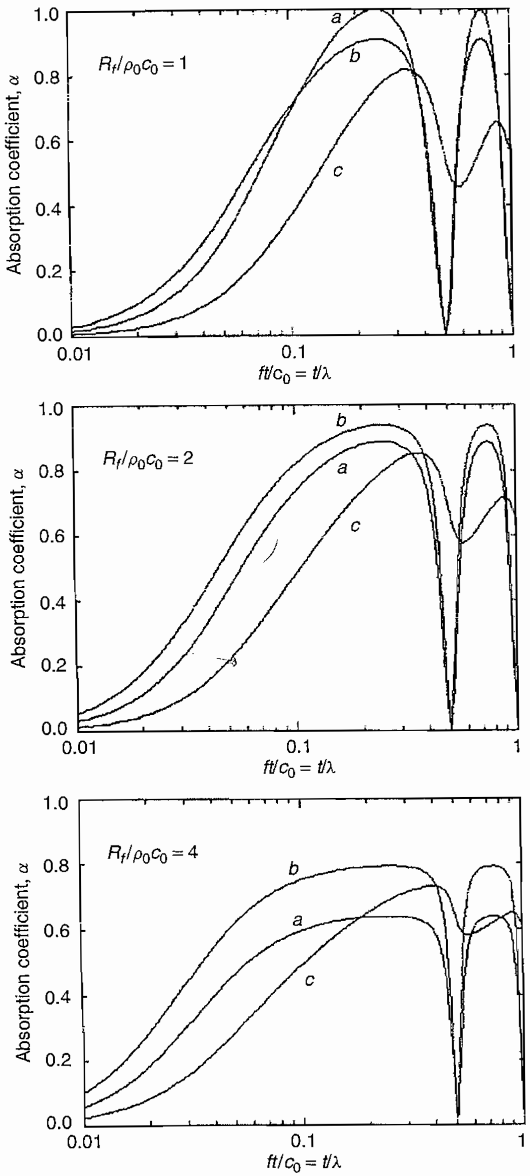

FIGURE 8.2 Sound absorption coefficient of a single, rigid, flow-resistive layer in front of an air space of thickness t backed by a hard wall as a function of the normalized frequency in the form of air space thickness–wavelength ratio $t/\lambda = tf/c_0$ with the normalized flow resistance of the layer, $R_f/\rho_0 c_0$, as the parameter: a, normal incidence; b, random-incidence, locally reacting air space; c, random-incidence, non–locally reacting air space. (After Ref. 1.)

of the air space exceeds one-eighth of the wavelength. For example, an air space thickness of 0.4 m (17 in.) or more is necessary to achieve a high degree of sound absorption at 100 Hz.

As we will discuss below, substantial low-frequency sound absorption can be achieved with an air space thickness of less than one-eighth of the wavelength if the porous layer is not rigid.

Limp Porous Layer

It is little known that sound absorbers using a limp, flow-resistive layer can provide high sound absorption at much lower frequencies than those with a rigid layer. However, caution should be exercised in designing such absorbers for applications where the sound pressure is very high. The limp, flow-resistive layer (e.g., heavy glass fiber cloth or stainless steel wire mesh) should be able to withstand the stresses owing to the high-amplitude sound-induced motion without fatigue. If the porous sound-absorbing layer is limp instead of being rigid, the mass per unit area of the layer and the stiffness per unit area of the air space between the layer and the hard wall result in a resonant system. Near the resonance frequency the limp porous layer will exhibit large-amplitude motion. Approximately, the resonance frequency f_{res} is given by[1]

$$f_{\text{res}} \approx \frac{1}{2\pi}\left(\frac{\kappa\rho_0(c_0)^2}{tm''}\right)^{1/2} \quad \text{Hz} \tag{8.13}$$

where $\kappa = 1.4$ is the adiabatic compression coefficient, t is the thickness of the air space in meters, and m'' is the mass per unit area of the limp porous layer in kilograms per square meter. The analytical model to predict the sound absorption coefficient of sound absorbers utilizing a limp porous screen is documented in reference 1. The computer program on the CD included in reference 1 allows prediction of the normal- and random-incidence sound absorption coefficient of such absorbers with locally reacting and non–locally reacting air space. The data in Figs. 8.3–8.5 were computed this way and show the sound absorption coefficient as a function of the normalized frequency, $f_n = t/\lambda = tf/c_0$, with the normalized flow resistance of the limp porous layer ($R_f/\rho_0 c_0$) as a parameter for various ratios of the mass of the limp layer and the mass of air in the air space behind, $\text{MR} = m''/t\rho_0$.

Figure 8.3 shows that the first maximum of the normal-incidence sound absorption coefficient occurs close to the mass–spring resonance frequency given by Eq. (8.13). The higher is the mass ratio $\text{MR} = m''/\rho_0 t$, the lower is the frequency of the peak sound absorption. For $\text{MR} = 16$ the frequency of the peak occurs at a frequency that corresponds to a normalized frequency $f_n = 0.03$. This is more than a factor of 8 lower than the peak at $f_n = 0.25$ one would obtain with a rigid porous layer. Also note that the first peak of the normal-incidence sound absorption coefficient is unity (100% absorption) if the mass ratio equals the normalized flow resistance (i.e., when $\text{MR} = R_f/\rho_0 c_0$). To achieve a relatively high

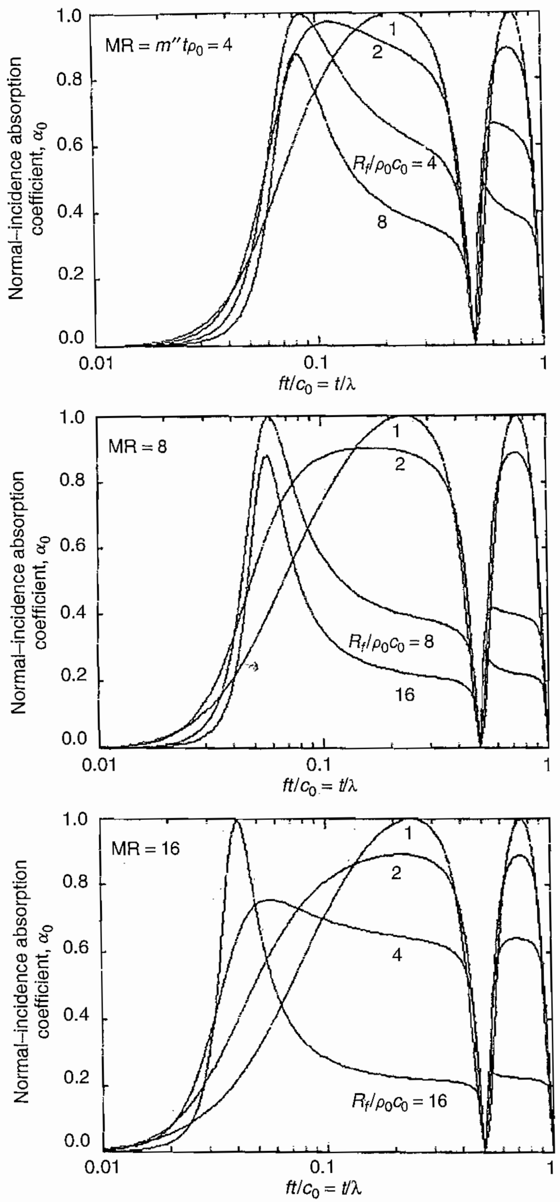

FIGURE 8.3 Normal-incidence absorption coefficient of a single, limp, flow-resistive layer in front of an air space of thickness t backed by a rigid wall as a function of the normalized frequency in the form of the thickness–wavelength ratio $t/\lambda = tf/c_0$ with the normalized flow resistance of the layer, $R_f/\rho_0 c_0$, as the parameter for mass ratios MR. (After Ref. 1.)

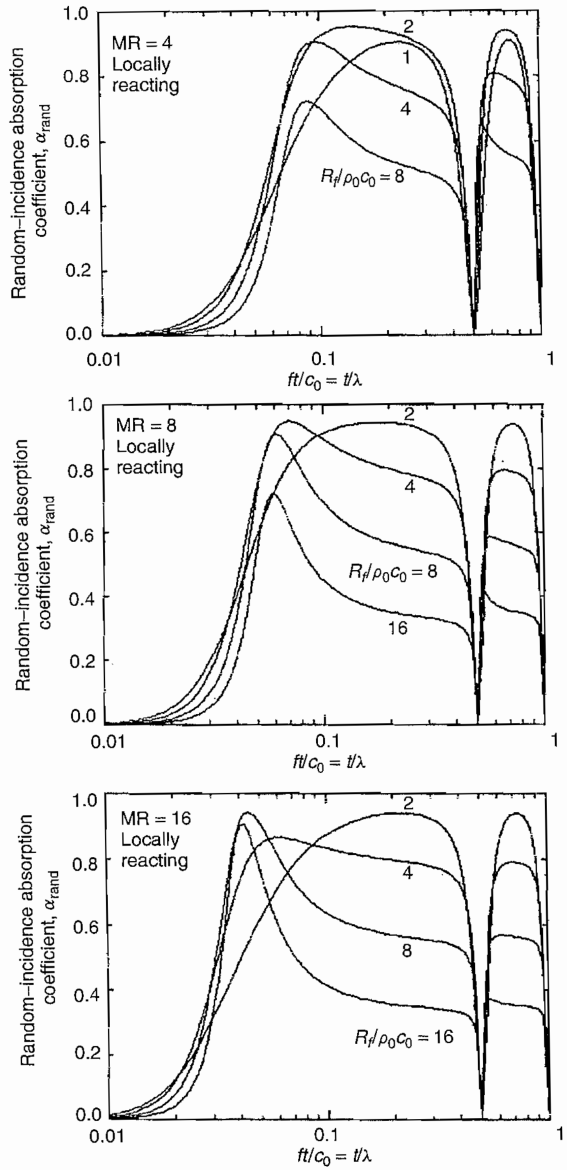

FIGURE 8.4 Random-incidence absorption coefficient of a single, limp, flow-resistive layer in front of a partitioned (locally reacting) air space of thickness t backed by a rigid wall as a function of the normalized frequency in the form of the thickness–wavelength ratio $t/\lambda = tf/c_0$ with the normalized flow resistance of the layer, $R_f/\rho_0 c_0$, as the parameter for mass ratios MR. (After Ref. 1.)

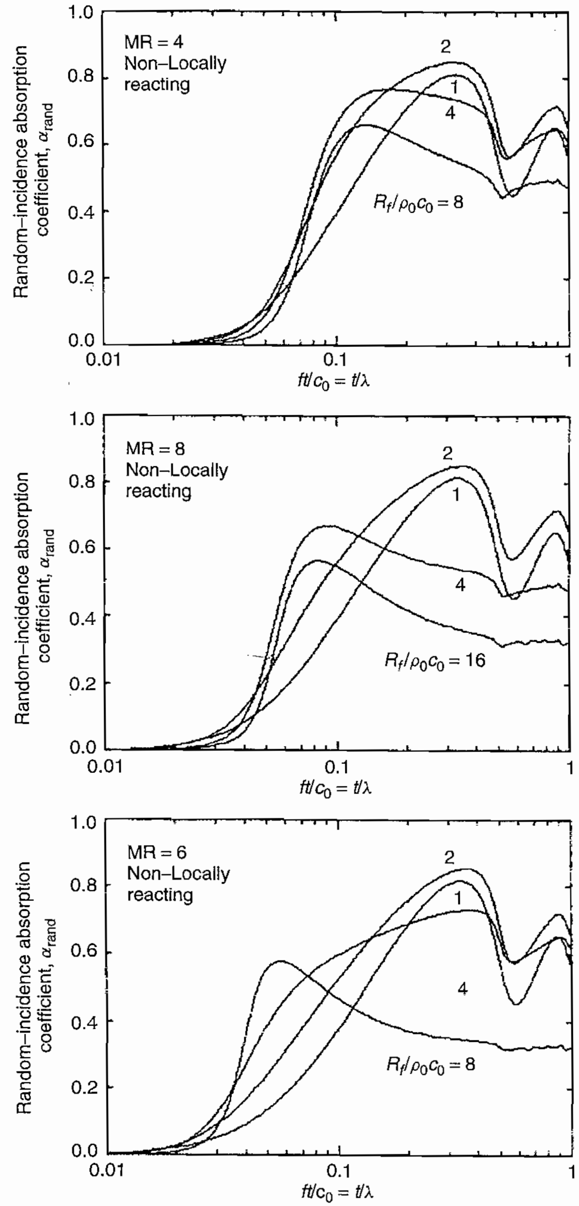

FIGURE 8.5 Random-incidence absorption coefficient of a single, limp, flow-resistive layer in front of a not-partitioned (non–locally reacting) air space of thickness t backed by a rigid wall as a function of the normalized frequency in the form of the thickness–wavelength ratio $t/\lambda = tf/c_0$ with the normalized flow resistance of the layer, $R_f/\rho_0 c_0$, as the parameter for mass ratios MR. (After Ref. 1.)

low-frequency absorption in a wide frequency band, a normalized flow resistance $R_f/\rho_0 c_0$ of between 2 and 3 seems to be a good choice.

Figure 8.4 shows the random-incidence sound absorption coefficient as a function of the normalized frequency computed for a locally reacting (partitioned) air space. Sufficient distance must be provided between the limp porous layer and the honeycomb configuration used to partition the air space to prevent the limp layer from hitting the honeycomb layer at the largest expected displacement amplitude. Curves of the absorption coefficient versus the normalized frequency have similar shape as those in Fig. 8.3 for normal incidence, except that no combination of the design parameters results in total absorption. To obtain substantial low-frequency sound absorption, the mass ratio MR ≈ 2 seems to be a good choice.

Figure 8.5 shows the random-incidence sound absorption coefficients for a non–locally reacting (unpartitioned) air space. Note the very different behavior from that observed for the partitioned air space in Figs. 8.2 an 8.3. The first, and undesirable, difference is that no combinations of parameters yield random-incidence sound absorption coefficients much above $\alpha_{rand} = 0.8$. The second, and desirable, attribute of the nonpartitioned air space is that there are no notches in the frequency response where the absorption coefficient would go to zero, as was the case for the partitioned air space.

Multiple Limp Porous Layers

As documented in reference 1, very high sound absorption at low frequencies can be achieved over nearly four octaves by placing a large number (up to 16) of limp, porous layers of low-flow resistance in front of a rigid wall. The computer program supplied with reference 1 allows the prediction of the normal- and random-incidence sound absorption coefficients of such absorbers and the optimization of performance by trial and error varying the flow resistance, mass per unit area, and number and position of the layers.

8.4 POROUS BULK SOUND-ABSORBING MATERIALS AND ABSORBERS

Porous bulk sound-absorbing materials are utilized in almost all areas of noise control engineering. This section deals with the following aspects:

1. description of the key physical attributes and parameters that cause a porous material to absorb sound,
2. description of the acoustical performance of porous sound absorbers used to perform specific noise control functions,
3. compilation of acoustical parameters that allow the quantitative design of sound-absorbing configurations on the bases of material and geometric parameters, and

4. experimental methods for measuring the acoustical parameters of porous sound-absorbing materials and the acoustical performance of porous sound absorbers.

Porous materials used for sound absorption may be fibrous, cellular, or granular. Fibrous materials may be in the form of mats, boards, or preformed elements manufactured of glass, mineral, or organic fibers (natural or man made) and include felts and felted textiles. Applications of fibrous materials in silencers require some form of protective covering. The most common covering consists of perforated metal with a fiberglass cloth behind. Sometimes metal screens are inserted between the perforated metal and fiberglass cloth. Cellular materials include polymer foams of varying degrees of rigidity and porous metals. For special applications increasing use is being made of porous metals (e.g., aluminum foams) as sound absorbers. During manufacture, before solidification, metal foams have closed cells, that is, without interconnections. At this stage such materials are poor sound absorbers. However, as liquid-metal foams solidify, thermal stresses occur. The solidified foams usually have cracked cell walls, which significantly increases sound absorption. In addition, by slightly rolling thin sheets of foam from, say, a thickness of 10 to 9 mm, further mechanical cracking occurs, and the interconnections between adjacent cells widen. This increases sound absorption even more. The result is an absorption coefficient versus frequency that has a maximum between 1 and 5 kHz and a peak value of up to 95%. By placing an air gap between metal foam and a rigid wall, one can shift the frequency curve to lower frequencies. In comparison with other materials, glass wool, for example, which gives high absorption over a wide frequency range, metal foams are not very good sound absorbers. However, the high weight-specific stiffness, good crash-energy absorption ability, and fire resistance of porous metals make them suitable for sound absorption panels in the aircraft and automotive industries.

Granular materials can be regarded as an alternative to fibrous and foam absorbers in many indoor and outdoor applications.[8] Sound-absorbing granular materials combine good mechanical strength and very low manufacturing costs. Granular materials may be unconsolidated (loose) or consolidated through use of some form of binder on the particles as in wood-chip panels, porous concrete, and pervious road surfaces. As well as man-made granular materials, there are many naturally occurring granular materials, including sands, gravel, soils, and snow. The acoustical properties of such materials are important for outdoor sound propagation.

A common feature of porous sound-absorbing materials is that the pores are interconnected and have typical dimensions below 1 mm, that is, much less than the wavelengths of the sounds of interest in noise control.

Porous materials must be considered to be elastic if they are in the form of flexible sheets. However, in many cases, the stiffness of the solid frame of the material is much greater than that of air so that the material may be treated as if it were rigid over a wide range of frequencies. This means that such materials can be treated as lossy, homogeneous media. This chapter will be confined to porous materials that may be treated as rigid framed.

How Rigid Porous Materials Absorb Sound

When excited by an incident sound wave, the air molecules in the pores of a porous material are made to oscillate. The proximity of the surrounding solid means that the oscillations result in frictional losses. An important factor that determines the relative contribution of frictional losses is the size (width) of the pores relative to the thickness of the viscous boundary layer. At low frequencies the viscous boundary layer thickness might be comparable with the pore width and the viscous loss is high. At high frequencies the viscous boundary layer thickness may be significantly less than the pore size and the viscous loss is small. At such high frequencies the oscillating flow is "pluglike." However, the presence of the solid causes changes in the flow direction and expansions and contractions of the flow through irregular pores, resulting in loss of momentum in the direction of wave propagation. This mechanism is relatively important at higher frequencies. In the larger pores and at lower frequencies heat conduction also plays a part in energy loss. During the passage of a sound wave, the air in the pores undergoes periodic compression and decompression and an accompanying change of temperature. If the solid part of the material is relatively heat conducting, then the large surface-to-volume ratio means that during each half-period of oscillation there is heat exchange and the compressions are essentially isothermal. At high frequencies the compression process is adiabatic. In the frequency range between isothermal and adiabatic compression the heat exchange process results in further loss of sound energy. In a fibrous material this loss is especially high if the sound propagates parallel to the plane of the fibers and may account for up to 40% of sound attenuation (energy lost per meter of propagation). The losses from forced mechanical oscillations of the skeleton of a porous material are generally so low that it is reasonable to neglect them.

Physical Characteristics of Porous Materials and Their Measurement

Porosity. The gravimetric measurement of porosity requires the weighing of a known volume of dry material. Since in inexpensive fibrous materials, such as mineral wool, the large droplets (or shot with diameter over 100 μm) may constitute up to 30% of the weight, their contribution to the acoustical porosity should be disregarded. Shot can be separated from fiber by a centrifuge process. The dry weight can be used together with the sample volume to calculate the bulk density ρ_B. Subsequently an assumed solid density is used to calculate the porosity h from

$$h = 1 - \frac{\rho_A}{\rho_B} \tag{8.14}$$

For glass fiber and mineral wool products the density of the fiber material is $\rho_B =$ 2450 kg/m^3. For silica sand, the density of the mineral grains is 2650 kg/m^3. A gravimetric method which may be used with some consolidated granular materials is to saturate the sample with water and deduce the porosity from the relative weights of the saturated and unsaturated samples. Mercury has been used as the pore-filling fluid in some applications (e.g., soils), but for many materials the introduction of liquids affects the pores. Following a proposal of Cremer and Hubert,[9] Champoux et al.[10] have developed a *dry* method of porosity determination which is based on the measurements of the change in pressure within a sample container subject to a small known change in volume. The lid of the container is a plunger, which is driven by a precise micrometer. The pressure inside the chamber is monitored by a sensitive pressure transducer and an air reservoir connected to the container through a valve serves to isolate the system from fluctuations in atmospheric pressure. The system has been estimated to deliver values of porosity accurate to within 2%. An important feature of the method from the point of view of acoustical properties is that it measures the porosity of connected air-filled pores. However, the gravimetric methods do not differentiate between sealed pores and connected pores. Recently a new method for determining porosity based on a simple measurement of displaced air volume has been proposed.[11] This has the advantage that it does not require compensation for temperature, as does the method of Champoux et al.[10]

An alternative method which may be used with some consolidated materials is to saturate the sample with water and deduce the porosity from the relative weights of the saturated and unsaturated samples.

An acoustical (ultrasonic) impulse method for measuring porosity using the impulse reflected at the first interface of a slab of air-saturated porous material has been proposed and has been shown to give good results for plastic foams[12–14] and random bead packing.[15]

The porosity of a stack of spherical particles depends on the form of the packing, ranging from 0.26 for the densest packing (face-centered-cubic) to 0.426 for simple-cubic packing.[16] A random packing of spheres has a porosity of 0.356.[17] An approximate value that may be assumed for the porosity of a granular material is 0.4.

Typical ranges of values of porosity are listed in Table 8.1.

Tortuosity. The tortuosity of a porous solid is a measure of the irregularity of the fluid-filled paths through the solid matrix. At very high frequencies, it is responsible for the difference between the speed of sound in air and the speed of sound through a rigid porous material. Tortuosity is related to the formation factor used to describe the electrical conductivity of a porous solid saturated with a conducting fluid. Indeed, tortuosity can be measured using an electrical conduction technique in which the electrical resistivity of such a saturated porous sample is compared to the resistivity of the saturating fluid alone. Thus

$$T = \frac{F}{h} \tag{8.15}$$

TABLE 8.1 Measured and Calculated Values of Porosity and Tortuosity

Material	Porosity, h	Method of Determination	Tortuosity, T	Method of Determination
Lead shot, 3.8 mm particle size	0.385	Measured by weighing	1.6	Estimated as $\alpha = 1/\phi^{0.5}$ (fits acoustic data)
			1.799	Cell model predictions[a]
Gravel, 10.5 mm grain size	0.45	Measured by weighing	1.55	Deduced by fitting surface admittance data
Gravel, 5–10 mm grain size	0.4	Measured by weighing	1.46	Deduced by fitting surface admittance data
Glass beads, 0.68 mm[b]	0.375	Unspecified	1.742	Measured[c]
			1.833	Cell model predictions[a]
Coustone[b]	0.4	Unspecified	1.664	Measured[c]
Foam YB10[b]	0.61	Unspecified	1.918	Measured[c]
Porous concrete	0.312	Measured	1.8	Deduced by fitting surface admittance data
Clay granulate, Laterlite, 1–3 mm grain size	0.52		1.25	Deduced by fitting surface admittance data (assuming porosity of 0.52)
Olivine sand	0.444	Measured	1.626	Cell model predictions[a]
Aluminum foam	0.93	Measured by weighing	1.1	Ultrasonic measurements (laser-generated pulses)
			1.07	Deduced by fitting surface admittance data
Polyurethane foam (Recticel Wetter, Belgium)				
Sample w1[d]	0.98	Measured	1.06	Measured
Sample w2[d]	0.97	Measured	1.12	Measured

[a]From Ref. 20.
[b]From Ref. 26.
[c]From Ref. 11.
[d]From Ref. 27.

where F is the formation factor defined by

$$F = \frac{\sigma_S}{\sigma_f} \tag{8.16}$$

where σ_f and σ_S are the electrical conductivities of the fluid and the fluid-saturated sample, respectively. These in turn are defined by

$$\sigma = \frac{GL}{A} \tag{8.17}$$

where L is the length of the sample, A is the area of the end of the sample, and G is the ratio of the resulting current to the voltage applied across the sample.

To measure the formation factor, first a cylindrical sample of the material is saturated with a conducting fluid (brine solution is convenient). Saturation is achieved by drawing the fluid through the sample after forming a vacuum above it. Agitation of the sample is also required if the pore sizes are small. A voltage is applied across the saturated sample placed between two similarly shaped electrodes at a known separation. The conductivity of the fluid is measured at similar voltages within a separate fluid-tight unit. The use of separate current and voltage probes assures a good contact between the end of the sample and the electrodes, eliminates problems associated with voltage drop at the current electrodes, and allows the simultaneous measurement of the electrical resistivities of the fluid and the saturated porous material.

The tortuosity of a random stacking of glass spheres is given by $1/\sqrt{h}$.[18] This has been verified for a range of porosities from 0.33 to 0.38 and is a special case of the relationship

$$T = h^{-n'} \tag{8.18}$$

where n' depends on grain shape and has the value 0.5 for spheres.[19]

An alternative derivation for stacked identical spheres[20] gives

$$T = 1 + \frac{1-h}{2h} \tag{8.19}$$

The equivalent formula for the tortuosity of a system of identical parallel fibers is

$$T = \frac{1}{h} \tag{8.20}$$

This means that the tortuosity of a typical fibrous material used in noise control is a little larger than 1 since the porosity is close to (but never greater than) 1. In a rigid porous material, tortuosity is one of the properties that contribute to the "structure factor" used in classical descriptions and is related to the "added mass" that is used in the theory of propagation of sound in porous and elastic materials.[21] The structure factor, introduced in classical texts, is intended to include frequency-dependent thermal effects (complex bulk modulus) and frequency-dependent effects due to fiber motion. This means it can *only* be determined by acoustical means. For characterizing the acoustical properties of a bulk porous material, tortuosity is preferred over the structure factor since it has clear physical meaning and can be deduced by nonacoustical means in many cases.

At the highest frequencies, the speed of sound inside the rigid porous material is equal to the speed of sound in air divided by the square root of tortuosity. Since it is primarily responsible for the acoustical properties of porous materials at high audible or ultrasonic frequencies, tortuosity can be deduced from ultrasonic measurements.[22]

Some representative values of tortuosity are listed in Table 8.1.

Flow Resistance and Flow Resistivity. The most important parameter in determining the acoustical behavior of thin porous materials is the airflow resistance R_f. For bulk-, blanket-, or board-type porous materials the flow resistivity (specific flow resistance per unit thickness) $R_1 = R_f/\Delta x$, where Δx is the thickness of the layer, is the key acoustical parameter. The flow resistivity is a measure of the resistance per unit thickness inside the material experienced when a steady flow of air moves through the test sample. Flow resistance R_f represents the ratio of the applied pressure gradient to the induced volume flow rate and has units of pressure divided by velocity. If a material has a high flow resistivity (high flow resistance per unit thickness), it means that it is difficult for air to flow through the surface. In disciplines other than noise control engineering (e.g., geophysics), it is more common to refer to air permeability (k), which is related to the inverse of flow resistivity ($k = \eta/R_1$, where η is the dynamic coefficient of air viscosity). Since flow resistivity is related to the inverse of permeability, high flow resistivity implies low permeability. Typically, low permeability results from very low surface porosity.

Flow resistance is measured as

$$R_f = \frac{\Delta p}{v} = \frac{TS\,\Delta p}{V} \quad \mathrm{N \cdot s \cdot m^{-3}} \text{ or } \mathrm{Pa \cdot s \cdot m^{-1}} \text{ (mks rayls)} \tag{8.21}$$

From this the flow resistivity is obtained as

$$R_1 = \frac{R_f}{\Delta x} \quad \mathrm{N \cdot s \cdot m^{-4}} \text{ or } \mathrm{Pa \cdot s \cdot m^{-2}} \text{ (mks rayls/m)} \tag{8.22}$$

where Δp is the static pressure differential across a homogeneous layer of thickness Δx, v is the velocity of the steady flow through the material, V *is* the volume of air passing through the test sample during the time period T, and S is face area (one side) of the sample.

Since R_f generally depends on the velocity v, it is customary to measure it at a number of different flow rates and extrapolate measured R_f versus v to R_f ($v = 0.05$ cm/s) because below this particle velocity the flow resistance of most fibrous materials does not depend any more on the velocity. The fact that, in general, flow resistivity depends on particle velocity becomes important when considering the behavior of porous absorbers at high sound levels.

The measurement of the flow resistance and flow resistivity of porous building materials has been standardized on a compressed-air apparatus.[23] A similar apparatus may be used to determine the flow resistivity of soils or granular materials (Fig. 8.6). In this measurement the pressure gradient across the sample in a fixed sample holder is monitored together with various (low) flow rates. Compressed air is passed through a series of regulating valves and a very narrow opening into chamber E. This creates an area of low pressure immediately in front of the three tubes connected to the rest of the system. Air is drawn from the environment through the sample as a result of the pressure differential. The rate of airflow through the system is controlled by three flowmeters, giving a total measurement

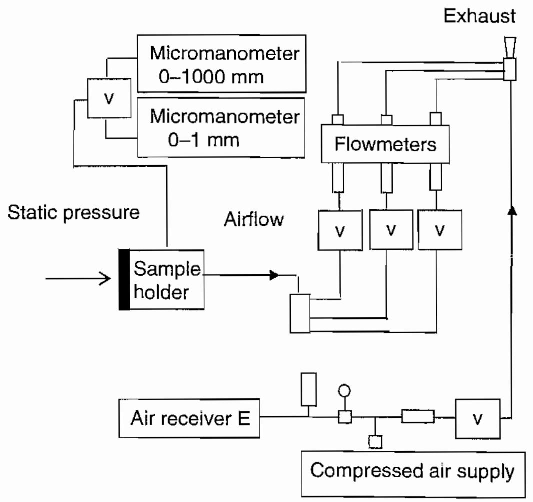

FIGURE 8.6 Concept sketch of a compressed-air apparatus for laboratory measurement of flow resistance.

range between 8.7 and 0.1 L/min. Typically the flow rate must be kept below 3 L/min to avoid structural damage to the sample.

A comparative method[24] makes use of a calibrated known resistance (a laminar-flow element) placed in series with the test sample. Variable-capacitance pressure transducers are used to measure pressure differences across both the test sample and the calibrated resistance. For steady, nonpulsating flow, the ratio of flow resistances equals the ratio of measured pressure differences. The airflow may also be controlled electronically. A unique method of measuring flow resistance by Ingard[1] does not require any flow-moving device, flow-rate meter, or static pressure differential sensor, just a stop watch. In this test setup the airflow (after the piston reaches its terminal velocity) is forced trough the sample, located at the open bottom end of the tube, at a constant rate driven by the static pressure differential $\Delta p = Mg/S$, determined by the weight, Mg, of a tightly sliding piston in the sample holder tube and by the cross-sectional area S of the piston. The factor $g = 9.81$ m/s^2 is the acceleration due to gravity. The flow resistance of the sample is then inversely proportional to the time T_L required for the piston to travel a specific distance L. The flow resistance of the sample is determined as $R_f = C[Mg\cos(\Phi)/LA^2]\,ST_L$, where A is the free surface area of the sample and Φ is the angle of tube axis with the vertical. For vertical tube orientation $\Phi = 0$. The small leakage flow between the piston and the tube wall, which is of consequence only if the sample has a very high flow resistance, is accounted for by the correction factor

$$C = \frac{1 + T_{L0}/T_L}{1 - T_L/T_{\text{Closed}}}$$

where T_{L0} and T_{Closed} are respectively the piston travel times with the sample removed and when the end of the tube is air tightly closed. The variation of the flow rate through the sample (needed to extrapolate the flow resistance to 5×10^{-4} m/s) can be accomplished by either changing the tube axis angle Φ or increasing the mass of the piston.

Empirical Prediction of Flow Resistivity. According to private communications with Richard Godfrey[6] of Owens Corning Corporation, the flow resistivity of fibrous sound-absorbing materials can be approximately predicted by a slightly modified version of Eq. 10.4 of the 1971 edition of this book. The modified equation is

$$R_1 \approx \frac{3450}{d^2}\left[\left(\frac{\text{SpGrGlass}}{\text{SpGrFiber}}\right)\rho_{\text{bulk}}\right]^{1.53} \quad \text{N} \cdot \text{m/s}^4 \qquad (8.23)$$

where d is the average fiber diameter in micrometers (10^{-6} m), SpGrGlass and SpGrFiber are the specific gravities of glass and that of the actual fiber material, and ρ_{bulk} is the bulk density (with shot contribution deducted) of the fibrous material in kilograms per cubic meter. Note that 1 μm $= 4 \times 10^{-5}$ in. and that $\rho_{\text{bulk}} \approx \rho_M h$, where ρ_M is the density of the fiber material and h is the porosity. It has been found that flow resistivity values measured according to the American Society of Mechanical Engineers (ASME) Standard E 522 for the entire glass fiber-based product line of different bulk densities and fiber diameters are successfully predictable by Eq. (8.23) with a correlation coefficient of 0.93. Equation (8.23) also can be used for predicting the flow resistivity of polymer-based fibrous sound-absorbing materials. For the same bulk density, the polymer fibers have approximately 2.5 times as much surface area and flow resistivity as glass fibers.

Theoretical Prediction of Flow Resistivity. For almost all granular or fibrous sound-absorbing materials, the flow resistivity cannot be predicted analytically on the basis of the geometry of the skeleton. It must be measured. For a few idealized absorber materials, such as materials made of identical spheres or parallel identical fibers, it is possible to make such a prediction. Since the prediction formulas identify important parameters that might be used to scale flow resistivity data measured for a specific material composition to other compositions in cases where direct measurement of the flow resistivity is not feasible, it is instructive to consider at least one idealized case where theoretical prediction is possible.

For stacked identical spheres with radius r it can be shown that[20]

$$R_1 = \frac{\eta}{k} = \frac{9\eta(1-h)}{2r^2h^2}\,\frac{5(1-\Theta)}{5 - 9\Theta^{1/3} + 5\Theta - \Theta^2} \qquad (8.24)$$

where h is the porosity and

$$\Theta = \frac{3}{\sqrt{2\pi}}(1-h) \cong 0.675(1-h) \qquad (8.25)$$

The equivalent formula for the flow resistivity of a system of identical parallel fibers of radius r is[25]

$$R_1 = \frac{16\eta h(1-h)}{r^2h^2\left[(1-8\Gamma)+8\Gamma(1-h)-(1-h)^2-2\,\ln(1-h)\right]} \tag{8.26}$$

where $\Gamma \approx 0.577$. This formula overestimates the flow resistivity of fibrous materials as a consequence of shot content, random fiber orientation, and distribution of fiber diameters in a real material.

Analytical Characterization of Porous Granular or Fibrous Sound-Absorbing Materials. For certain idealized microstructures such as parallel, identical cylindrical or slitlike pores, it is possible to make straightforward analytical predictions of the acoustical properties.[1,19,21] Although analytical characterization of porous granular or fibrous sound-absorbing materials with arbitrary microstructures is possible, it is a relatively complex procedure.[27–31] Moreover, at present, many of the required parameters are not routinely available to practicing noise control engineers. Consequently, the analysis is not reviewed in this chapter. For a comprehensive introduction to recent analytical treatments, the reader should consult reference 21. Semiempirical formulas for the acoustical properties of fibrous materials have been derived based on such a sophisticated analytical treatment.[32] It should be noted, also, that empirical formulas have been derived that predict the acoustical properties of granular media from knowledge only of porosity, grain density, and mean grain size.[33]

Acoustical Properties of Porous Materials. The acoustical properties of porous sound-absorbing materials are characterized by their complex propagation constant k_a and complex characteristic impedance Z_{Ca}, which are defined by

$$p(x,t) = \hat{p}e^{-jk_ax}e^{j\omega t} \quad \text{N/m}^2 \tag{8.27}$$

$$\langle p(x,t)\rangle_y = Z_{Ca}\langle v_x(x,t)\rangle_y \quad \text{N/m}^2 \tag{8.28}$$

where $\hat{p}$ represents the amplitude at $x = 0$ and $\langle\cdots\rangle$ represents an average perpendicular to the propagation direction (x) over an area that is small compared with the wavelength but large compared with the size of pores. The propagation constant

$$k_a = \beta - j\alpha$$

includes the attenuation constant α, which may be obtained by using a probe tube microphone to measure the decrease of the sound pressure level (in nepers per meter) of a plane sound wave propagating in a very thick layer of material. The phase constant β is obtained by measuring the change of phase with distance. It is equal to the angular frequency divided by the frequency-dependent sound speed within the material. The complex characteristic impedance $Z_{Ca} = R_{Ca} - jX_{Ca}$ is obtained by measuring the surface impedance of a thick layer (sufficiently thick

that reflection from the end is not detectable) of the absorber material placed in an impedance tube.

An alternative to use of a thick sample with a practically "infinite length" is to use a sample of known finite length and to measure the transfer function between two microphones located in an impedance tube with the loudspeaker source at one end and the sample at the other (closed) end.[34] A broadband input signal such as white noise or a sine sweep can be used. By means of a frequency analysis, output signals from the microphones are used to calculate the transfer function, which is converted to the surface impedance of a sample. The characteristic impedance and propagation constant of a sample can be obtained as long as two distinct sets of surface impedance are measured. This can be realized by using either two samples of different thicknesses[35] or a single sample backed with two different lengths of air cavities.[36] For the former, the two-thickness method, it is convenient if the length of the second sample is double that of the first. In the two-cavity method, the difference in the lengths of the air cavities needs to be tuned to fit the frequency range of interest together with the tube diameter and the microphone spacing.

Empirical Predictions from Regression Analyses of Measured Data

There are two families of parameters that determine the sound absorption coefficient. The characterization would be simplest if both k and Z_C could be expressed in terms of a single parameter. Figure 8.7a shows the measured[37] normal-incidence sound absorption coefficient α_0 of different Rockwool materials of practically infinite thickness (between 0.5 and 1 m, depending on the bulk density of the absorber material) as a function of frequency with bulk density of the material as parameter. Figure 8.7a clearly indicates that the bulk density is not the parameter that would collapse the measured data points into a single curve.

In 1970, Delany and Bazley[38] used many measurements on fibrous materials to deduce semiempirical formulas based on the dimensioned parameter (f/R_1). Equations (8.29a) and (8.29b) are valid only if the frequency f is entered in hertz (s^{-1}) and the flow resistivity R_1 in mks rayls per meter ($\text{N}\cdot\text{s}\cdot\text{m}^{-4}$). Although they have been used widely and successfully, Delany and Bazley's formulas give rise to unphysical results at low frequencies. In particular, the real part of the surface impedance of a rigid-backed layer goes negative. Miki's model[39] represents a modification of these formulas based on Delany–Bazley's data and an electrical analogy for the acoustical properties of porous materials. Miki's formulas are as follows:

$$k_{an} = \frac{k}{k_0} = 1 + 0.109\left(\frac{\rho_0 f}{R_1}\right)^{-0.618} - j0.160\left(\frac{\rho_0 f}{R_1}\right)^{-0.618} \tag{8.29a}$$

$$Z_{Cn} = \frac{Z_C}{Z_0} = 1 + 0.070\left(\frac{\rho_0 f}{R_1}\right)^{-0.632} - j0.107\left(\frac{\rho_0 f}{R_1}\right)^{-0.632} \tag{8.29b}$$

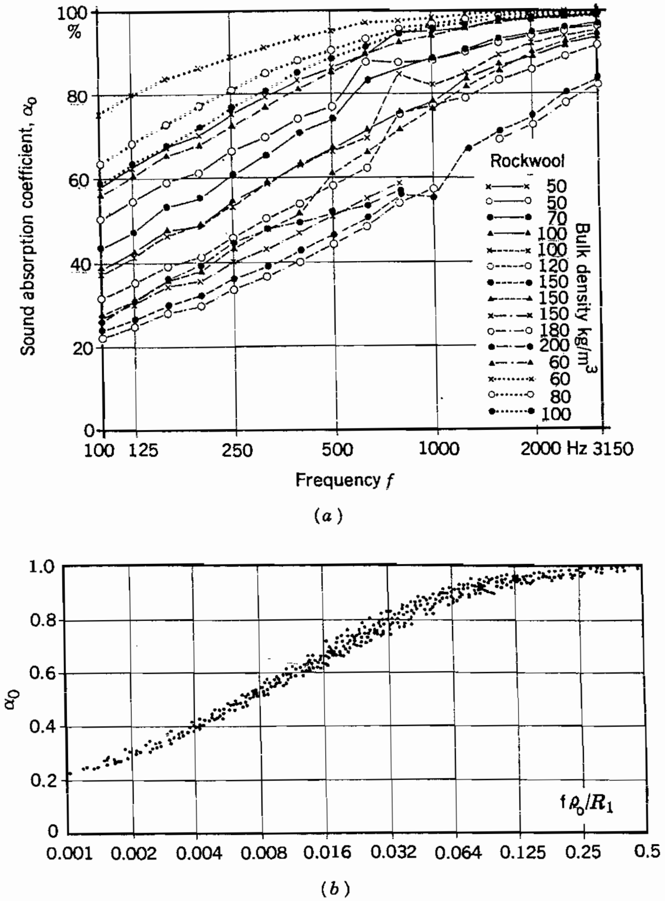

FIGURE 8.7 Normal-incidence sound absorption coefficients of different rock wool materials of practically infinite thickness (0.5–1 m) measured in an impedance tube plotted as a function of (*a*) frequency with bulk density ρ_A as parameter and (*b*) nondimensional frequency parameter $\rho_0 f/R_1 = \rho_0 c_0/(R_1\lambda)$.

Figure 8.7*b* shows the same data points as Fig. 8.7*a* but now as a function of the *dimensionless* variable $E = \rho_0 f/R_1$ on the horizontal scale, where ρ_0 is the density of air, f is the frequency, and R_1 is the flow resistivity of the bulk material at the density at which α_0 was measured. Clearly $E = \rho_0 f/R_1 = \rho_0 c_0/\lambda R_1$ is the single parameter that collapses all measured data. According to Fig. 8.7*b*, even for a layer of practically infinite thickness, very high sound absorption is obtainable only in the frequency range where $(\lambda/4)R_1 < \rho_0 c_0$. To fulfill this requirement at low frequencies, where λ is large, requires the use of a sound-absorbing material of low flow resistivity. The normalized, dimensionless frequency variable

$E = \rho_0 f/R_1$ is useful in describing not only the sound-absorbing capability of the semi-infinite layer of fibrous material but also the propagation constant and characteristic impedance of the bulk material.

It is useful to present the propagation constant and characteristic impedance in a dimensionless manner as

$$k_{an} = \frac{k}{k_0} = \frac{a - jb}{k_0} = a_n - jb_n \tag{8.30a}$$

$$Z_{Cn} = \frac{Z_C}{Z_0} = R - jX \tag{8.30b}$$

where $k_0 = \omega/c_0$ is the wavenumber in air and $Z_0 = \rho_0 c_0$ is the characteristic impedance of the gas filling the voids between the fibers for plane waves.

Figures 8.8 and 8.9 show plots of the real and imaginary parts of the normalized propagation constant k_{an} and that of the normalized characteristic impedance Z_{Cn} for a large variety of mineral wool sound-absorbing materials plotted as a function of the normalized frequency parameter, indicating that indeed the normalized frequency parameter $E = \rho_0 f/R_1$ is a universal descriptor of fibrous porous sound-absorbing materials. The data presented in Figs. 8.8 and 8.9 and similar curves for glass fiber materials were obtained by careful measurements of the acoustical and material characteristics (*a, b, R, X*, and R_1) of over 70 different types of materials.[38]

The solid lines in Figs. 8.8 and 8.9 result from the regression analyses of the data and have the form

$$k_{an} = \frac{k}{k_0} = (1 + a''E^{-\alpha''}) - ja'E^{-\alpha'} \tag{8.31a}$$

$$Z_{Cn} = \frac{Z_C}{Z_0} = (1 + b'E^{-\beta'}) - jb''E^{-\beta''} \tag{8.31b}$$

The regression parameters a', a'', b', b'', α', α'', β', and β'' in Eqs. (8.31) are compiled in Table 8.2 There are different regression parameters for the normalized frequency regions below and above $E = 0.025$. It was found that measured fibrous materials could be divided into two categories: (1) mineral wool and basalt wool and (2) glass fiber.

Polyester Fiber Materials

Polyester fiber materials are used increasingly to replace glass and mineral fiber materials in situations where there is concern to keep the air completely free of fibers suspected to have an adverse influence on health. An example material consists of a mix of two kinds of fibers: (1) polyethylenterephtalate and (2) a core of polyethylenterephtalate and a lining of copolyester. The raw mix is treated at 150°C to melt the external lining of the "bicomponent" fibers and hence form a skeleton of thermally bound fibers. The fiber diameters are between

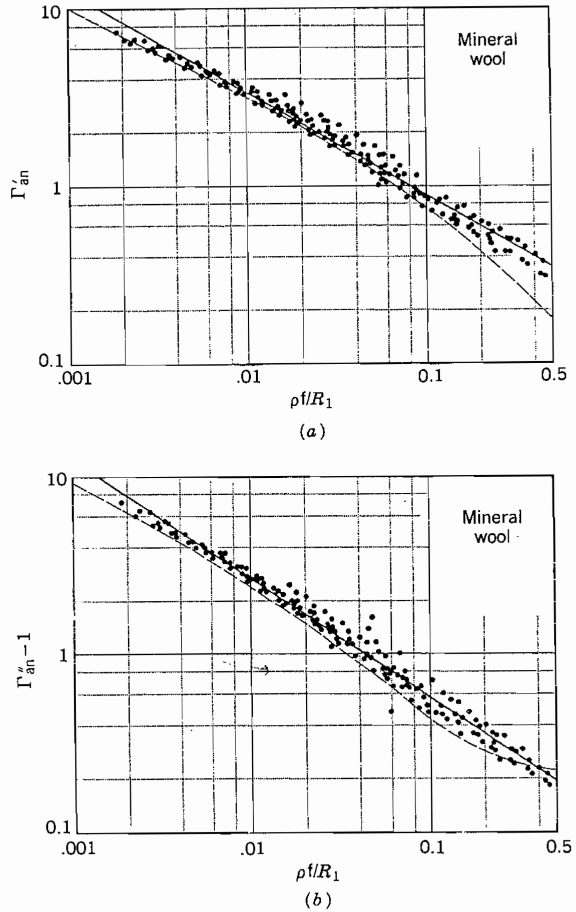

FIGURE 8.8 Measured normalized propagation constant $k_{an} = k/k_0 = a_n + ib_n$ for mineral wool as a function of normalized frequency parameter $E = \rho_0 f/R_1$: (——) regression line: Eq. (8.31a) and Table 8.2; (- - - -) prediction for cylindrical pores.[19,21,27]

TABLE 8.2 Regression Coefficients for Predicting Propagation Constant and Characteristic Impedance of Fibrous Sound-Absorbing Materials

Material	E Region	b'	β'	b''	β''	a''	α''	a'	α'
Mineral and basalt wool	$E \leq 0.025$	0.081	0.699	0.191	0.556	0.136	0.641	0.322	0.502
	$E > 0.025$	0.0563	0.725	0.127	0.655	0.103	0.716	0.179	0.663
Glass fiber	$E \leq 0.025$	0.0668	0.707	0.196	0.549	0.135	0.646	0.396	0.458
	$E > 0.025$	0.0235	0.887	0.0875	0.770	0.102	0.705	0.179	0.674

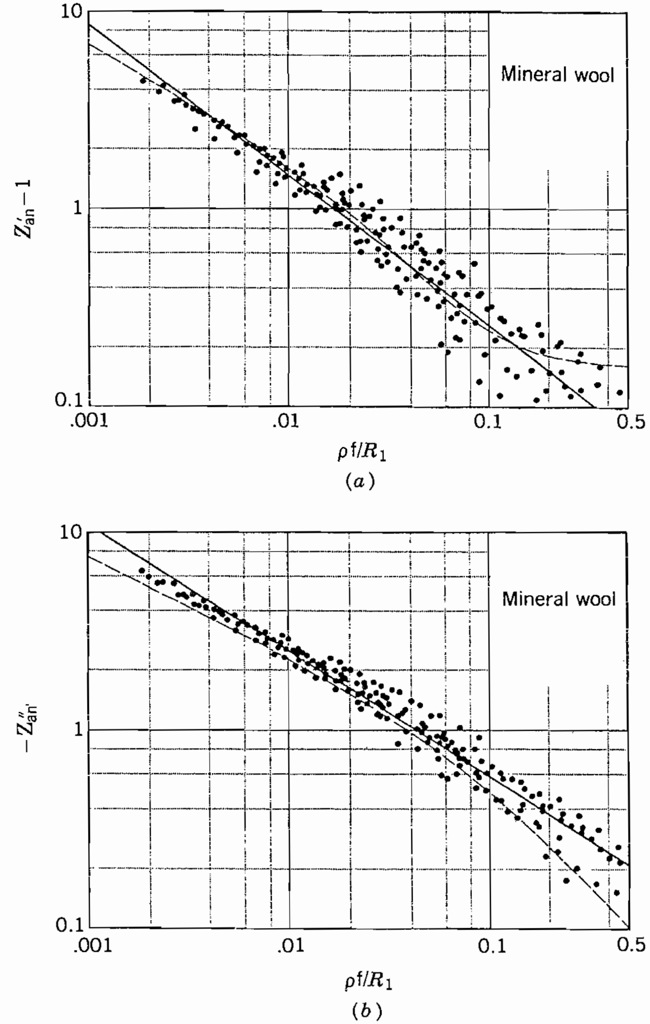

FIGURE 8.9 Measured normalized characteristic impedance $Z_{Cn} = Z_C/Z_0 = R + iX$ for mineral wool as a function of normalized frequency parameter $E = \rho_0 f/R_1$: (——) regression line: Eq. (8.29b); (- - - -) prediction for cylindrical pores.

17.9 and 47.8 μm (mean 33 μm) and have a mean length of 55 mm. Based on measurements of 38 samples, the flow resistivity has been found to obey the relationship[40]

$$R_1 D^2 = 26\rho_A^{1.404} \tag{8.32}$$

where D is the mean diameter in micrometers and ρ_A the bulk density in kg/m^3.

TABLE 8.3 Regression Coefficients for Predicting Propagation Constant and Characteristic Impedance of Polyester Fiber Materials

Material	b'	β'	b''	β''	a'	α'	a''	α''
Polyester fiber	0.159	0.571	0.121	0.530	0.078	0.623	0.074	0.660

Regression coefficients for predicting acoustical properties of polyester fiber materials are given in Table 8.3.[38]

Plastic Foams

Since concerns about fire hazard and release of toxic combustion products can be overcome largely by suitable treatments, plastic foams are used increasingly for noise control applications. A large variety of plastic foams are available with several different types of physical structure. Polyurethane foams, based on polyester or polyether polyols, are used most commonly. These foams can be fully or partially reticulated, that is, with all membranes or with varying proportions of membranes between cells removed. Formulas (8.31) with similar regression coefficients to those for fibrous materials are applicable to plastic foams.[41,42] However, unlike with fibrous materials, it has not been found necessary to distinguish between E-regions. The relevant regression coefficients are listed in Table 8.4.

The first row of Table 8.4 also shows the comparable values obtained from the empirical formulas of Delany and Bazley (ref. 38). Although these formulas have been superseded by those due to Mechel (ref. 37) and Miki (ref. 39), they serve to indicate that the coefficient values for plastic foams are significantly different and that the Delany and Bazley relationships would not generally give satisfactory predictions for the bulk properties of plastic foams.

TABLE 8.4 Regression Coefficients for Predicting Propagation Constant and Characteristic Impedance of Plastic Foams

Material	b'	β'	b''	β''	a'	α'	a''	α''
Mineral and glass fiber	0.0571	0.754	0.087	0.732	0.0978	0.700	0.189	0.595
Fully reticulated polyurethane foam, $60 \le R_1 \le 6229$ (Cummings/Beadle)	0.0953	0.491	0.0986	0.665	0.174	0.372	0.167	0.636
Mixed plastic foams,[42] $2900 \le R_1 \le 24300$	0.209	0.548	0.105	0.607	0.188	0.554	0.163	0.592
Fully reticulated polyurethane foam, $380 \le R_1 \le 3200^a$	0.114	0.369	0.0985	0.758	0.136	0.491	0.168	0.795
Partly reticulated polyurethane foam, $R_1 = 10{,}100^b$	0.279	0.385	0.0881	0.799	0.267	0.461	0.158	0.700

Effects of Temperature

In sound absorbers or silencers designed to operate at high temperatures, it is important to know the acoustical characteristics of the fibrous porous sound-absorbing materials at design temperature. Fortunately, it is not necessary to measure the propagation constant k and characteristic impedance Z_C at design temperature T because the values of these acoustical characteristics measured at room temperature, T_0, can be scaled. The dimensionless frequency variable $E = \rho_0 f/R_1$ must be evaluated at design temperature. Consider that the influence of temperature on ρ and η is

$$\rho(T) = \rho(T_0)\frac{T_0}{T} \tag{8.33}$$

$$\eta(T) = \eta(T_0)\left(\frac{T}{T_0}\right)^{0.5} \tag{8.34}$$

where T and T_0 are the design temperature and room temperature, respectively, measured on an absolute scale (i.e., Kelvin and Rankine; $\mathrm{K} = {}^\circ\mathrm{C} + 273$). Considering that $\rho = \rho_0(T/T_0)^{-1}$ and $c = c_0(T/T_0)^{1/2}$, the acoustical characteristics at design temperature T (in Kelvin) are determined as follows:

$$b(T) = b[E(T)]\frac{\omega}{c_0}\left(\frac{T}{T_0}\right)^{-1/2} \tag{8.35a}$$

$$Z_C(T) = Z_{Cn}[E(T)](\rho c_0)\left(\frac{T}{T_0}\right)^{-1/2} \tag{8.35b}$$

where $b[E(T)]$ and $Z_{Cn}[E(T)]$ are the normalized attenuation constant and normalized characteristic impedance according to Eqs. (8.30) computed for $E = E(T)$ determined from Eqs. (8.34) and (8.35). When fibrous sound-absorbing materials are first used in high-temperature applications, the material undergoes changes. For mats and boards the binder burns off. This decreases the bulk density to a negligible amount. The burning off of the binder does not appreciably change the flow resistivity. After the first high-temperature exposure the glass or mineral fibers thicken. Their virgin diameter d_V increases to the burned-off diameter $d_{BOF} = d_V + 0.5$. This increase is approximately 0.5 μm. This increase in fiber diameter and corresponding decrease in flow resistivity can be accounted for by correcting flow resistivity measured at room temperature by multiplying it by the factor $(1 + 0.5/d_V)^{-2}$ when calculating $E_{BOF}(T_0) = f\rho_0/R_1(1 + 0.5/d_V)^{-2}$.

Example 8.1. Compute the real and imaginary parts of the normalized propagation constant and characteristic impedance of a very (practically infinite) thick layer of glass fiber at a frequency of 100 Hz at 20°C and for 500°C and determine α_N using the regression parameter values in Table 8.2. The flow resistivity of the fibrous material at 20°C is $R_1(T_0) = 16{,}000\ \mathrm{N \cdot s/m^4}$ and $\rho_0 = 1.2\ \mathrm{kg/m^3}$.

Solution

$$T_0 = 273 + 20 = 293\ \mathrm{K} \qquad T = 273 + 500 = 773\ \mathrm{K}$$

$$E(T_0) = \frac{\rho_0 f}{R_1} = 1.2 \times \frac{100}{16{,}000} = 0.0075, \quad \text{which is} < 0.025$$

$$E(T) = E(T_0)\left(\frac{T}{T_0}\right)^{-1.65} = 0.0075\left(\frac{773}{293}\right)^{-1.65} = 1.5 \times 10^{-3},$$

which is <0.025

The regression parameters from Table 8.2 are

$$a' = 0.396 \qquad a'' = 0.135 \qquad \alpha' = 0.458 \qquad \alpha'' = 0.646$$
$$b' = 0.0668 \qquad b'' = 0.196 \qquad \beta' = 0.707 \qquad \beta'' = 0.549$$

According to Eqs. (8.35), we obtain the following:

Parameter	At 20°C	At 500°C
$b = a'E^{-\alpha'}$	3.72	7.78
$a = 1 + a''E^{-\alpha''}$ a	4.18	10.0
$R = 1 + b'E^{-\beta'}$ R	3.12	7.62
$X = b''E^{-\beta''}$	2.88	6.9

The normal-incidence sound absorption coefficient according to Eq. (8.36) is

$$\alpha_N = 4\frac{Z'_{an}}{Z'^2_{an} + 2Z'_{an} + 1 + Z''^2_{an}}$$

yielding

$$\alpha_N = \begin{cases} 0.49 & \text{for } 20^\circ\mathrm{C} \\ 0.25 & \text{for } 500^\circ\mathrm{C} \end{cases}$$

8.5 SOUND ABSORPTION BY LARGE FLAT ABSORBERS

When considering sound absorption, the portion of a sound wave incident on the absorber that is absorbed is a quantity of interest. This is easiest to define when

the surface of the absorber is flat and sufficiently large that sound waves scattered at the edges of the absorber can be neglected. For a plane incident sound wave, it is possible to assign a sound energy absorption coefficient α for each point on the absorber surface given by

$$\alpha = \frac{\text{absorbed energy}}{\text{incident energy}} = 1 - |R^2| \tag{8.36}$$

where R is the reflection factor, which is defined as the ratio of the reflected and incident sound pressures at the interface. A high sound absorption coefficient ($\alpha \to 1$) requires that $|R| \to 0$. Note that $|R| = 0.1$ corresponds to $\alpha = 0.99$. In this chapter we shall deal only with infinitely large, flat, homogeneous absorbers. Edge effects manifest themselves in increased sound absorption with increasing perimeter–surface area ratio of the absorber.[45] Edge effects are involved also when numerical values greater than 1 are obtained for random-incidence absorption coefficients measured in reverberation rooms.

Plane Sound Waves at Normal Incidence

For plane waves of sound incident perpendicularly to an absorber it is sufficient to know the complex normal specific *surface impedance* $Z_1 = Z_1' - jZ_1''$ of the absorber, which is the ratio of sound pressure to the *normal* component of the particle velocity at the interface (see Chapter 1). The reflection factor and absorption coefficient are related by

$$R = \frac{Z_1 - Z_0}{Z_1 + Z_0} \qquad \alpha = \frac{4Z_1'Z_0}{(Z' + Z_0)^2 + Z_1''^2} \tag{8.37}$$

where $Z_0 = \rho_0 c_0$ is the characteristic impedance of air for plane waves and ρ_0 is the density and c_0 the speed of sound in air.

For sound absorbers consisting of highly porous layers with perforated or cloth facings of smaller porosity, a modified air-side surface impedance must be used in Eq. (8.37). This is obtained by taking the air-side volume velocity averaged over the face area of the absorber. If an absorber with surface impedance Z_i is covered by a perforated facing with porosity h, then $Z_1 = Z_i/h$.

If $|R| \to 0$, Eq. (8.37) indicates that $Z_1 \to Z_0$. This means that the ideal absorber should have a surface impedance similar to that of unbounded air. For a thick (effectively semi-infinite) layer, this requires that the characteristic impedance of porous sound-absorbing materials, Z_C, should be only slightly above that for air, Z_0, and so it is imperative to keep the porosity high. For fibrous sound-absorbing materials, the porosity should be in the range of 0.95–0.99 and for perforated facings the porosity should be above 0.25.

This is illustrated in Fig. 8.10, which shows random-incidence absorption coefficients σ_R(rev) for various configurations with a glass fiber fabric or perforated plate covering measured in a reverberation room. Note the relatively

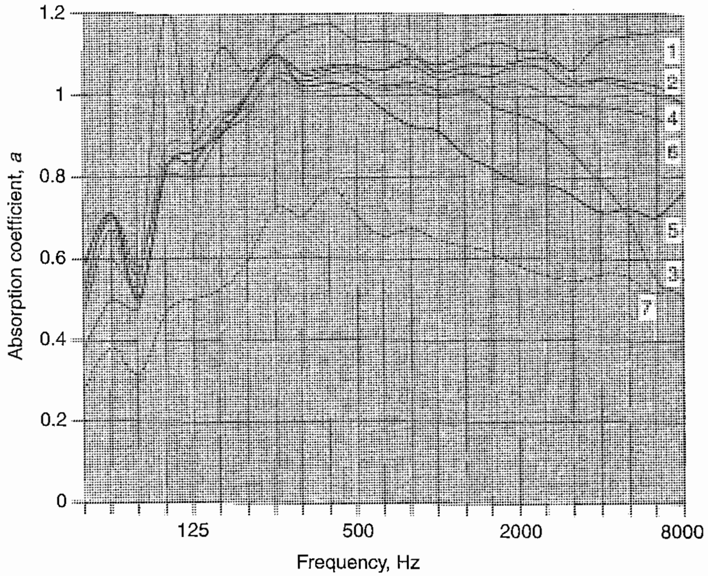

FIGURE 8.10 Random-incidence sound absorption coefficients of 200-mm-thick exhaust silencer pillows (basalt fiber core, density 125 kg/m^3) as a function of frequency measured in a reverberation room: (1) high-porosity fabric covering, equivalent flow resistivity 12 kPa · s · m^{-2}; (2) perforated sheet (32% open area) over high-porosity fabric covering; (3) perforated sheet (17% open area) over high-porosity covering; (4) high-porosity fabric covering and fiberglass facing over basalt fiber core; (5) low-porosity fabric covering, equivalent flow resistivity 43 kN · m · s^{-4}; (6) perforated sheet (32% open area) and fiberglass facing over basalt fiber core; (7) perforated sheet (17% open area), low-porosity fabric covering and fiberglass facing. (Courtesy of John Bowman, Lancaster Glass Fiber, Ltd.)

poor results for the configurations of low-percentage open-area perforated-plate (17%), low-porosity, high-flow-resistivity fabric covering (43,000 mks rayls/m = 100 $\rho_0 c_0$ per meter = 2.4 $\rho_0 c_0$ per inch). Further note that the measured values of α_R(rev) exceed unity. The reasons for this behavior have been discussed in the introductory part of this chapter.

Normal Incidence on a Porous Layer in Front of a Rigid Wall

A rigid wall represents a nearly [see Eq. (8.4)] perfect acoustical reflector. It is an acoustically hard surface. When a porous layer is placed on such an acoustically hard backing, the surface impedance is controlled by the combination of the incident and (multiple) reflected sound waves in the layer, yielding

$$Z_1 = Z_{Ca} \coth(jk_a d) = -jZ_{Ca} \cot(k_a d) \quad \text{N} \cdot \text{s/m}^3 \tag{8.38a}$$

where d is the layer thickness and Z_{Ca} is the characteristic impedance.

Equation (8.38a) may be expressed as

$$Z_1 = Z_{Ca} \frac{\sinh(bd)\cosh(bd) - j\,\sin(ad)\cos(ad)}{\cosh^2(bd) - \cos^2(ad)} \quad \text{N} \cdot \text{s/m}^3 \tag{8.38b}$$

The impedance given by Eqs. (8.38) exhibits the following behavior:

(a) When $d \ll \frac{1}{4}\lambda_a$ [$\lambda_a = 2\pi/a$ is the wavelength in the absorbing material, and a is defined in Eq. (8.30a)], which is the case when the layer is thin or the frequency is low, the magnitude of $\coth(jk_{an}d)$ is always large and the lack of impedance matching between Z_1 and Z_0 leads to a small sound absorption coefficient. This is the reason there is no "sound-absorbing paint" and that rugs absorb sound only modestly.

(b) When d is sufficiently large compared with the wavelength inside the material and the attenuation constant is not too small, the acoustical behavior of the layer approximates that of an "infinitely thick" layer. In this case $\coth(jk_{an}d) \to 1$ and the surface impedance is the same as the characteristic impedance.

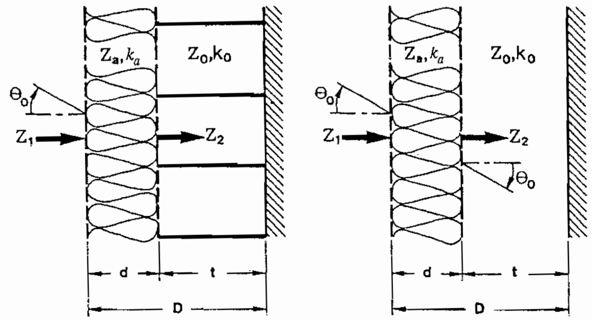
(c) When $\coth(jk_{an}d)$ is minimum, the surface impedance of the hard-backed layer is minimum and the absorption coefficient takes its maximum value. Consideration of the expanded form in Eq. (8.38b) indicates that, for $bd > 0$, which is the only situation of interest, the real part is never zero. So the normalized surface impedance is minimum approximately when the imaginary part is zero. In fact, this condition gives a slight underestimate of the frequency of maximum absorption, whereas $\cos(ad) = 0$, corresponding to $d = \frac{1}{4}\lambda_a$, gives an overestimate.

In general the absorption coefficient is maximum at a frequency that is somewhat less than the frequency at which the layer is a quarter-wavelength thick. Doubling the layer thickness halves the frequency of maximum absorption.

For practical purposes a layer of thickness d can be considered "infinitely thick" if $bd > 2$. For such conditions $Z_1 = Z_{Ca}$. The higher the flow resistivity of the porous material, the more Z_1 exceeds Z_0. Even in the extreme case of practically infinite layer thickness (which at low frequencies and low flow resistivity becomes very large), the sound absorption coefficient will be small. As frequency increases, the general tendency is $Z_{Ca} \to Z_0/h$, and for highly porous absorbers where $h \approx 1$, the good impedance matching results in a high absorption coefficient.

Sound-Absorbing Layer Separated from a Rigid Wall by an Air Space. The sound-absorbing configuration depicted in Fig. 8.11 is frequently used in practical applications (e.g., hung acoustical ceilings). The impedance of a layer of air of thickness t in front of a rigid wall is

$$Z_2 = -jZ_0 \cot(k_0 t) \quad \text{N} \cdot \text{s/m}^3 \tag{8.39}$$



(a) (b)

FIGURE 8.11 Combination of a bulk-reacting absorber layer with (*a*) an air gap such that sound can only travel perpendicular to the hard wall and (*b*) an air gap such that sound can travel parallel to the hard wall.

where $k_0 = \omega/c_0 = 2\pi\lambda_0/c_0$ is the acoustical wavenumber for air. The internal reflection coefficient at the back of the layer is $R_B = (Z_2 - Z_{Ca})/(Z_2 + Z_{Ca})$ and the surface impedance at the front of the layer is

$$Z_1 = Z_C\left(\frac{Z_2 + jZ_{Ca}\tan(k_a d)}{Z_{Ca} + jZ_2\tan(k_a d)}\right) \quad \text{N}\cdot\text{s/m}^3 \tag{8.40a}$$

where Z_C is the normalized characteristic impedance of the porous layer, k_a is the (not-normalized) propagation constant in the porous layer, and d is the layer thickness. Note that Z_2 is zero when $t = \frac{1}{4}\lambda_0$; that is, the impedance Z_s of the absorbing layer backed by zero impedance is given by $Z_s = jZ_C\tan(k_a d) = Z_C\tanh(jk_a d)$. If the impedance of the absorbing layer backed by a hard wall [i.e., with $Z_2 \to \infty$ in Eq. (8.40a) or from Eq. (8.38a)] is denoted by Z_h, then $Z_{Ca} = \sqrt{Z_h Z_s}$. So Eq. (8.40a) can be written in the form

$$Z_1 = \frac{Z_h(Z_2 + Z_s)}{Z_2 + Z_s} = Z_h\frac{1 + Z_s/Z_2}{1 + Z_s/Z_2} \quad \text{N}\cdot\text{s/m}^3 \tag{8.40b}$$

The reflection factor and absorption coefficient a are computed by using Z_1 in Eq. (8.37). For small air space thickness such that $t/\lambda_0 < \frac{1}{8}$, $|Z_h| \gg |Z_w|$ and the following approximation is valid:

$$Z_1 \approx \frac{Z_h}{1 + Z_h/Z_2} \quad \text{N}\cdot\text{s/m}^3 \tag{8.41}$$

When the thickness of the absorbing layer is not too small, that is, $|Z_h| \ll |Z_2|$, Eq. (8.41) results in $Z_1 \approx Z_h$. Consequently at low frequencies a very thin air space between the absorbing layer and the rigid wall is ineffective.

As long as the layer thickness is small compared with the wavelength ($d < \frac{1}{8}\lambda_a$), the air space behind the absorbing layer results in a reduction of the surface impedance and at low frequencies the magnitude of the surface impedance shifts toward the characteristic impedance of air Z_0. This results in a decrease of the reflection factor R and a corresponding increase of the normal-incidence sound absorption coefficient. The largest improvement is observed when the thickness of the air space is a quarter of a wavelength, $t = \frac{1}{4}\lambda_0$.

When the air space thickness corresponds to a multiple of $\frac{1}{2}\lambda_0$, $\sin(k_0 t) \to 0$ and Z_2 is very large [see Eq. (8.39)]. At such frequencies, the air space becomes totally ineffective.

Oblique Sound Incidence

For oblique sound incidence one must distinguish between locally reacting and bulk-reacting absorbers. Locally reacting absorbers are those where sound propagation parallel to the absorber surface is prohibited, as, for example, in partitioned porous layers, porous layers backed by a partitioned air space as depicted on the left in Fig. 8.1, in Helmholtz resonators with partitioned volumes, and in small plate absorbers. Local reaction is a good approximation to absorber behavior also when the flow resistivity is relatively high, causing the transmitted wave to bend toward the normal to the surface. This is true, for example, at high densities or in granular media consisting of small particles. In bulk-reacting absorbers, such as a low-flow-resistivity porous layer, possibly with an unpartitioned air space behind it (Fig. 8.11*b*), sound propagation in the direction parallel to the absorber surface is possible in the sound-absorbing layer or in the air space behind it. The term "locally reacting" results from the fact that the particle velocity at the interface depends only on the *local* sound pressure. For bulk-reacting absorbers, the particle velocity at the interface depends not only on the local sound pressure but also on the particular distribution of the sound pressure in the entire absorber volume. Certain materials are inherently anisotropic; that is, the properties vary with direction through the material. This is true, for example, of fibrous materials where the fibers lie in planes parallel to the surface. Strictly, in such materials the propagation constant and characteristic impedance are a function of angle. However, this complication will not be considered further here.

Oblique-Incidence Sound on Locally Reacting Absorber. Locally reacting absorbers are characterized by a surface impedance Z_1 that is independent of the angle of incidence θ_0. The reflection factor $R(\theta_0)$ for locally reacting absorbers is determined by how well the surface impedance Z_1 matches the field impedance of $Z_0/\cos\theta_0$ and is given by

$$R(\theta_0) = \frac{Z_1\cos\theta_0 - Z_0}{Z_1\cos\theta_0 + Z_0} \tag{8.42}$$

Equation (8.42) indicates that best impedance match, and correspondingly the lowest reflection factor for a given incidence angle θ_0, is achieved by $|Z_1| > Z_0$

and that such "overmatched" surface impedances will yield absorption maxima at a specific angle of incidence.

Oblique-Incidence Sound on Bulk-Reacting Absorber. Mineral-fiber and open-pore foams are the most frequently used bulk-reacting sound-absorbing materials. As long as the materials may be treated as isotropic, the acoustical behavior of these materials can be fully characterized by their propagation constant k_a and characteristic acoustical impedance Z_a. Methods for measuring and predicting these key acoustical parameters are given in Section 8.4 under Physical Characteristics of Porous Materials and their Measurement.

Semi-Infinite Layer. Figure 8.12 shows the incident, reflected, and transmitted waves at the interface. The combination of these waves must satisfy the following boundary conditions: (1) equal normal components of the impedances and (2) equality of the wavenumber components parallel to the interface. The second of these requirements yields the refraction law

$$\frac{\sin\theta_1}{\sin\theta_0} = \frac{k_0}{k_a} \tag{8.43}$$

where θ_1 is the complex propagation angle of the sound inside the absorber. The complex reflection factor is given by

$$R(\theta_0) = \frac{1 - (Z_0/Z_1)\cos\theta_0}{1 + (Z_0/Z_1)\cos\theta_0} \tag{8.44a}$$

and

$$Z_1 = \frac{Z_{Ca}}{[1 - (k_0/k_a)^2 \sin\theta_0^2]^{1/2}} \quad \mathrm{N\cdot s/m^3} \tag{8.44b}$$

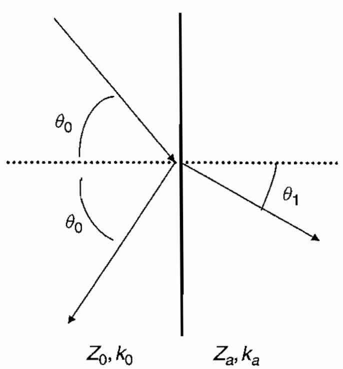


FIGURE 8.12 Reflection and transmission of an oblique-incidence sound wave by a semi-infinite, bulk-reacting absorber.

Finite-Layer Thickness. For a finite layer of bulk-absorbing material of thickness d in front of a hard wall, the reflection factor is

$$R(\theta_0) = \frac{1 - (Z_0/Z_{1d})/\cos\theta_0}{1 + (Z_0/Z_{1d})\cos\theta_0} \tag{8.45}$$

where $Z_{1d} = (Z_{Ca}/\cos\theta_1)\coth(jk_a d\cos\theta_1)$ and θ_1 is defined in Eq. (8.43),

Multiple Layers. Absorbers may consist of a porous sound-absorbing layer with an air space behind, as illustrated in Fig. 8.11, or a number of porous layers of different thicknesses and different acoustical characteristics (Fig. 8.13). Analytical expressions describing the absorber functions and design charts to predict the sound absorption coefficients for those multiple-layer absorbers are provided in reference 46.

Random Incidence. In a diffuse sound field where the intensity $I(\theta) = I$ is independent of the incident angle θ, the sound power incident on a small surface area dS of an absorber is given as

$$dW_{\mathrm{inc}} = I\,dS \int_0^{2\pi} d\phi \int_0^{\pi/2} \cos\theta\,\sin\theta\,d\theta = \pi I\,dS \tag{8.46}$$

and the absorbed portion as

$$\begin{aligned} dW_a &= I\,ds \int_0^{2\pi} d\phi \int_0^{\pi/2} \alpha(\theta)\cos\theta\,\sin\theta\,d\theta \\ &= 2\pi I\,dS \int_0^{\pi/2} \alpha(\theta)\cos\theta\,\sin\theta\,d\theta \end{aligned} \tag{8.47}$$

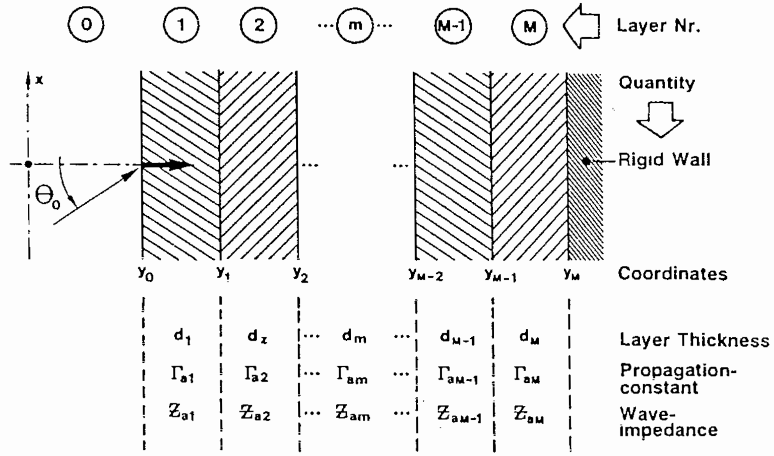

FIGURE 8.13 Multiple-layer absorber.

So the random-incidence sound absorption coefficient is given by

$$\alpha_R = \frac{dW_a}{dW_{\mathrm{inc}}} = 2\int_0^{\pi/2} \alpha(\theta)\cos\theta\,\sin\theta\,d\theta \qquad (8.48)$$

Random-Incidence Sound Absorption Coefficient of Locally Reacting Absorbers. When the constituent materials of a multiple-layer absorber are locally reacting, the combination of Eqs. (8.2), (8.42), and (8.48) will yield the random-incidence sound absorption coefficient. The surface impedance Z_1 that is required for the computation of the random-incidence absorption coefficient can be measured in an impedance tube or computed, and the true random-incidence sound absorption coefficient α_R can be determined as[4]

$$\alpha_R = \frac{8}{|z|}\cos(\beta)\left\{1 + \frac{\cos 2\beta}{\sin\beta}\arctan\left(\frac{|z|\sin\beta}{1+|z|\cos\beta}\right) - \frac{\cos\beta}{|z|}\ln(1+2|z|\cos\beta+|z|^2)\right\} \qquad (8.49)$$

where $z = Z/\rho_0 c_0$ is the normalized wall impedance and
$\beta = \arctan[\mathrm{Im}(z)/\mathrm{Re}(z)]$.

The maximum value of the true $\alpha_R(\max) = 0.955$ that occurs at a normalized wall impedance of $|z| = 1.6$ and $\beta \approx \pm 30°$ indicates that no locally reacting sound absorber can achieve total absorption or even the 99% absorption that is required as a minimum for the walls of anechoic chambers. The random-incidence sound absorption coefficient measured in a reverberation room, $\alpha_R(\mathrm{rev})$, as described in Chapter 7, can yield physically impossible values above unity (sometimes in excess of 1.2). To avoid confusion, the computed physically correct random-incidence coefficient represented by α_R and that measured with the reverberation room method should have a different symbol, namely $\alpha_R(\mathrm{rev})$.

Random-Incidence Sound Absorption Coefficient of Bulk-Reacting Absorbers. For bulk-reacting absorbers the integration in Eq. (8.48) can only be evaluated numerically. It is more appropriate to use the geometric and acoustical characteristics of the porous liner than its impedance to generate design charts for general use.

8.6 DESIGN CHARTS FOR FIBROUS SOUND-ABSORBING LAYERS

For design use it is useful to have charts where the sound absorption coefficient is plotted as a function of the first-order parameters of the absorber, such as thickness *d*, flow resistivity R_1, and frequency *f*. This section contains such design charts. Design charts for a multiple-layered absorber, such as shown in Fig. 8.13, are given in reference 46.

Monolayer Absorbers

As shown in Fig. 8.7*b*, the key acoustical parameters k_a and Z_{Ca} of fibrous sound-absorbing materials depend only on a single material parameter, namely the flow resistivity R_1 (specific flow resistance per unit thickness). Consequently, the absorption coefficient can be computed and plotted as a function of two dimensionless variables:

$$F = \frac{d}{\lambda} = \frac{fd}{c_0} \quad \text{and} \quad R = \frac{R_1 d}{Z_0} \qquad (8.50)$$

Then $k_0 d = 2\pi F$ and $E = \rho_0 f/R_1 = F/R$. At oblique incidence, the angle θ is the third input variable. In the design charts contour lines of constant values of α are plotted on a log-log chart of R versus F. A variation of frequency f produces a horizontal path, an increase of the flow resistivity R_1 causes an upward move, and an increase in layer thickness d leads to a diagonally upward shift to the right. Frequency curves for an absorber layer may be derived by a horizontal intersection, with a starting point determined by the individual parameter values.

Figure 8.14 shows lines of constant absorption of a monolayer absorber for *normal incidence* (the absorber may be bulk or locally reacting). The maximum absorption is reached at about $R = 1.2$ for $F = 0.25$, that is, at a thickness d equal to a quarter of a free-field wavelength and at the flow resistance of the layer of $1.2Z_0$. Higher resonances at odd multiples of a quarter wavelength are visible for a small flow resistance. The "summit line" of the first maximum, which goes through the points of relative maxima of a at the first resonance, is inclined so

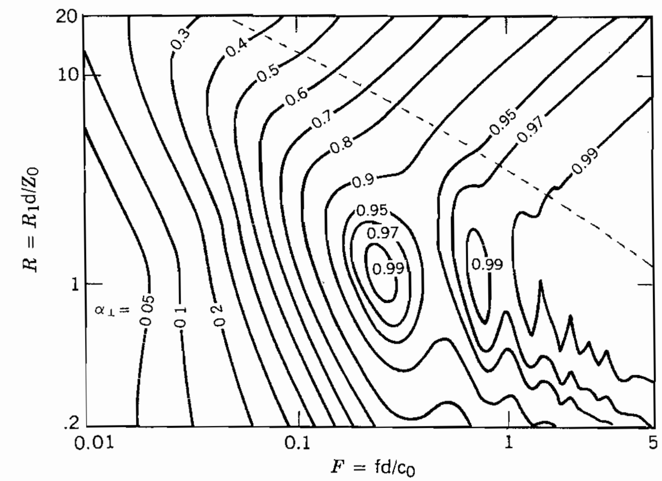

FIGURE 8.14 Lines of constant absorption at normal-incidence sound; absorption coefficient for fibrous absorbers of thickness d and flow resistivity R_1; no air space.

that the first relative maximum will occur below $F = 0.25$ for flow resistances such that $R > 1$, and the first relative maximum of the frequency curve will occur at somewhat higher frequencies than $F = 0.25$ for flow resistances such that $R < 1$. The higher orders of resonances are relatively stationary in frequency as R varies.

At *oblique incidence* the sound absorption for small angles, below about $\theta = 30°$, is only modified slightly. The modifications in $\alpha(\theta)$ are pronounced for larger angles with locally reacting absorbers. The curves on the left in Figs. 8.15 *a–c* were computed for a locally reacting absorber for θ values of 30°, 45°, and 60°. The resonance structure of the contour plots becomes very distinct at low flow resistances and high frequencies.

Curves on the right in Figs. 8.15*a–c* show the analogous contour plots of $\alpha(\theta)$ for the same values of θ but now for bulk-reacting (isotropic) absorber layers. Compared to those for a local-reacting absorber, the contours are relatively continuous. The maxima of absorption are shifted downward toward smaller R values for larger angles.

The *random-incidence* absorption coefficients α_R for locally reacting and bulk-reacting absorbers are plotted on the left and right, respectively, in Fig. 8.16. For locally reacting absorbers the absolute maximum of $\alpha_R = 0.95$ is attained for a matched flow resistance $R = 1$ at $F = 0.367$, that is, at a thickness $d = 0.367\lambda_0$, which is larger than a free-field quarter wavelength $\frac{1}{4}\lambda_0$. With homogeneous isotropic absorbers, the absorption coefficient α_R becomes larger than with locally reacting absorbers. Only a weak resonance maximum (belonging to the second resonance) is observed with homogeneous absorbers. The contour lines of absorption are smooth and steady.

Key Information Contained in Design Charts. Many of the general conclusions that were known qualitatively can be answered now in a quantitative manner by studying Figs. 8.14–8.16.

Determining Thickness of Absorber. What is the thickness d_∞ from which an absorber layer starts to behave acoustically as infinitely thick and yields no further increase in absorption? This thickness starts where the contour lines become 45° diagonally straight lines. The exact position of the curve for thickness d_∞ will depend on the criterion chosen and on the tolerance allowed. If, at this limit, the final value of α is supposed to be reached with a deviation between 1 and 3%, then the limit curve for normal incidence (in Fig. 8.14) is defined by

$$F = 7.45R^{-1.67} \tag{8.51}$$

The layer becomes practically infinite when the sound attenuation during propagation of the sound wave through the layer from the surface to the rigid rear wall is $8.68\Gamma_a' d_\infty = 24$ dB, as first derived in reference 2. This is a much higher attenuation than usually assumed as sufficient (about 6–10 dB) for neglecting the influence of the reflection from the rigid wall on the sound absorption at the front side of the absorber layer.

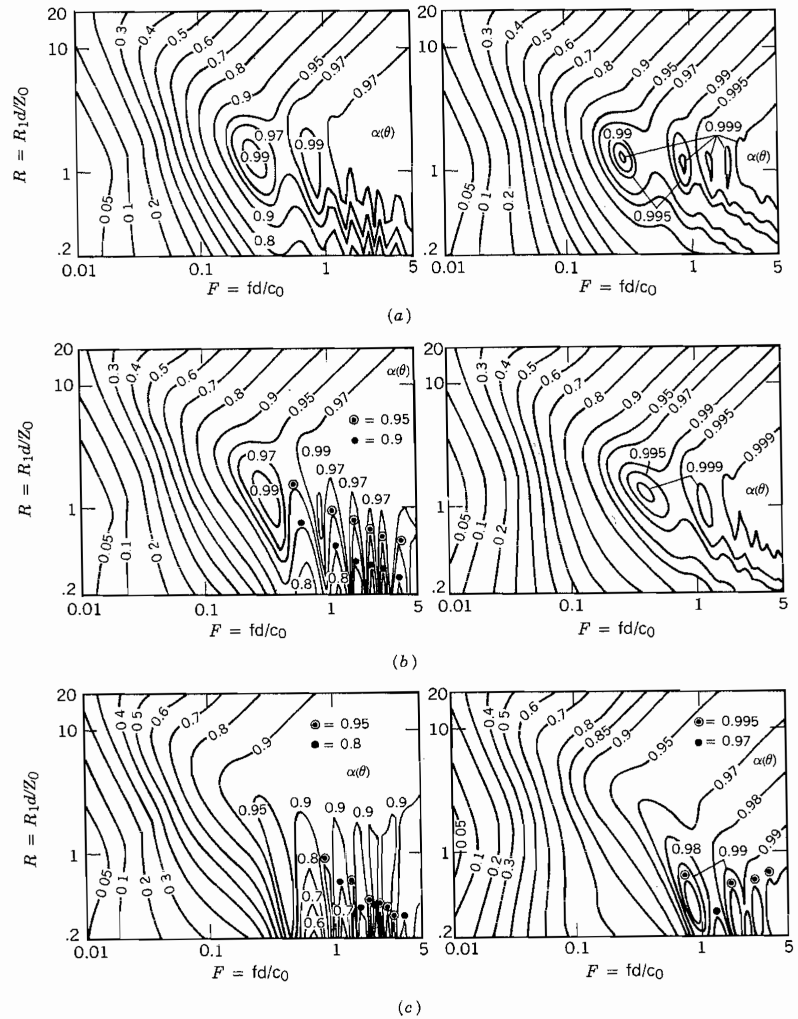

FIGURE 8.15 Lines of constant absorption $\alpha(\theta)$ for fibrous absorbers of thickness d and flow resistivity R_1 for discrete angles of incidences θ; no air space. Left: locally reacting. Right: bulk reacting. *(a)* $\theta = 30°$; *(b)* $\theta = 45°$; *(c)* $\theta = 60°$.

The relationships for "practically infinite" layer thickness d_∞ for which $\Delta L(d_\infty) = 24$ dB can be formulated as

$$f d_\infty^{2.67} R_1^{1.67} = 59 \times 10^6 \quad \text{for } \theta = 0° \tag{8.52a}$$

$$f d_\infty^{2.56} R_1^{1.56} = 34.3 \times 10^6 \quad \text{for } \theta = 45°, \quad \text{locally reacting and random incidence} \tag{8.52b}$$

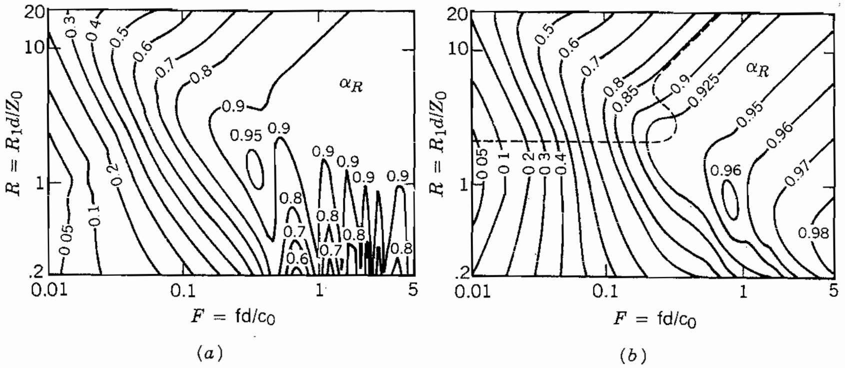

FIGURE 8.16 Lines of constant random-incidence absorption coefficient α_R for fibrous absorbers of thickness d; no air space: (*a*) locally reacting liner; (*b*) bulk-reacting liner.

$$f d_\infty^{2.4} R_1^{1.4} = 7.7 \times 10^6 \quad \text{for } \theta = 45°\text{, bulk reacting} \tag{8.52c}$$

$$f d_\infty^{2.2} R_1^{1.2} = 1.1 \times 10^6 \quad \text{for random-incidence bulk reacting} \tag{8.52d}$$

where f = frequency, Hz
d_∞ = layer thickness, m
R_1 = flow resistivity, N · s/m^4

Optimal Choice of Flow Resistance. Optimal values for the normalized specific flow resistance of the layer, $R = R_1 d/Z_0$, plotted on the vertical scale of Figs. 8.14–8.16, depend on what the designer wants to accomplish.

If the aim is to maximize the sound absorption coefficient, then the optimal choice of normalized specific flow resistance R is in the range of 1–2 for both locally reacting and bulk-reacting absorbers and for normal, oblique, or random angles of sound incidence with the exception of bulk-reacting absorbers for $\theta > 45°$ incidence where $R = 0.7$ yields the best results.

The absorption coefficient depends strongly on flow resistivity R_1, where the curves in Figs. 8.14–8.16 have nearly horizontal contours. The design charts reveal that the typical orientation of the curves of constant α is nearly vertical, indicating only a slight dependence on R_1. This is fortunate because our ability to determine R_1 and our accurate control over its value in the manufacturing process are limited.

Bulk-Reacting versus Locally Reacting Absorbers. A comparison of two graphs in Fig. 8.16 indicates that the random-incidence sound absorption coefficient of locally reacting and bulk-reacting absorbers of the same thickness is practically identical (within 10%) in the left upper quadrant, where $R > 2$ and $F = fd/c_0 < 0.25$, above the dotted line in the graph on the right in Fig. 8.16.

A comparison of $\theta = 45°$ curves in Fig. 8.15*b* with the random-incidence curves presented in Fig. 8.16 indicates that the $\theta = 45°$ curves for both locally reacting and bulk-reacting absorbers agree with the random-incidence curves within an error of 5%, except in the range where $\alpha > 0.9$, which is of little practical interest. This close agreement between $\alpha(45°)$ and α_R indicates that it is permissible to compute $\alpha(45°)$ instead of the much more difficult α_R.

Two-Layer Absorbers

The two-layer absorbers shown in Fig. 8.11 have a layer of fibrous sound-absorbing material of thickness d backed by an air space of thickness t, with total thickness $D = d + t$. Figure 8.11*a* shows a partitioned (e.g., in a honeycomb pattern) air space resulting in a locally reacting absorber, and Fig. 8.11*b* shows an unpartitioned air space resulting in a bulk-reacting absorber. The sound absorber types shown in Fig. 8.11 are usually employed when it is impractical to fill the entire absorber thickness with porous material because no fibrous material of sufficiently low flow resistivity is available to keep the normalized flow resistance $R = R_1 d/Z_0 < 2$. Based on the analyses described in reference 5, design charts similar to those presented in a preceding section for monolayer absorbers were computed.

Figure 8.17 shows contour maps of the random-incidence sound absorption coefficient α_R in a diffuse sound field for a bulk absorber layer of thickness d in front of a locally reacting air gap of thickness t (see Fig. 8.11*a*) for three fractions, $d/D = 0.25, 0.5, 0.75$, absorber thickness d, and total thickness $D = d + t$. Because the two-layer design curves in Fig. 8.17 are not plotted as functions of the total layer thickness D, they are not directly comparable with the monolayer design curves presented in Fig. 8.16. Some differences may be noticed by comparing these figures with Fig. 8.16, which applies to the bulk monolayer absorber.

First, the variable $F = fd/c_0$ for maximum absorption in the first resonance maximum is shifted toward smaller values with decreasing d/D, which results in higher absorption at low frequencies for less absorber material thickness. Generally, however, the reduction in weight of the material is not as large. The horizontal shift of the absorption maximum toward lower F values, when realized by a reduction in d, makes a larger flow resistivity necessary on the ordinate in order to hold R on a constant value. The increase in R_1 is achieved mostly by an increase of the material bulk density ρ_A. For most fibrous absorber materials R_1 is proportional to about $\rho_A^{1.5}$. Hence, only a small net reduction in absorber material is possible by the addition of an air gap.

For thick absorber layers, that is, for large d, the air gap has no effect, as expected. The limit for the onset of an "infinite" thickness is the same as with the monolayer absorber.

The resonance structure of the layered absorber with small d/D resembles more that of the locally reacting monolayer absorber (see Fig. 8.16*a*). The character of the bulk-reacting monolayer absorber plot (see Fig. 8.16*b*), which must be the asymptotic limit for increasing d/D, becomes dominant for $d/D \geq 0.5$.

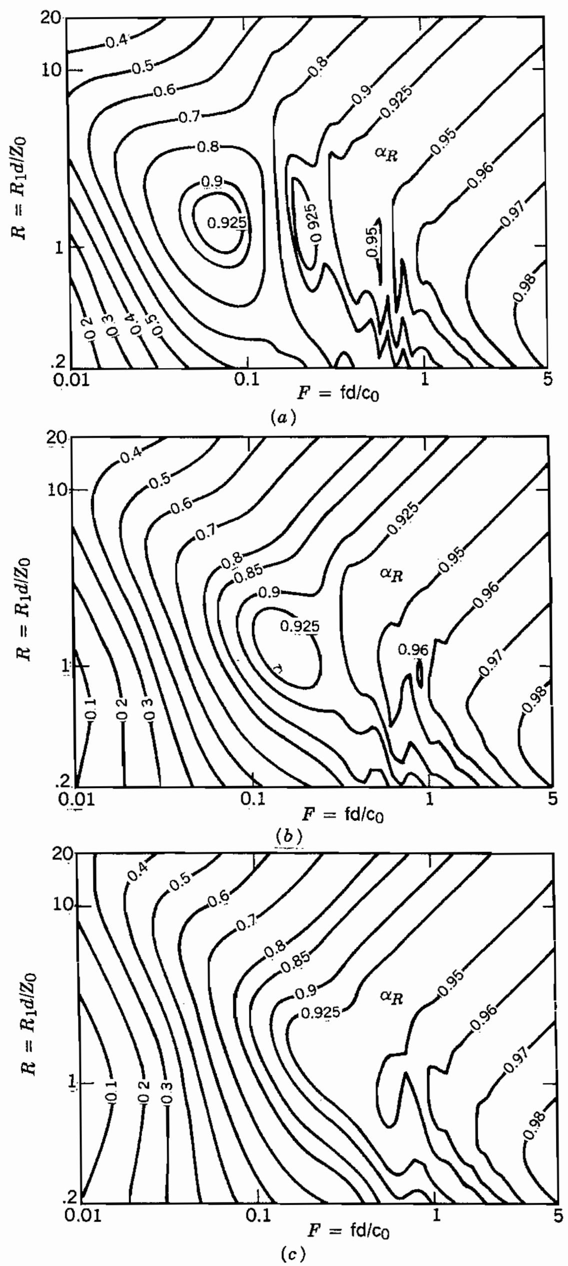

FIGURE 8.17 Lines of constant random-incidence absorption coefficient α_R for a bulk-reacting absorber layer of thickness d in front of a locally reacting air gap of thickness t for thickness ratios $d/D = d/(d+t)$ of (*a*) 0.25, (*b*) 0.5, and (*c*) 0.75.

The sound absorption coefficient of a porous layer of thickness d with an air gap behind it is generally higher than that of a monolayer with equal d. However, the absorption of the layered absorber is smaller than that of a monolayer absorber with equal total thickness $d' = D$. In the range $R > 1$, the absorption of a layered absorber with $d/D = 0.75$ corresponds to that of a monolayer absorber with thickness $d' = 1.25d$ and the absorption of a layered absorber with $d/D = 0.5$ corresponds to that of a monolayer having a thickness $d' = 1.67d$. The quite different character of the plot for $d/D = 0.25$ excludes a similar equivalence.

Finally, the lines of constant α_R of the layered absorber have strong deflections toward the left for values of α_R between about 0.7 and 0.9. As a consequence, the optimum flow resistance $R_1 d$ (which is defined by the leftmost point of a curve) has a more distinct meaning than with monolayer absorbers.

Design graphs for layered absorbers with bulk-reacting absorber layers in front of a bulk-reacting air gap (see Fig. 8.7*b*) are given in reference 45.

Multilayer Absorbers

Multilayer absorbers, such as shown in Fig. 8.13, have been treated in reference 4. Best results are obtained if the flow resistivity of the layers, R_1, increases from the interface toward the rigid wall. These results obtained with such multilayer absorbers are somewhat better than those obtained with a monolayer absorber of equal thickness. However, the improvements seldom justify the added cost and complexity. Of course, Fig. 8.13 represents an idealization of practical constructions (see Fig. 8.18) which combine multiple porous layers with perforations and slots.

It should be noted, however, that even the most elaborate multiple-layer absorber cannot match the random-incidence sound absorption performance of anechoic wedges.

Thin Porous Surface Layers

Thin porous surface layers such as mineral wool felt sprayed on plastic, steel wool, mineral wool, or glass fiber cloth; wire mesh cloth; and thin perforated metal are frequently used to provide mechanical protection. They also reduce the

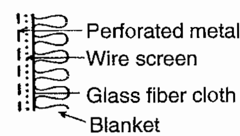

FIGURE 8.18 Multilayered absorber with perforated porous layer structure.

loss of fibers. The acoustical properties of such thin layers are characterized by their flow resistance $R_s = \Delta p/v$ and their mass per unit area ρ_s. The surface impedance is

$$Z_s = \begin{cases} R_s & \text{(fixed)} \quad (8.53a) \\ \dfrac{(j\omega\rho_s)R_s}{j\omega\rho_s + R_s} & \text{(free)} \quad (8.53b) \end{cases}$$

which must be added to the wall impedance of the absorber. If the porous surface layer is not free to move, Eq. (8.53a) is used. For surface layers that are free to move due to the pressure differential produced by their flow resistance, Eq. (8.53b) is used.

Tables 8.5 and 8.6 provide design information on wire mesh cloth and glass fiber cloth, respectively. The flow resistance values listed in these tables represent the linear part of the flow resistance, which is appropriate for design use only if the particle velocity is low. At high sound pressure levels (above 140 dB), the nonlinear behavior of the flow resistance must be determined by measuring the flow resistance as a function of the face velocity.

Sintered porous metals have been developed for silencers in jet engine inlets. If backed by a honeycomb-partitioned air space, they provide good sound absorption and remain linear up to high sound pressure levels and for high-Mach-number grazing flow. Their additional advantage is that they do not require any surface protection. Table 8.7 gives the flow resistance R_s and mass per unit area ρ_s for some commercially available porous metal sheets.

Steel wool mats typically have a thickness from 10 to 45 mm, mass per unit area ρ_s from 1 to 3.8 kg/m^2, and a specific flow resistance R_s from 100 to 500 N · s/m^3. Recently, such steel wool mats needled on mineral wool of specified thickness and density have become available on special order.

Perforated metal facings, when they rest directly on a porous sound-absorbing layer, can be accounted for by a series impedance Z_s given by

$$Z_s = \frac{j\omega\rho_0}{\varepsilon}\left\{l + \Delta l\left[H(1 - |v_h|) - j\frac{\Gamma_a}{k_0}\frac{Z_a}{Z_0}\right]\right\} \quad (8.54)$$

[b] Nonlinearity factor, calculated as the ratio of flow resistances obtained at flow velocities of 500 and 20 cm/s, respectively.

where ε is the fractional open area of the perforated facing, l is the plate thickness, Δl is the end correction length of the perforations given in Section 8.5, H is a step function that is unity for $|v_h| \leq 1$ m/s and zero for $|v_h| > 1$ m/s, and v_h is the particle velocity in the holes of the perforations. For thin, unrestrained perforated surface protection plates, it is necessary to take the parallel combination of Z_s and $j\omega\rho_s$ according to Eq. (8.53b).

8.7 RESONANCE ABSORBERS

In building acoustics the most frequently used type of resonant absorber is the Helmholtz resonator, consisting of the mass of an air volume in a cross-sectional area restriction (such as holes or slits in a covering plate) and the compliance of the air volume behind the covering plate. In the narrow frequency range, centered at their resonance frequency, the resonators "soak in" the acoustical energy from a large room volume in the vicinity of the neck. This high energy concentration results in high local sound pressures at the neck (and in the internal volume) which are much higher than that one would register with the resonator opening closed. On the room side, this near-field sound pressure decays exponentially with increasing distance. In architectural application of resonance absorbers care should be exercised not to locate them too near to any member of the audience to avoid distortion of the auditory experience. The open bottles embedded in the vertical portion of the seats in ancient Greek amphitheaters indicate that this local amplification of the sound field in the vicinity of acoustical resonators was known more than 2000 years ago. What was not known, which misguided their application, was that the amplification occurs only in a narrow frequency band and cannot locally amplify such broadband signals as speech. Such a Helmholtz resonator (named after the nineteenth-century German physicist Ludwig Helmholtz, who was first to utilize its narrow-band tuning to analyze the spectral composition of complex sounds) is shown in Fig. 8.19. In the following treatment it is assumed that all dimensions of a single resonator are small compared with the acoustical wavelength (except in the case of two-dimensional resonators with slits) and that the skeleton of the resonator is rigid.

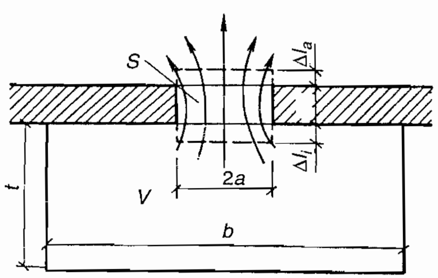

FIGURE 8.19 Key geometric parameters of a Helmholtz resonator.

Acoustical Impedance of Resonators

The specific acoustical impedance of the resonator opening Z_R is the sum of the impedance of the enclosed air volume Z_v and that of the air volume that oscillates in and around the resonator mouth Z_m, namely,

$$Z_R = Z_v + Z_m = (Z'_v + jZ''_v) + (Z'_m + jZ''_m) \quad \text{N} \cdot \text{s/m}^3 \tag{8.55}$$

The volume impedance $Z_v = jZ''_v$ is purely imaginary and predominantly of spring character while the mouth impedance has a real part Z'_m and an imaginary part Z''_m and is predominantly of mass character.

The impedance of a rectangular resonator volume is

$$Z_v = jZ''_v = -j\rho_0 c_0 \cot(k_0 t)\frac{S_a}{S_b} \quad \text{N} \cdot \text{s/m}^3 \tag{8.56a}$$

where S_b is the surface area of the resonator cover plate, $S_a = \pi a^2$ is the area of the resonator mouth, t is the depth of the resonator cavity, and $V = S_b t$ is the resonator volume. If the resonator dimensions are small compared with the wavelength ($k_0 t \ll 1$), Eq. (8.56a) yields

$$Z_v = jZ''_v = -j\frac{\rho_0 c_0^2}{\omega}\frac{S_a}{V} \quad \text{N} \cdot \text{s/m}^3 \tag{8.56b}$$

Thus, when all the dimensions are smaller than the wavelength of interest, the shape of the air cavity does not matter.

The impedance of the resonator mouth Z_m consists of components related to the oscillations of air internal to the mouth, within the mouth, and external to the mouth of the resonator plus the impedance of the screen (Z_s) that may be placed across the resonator mouth to provide resistance. For circular resonator openings of radius a and orifice plate thickness l, the resulting total impedance is given by

$$Z'_m = \rho_0\left[\sqrt{8\nu\omega}\left(1 + \frac{l}{2a}\right) + \frac{(2\omega a)^2}{16c_0}\right] + Z_s \quad \text{N} \cdot \text{s/m}^3 \tag{8.57a}$$

$$Z''_m = \omega\rho_0\left[l + \left(\frac{8}{3\pi}\right)2a\right] + \left(l + \frac{1}{2a}\right)\sqrt{8\nu\omega} \quad \text{N} \cdot \text{s/m}^3 \tag{8.57b}$$

where ν is the kinematic viscosity ($\nu = 1.5 \times 10^{-6}$ m^2/s for air at room temperature). The quantity $0.5(8\nu/\omega)^{1/2}$ is the viscous boundary layer thickness.[1]

In general, the first term in Eq. (8.57a) applies only for smooth orifice edges. For sharp orifice edges it can be many times higher. Also note that the second term in Eq. (8.57b) is usually small compared with the first term and can be neglected.

The results of Eqs. (8.57) for circular orifices and for a single resonator can be generalized for other orifice shapes and for situations where the orifice is located on a large wall or at a two- or three-dimensional corner. This generalized form is

$$Z'_m = \frac{P(l + P/2\pi)}{4S_a}\rho_0\sqrt{8\nu\omega} + \rho_0 c_0 \frac{k_0^2 S_a/\Omega}{1 + k_0^2 S_a/\Omega} + Z_s \quad \text{N s/m}^3 \tag{8.58a}$$

$$Z''_m = j\omega\rho_0\left[l + 2\,\Delta l + \frac{P(l + P/2\pi)}{4S_a}\sqrt{8\nu/\omega}\right] \quad \text{N}\cdot\text{s/m}^3 \tag{8.58b}$$

where P is the perimeter of the orifice, S_a is its surface area, and Ω is the spatial angle the resonator "looks into":

$$\Omega = \begin{cases} 4\pi & \text{for resonator away from all walls} \\ 2\pi & \text{flush mounted on wall far from corners} \\ \pi & \text{flush mounted on wall at two-dimensional corners} \\ \frac{1}{2}\pi & \text{flush mounted on wall at three-dimensional corners} \end{cases}$$

The quantity $\Delta l = 16a/3\pi$ represents the combined internal and external end corrections.

Resonance Frequency

The resonance frequency f_0 of the Helmholtz resonator occurs where Z''_m and Z''_v are equal in magnitude. Combination of Eqs. (8.56b) and (8.57b) yields

$$f_0 = \frac{c_0}{2\pi}\sqrt{\frac{S_a}{V\langle\cdots\rangle}} \cong \frac{c_0}{2\pi}\sqrt{\frac{S_a}{V(l + 16a/3\pi)}} \tag{8.59}$$

where $\langle\cdots\rangle = l + \Delta l$ represents the quantity in square brackets in Eq. (8.58b).

The viscous terms in (8.57b) are ignored in (8.59). However, this is usual when calculating a resonance frequency because the viscous contribution is small. For resonators where the area of the mouth, S_a, is not much smaller than the area of the top plate of the resonator, the proximity of the side walls of the cavity influences the flow in the resonator mouth. In this case it is necessary to determine the combined end correction from $\Delta l = 8a/3\pi + \Delta l_{\text{int}}$.[47]

Absorption Cross Section of Individual Resonators

For individual resonators (or groups of resonators where the distance between the individual resonators is large enough that interaction is negligible), the absorption coefficient α is meaningless. In this case, the sound-absorbing performance must be characterized by the absorption cross section A of the individual resonator. The absorption cross section is defined as that surface area (perpendicular to the direction of sound incidence) through which, in the undisturbed sound wave (resonator not present), the same sound power would flow through as the sound power absorbed by the resonator.

The power dissipated in the mouth of a resonator is

$$W_m = 0.5|v_a|^2 S_a R_T = \frac{0.5 \times 2^n |p_{\text{inc}}|^2 S_a R_T}{|Z_R|^2} \quad \text{W} \tag{8.60}$$

Accordingly, the absorption cross section is

$$A = \frac{2^n \rho_0 c_0 S_a R_T}{|Z_R|^2} \quad \text{m}^2 \tag{8.61}$$

where $n = 0$ for resonators placed in free space, $n = 1$ if the resonators are flush mounted in a wall, $n = 2$ if the resonators are at the junction of two planes, and $n = 3$ if the resonators are in a corner; $R_T = Z'_m + Z_{\text{rad}}$ is the total resistance.

At the resonance frequency f_0, where $Z''_v + Z''_m = 0$, the absorption cross section reaches its maximum value A_0:

$$A = 2^n \frac{S_a \rho_0 c_0}{R_{\text{rad}}}\left[\frac{R_T/R_{\text{rad}}}{|1 + R_T/R_{\text{rad}}|^2}\right] \quad \text{m}^2 \tag{8.62a}$$

For a flush-mounted ($n = 1$) circular resonator area $S_a = \pi a^2$, the radiation resistance is $R_{\text{rad}} = 2(\pi a)^2 \rho_0 c_0/\lambda_0^2$, and Eq. (8.62a) yields

$$A = \frac{1}{\pi}\lambda_0^2\left[\frac{R_T/R_{\text{rad}}}{|1 + R_T/R_{\text{rad}}|^2}\right] \quad \text{m}^2 \tag{8.62b}$$

where λ_0 is the wavelength at the resonance frequency of the resonator. The maximum value of the absorption cross section is obtained by matching the *internal* resistance to the radiation resistance at the resonance frequency, yielding ($R_T = R_{\text{rad}}$)

$$A_0^{\max} = \frac{\lambda_0^2}{4\pi} \quad \text{m}^2 \tag{8.63}$$

According to Eq. (8.63), a matched resonator tuned to 100 Hz can achieve absorption cross section $A_0^{\max} = 0.92\ \text{m}^2$.

According to Eq. (8.61), the frequency dependence of A can be presented in generalized form as

$$\frac{A(f)}{A_0} = \frac{1}{1 + Q^2\phi^2} \tag{8.64}$$

where the Q of the resonator and the normalized frequency parameter ϕ are given as

$$Q = \frac{Z''_m(\omega_0)}{Z'_m(\omega_0)} \qquad \phi = \frac{f}{f_0} - \frac{f_0}{f}$$

Figure 8.20 shows the normalized absorption cross section A/A_0 as a function of the normalized frequency ϕ with Q as the parameter, indicating that the

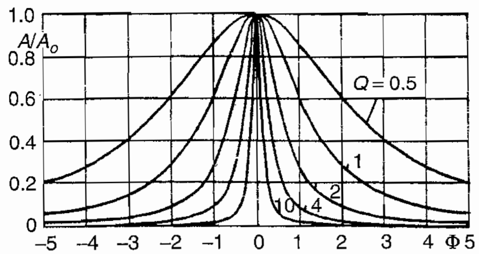

FIGURE 8.20 Normalized absorption cross section A/A_0 as function of normalized frequency ϕ with Q as parameter.

normalized bandwidth of the absorption cross section f_0/Q corresponds to the relative bandwidth $\Delta f/f_0 = 1/Q$.

Consequently, the choice of Q determines the relative shape of the absorption curve and the factor in the square brackets in Eq. (8.62b) determines the height of the curve at resonance. To obtain optimal absorption characterized by high absorption at resonance A_0 and wide bandwidth requires resistance matching $R_T = R_{\text{rad}}$ and a relatively low value of Q.

Nonlinearity and Grazing Flow

The oscillating air mass (that includes the end-correction term) is a measure for the reversible kinetic energy of the acoustical resonator. Reversibility and spatial coherence diminish with increasing turbulence due to jet flow through the orifice caused by high-amplitude sound and by the grazing flow of velocity U_∞. Both reduce the air mass that participates in the oscillating motion and consequently increase resonance frequency and increase the losses of the resonator.

Nonlinearity and grazing flow affect only the mouth impedance Z_m of the resonator orifice. Table 8.8 is a compilation of the nonlinear effects owing to high sound pressure level and grazing flow for a perforated plate. The round holes are regularly distributed. The porosity of the perforated plate is $\varepsilon = \pi a^2/b^2$, where a is the hole radius and b the hole spacing. The amplitude nonlinearity is characterized by the particle-velocity-based Mach number $M_0 = v/c_0$, which is the ratio of the particle velocity in the resonator orifice and the speed of sound in air. The grazing flow nonlinearity is characterized by the flow-velocity-based Mach number $M_\infty = U_\infty/c_0$, where U_∞ is the velocity of the grazing flow far from the wall. The formulas presented in Table 8.8 are analytical results adjusted to yield agreement with measured data.[48] The impedances in Table 8.8 are values averaged over the plate surface.

Internal Resistance of Resonators

The most difficult part of resonator design is the prediction of the internal resistance. In the earlier section Acoustical Impedance of Resonators (page 265) formulas were given to predict the friction loss resistance [first term in Eq. (8.57a)], which is valid only for rounded orifice perimeter. Additional resistance due to sharp edges cannot be predicted analytically. Table 8.8 contains formulas to predict resonator resistance due to nonlinear effects owing to high sound pressure level and grazing flow.

Should it be desirable to obtain higher loss resistance than provided by friction and nonlinear effects (e.g., obtaining larger absorption bandwidth), porous materials such as a screen, felt, or layer of fibrous sound-absorbing material must be placed in (or behind) the resonator orifice. Figure 8.21 shows some of the more frequently used ways to increase resonator resistance. In Fig. 8.21, R_1 is the flow resistivity of the porous material, d is its thickness, t_1 is its distance from the back side of the cover plate, t is the depth of the resonator cavity, $2a$ is the diameter of the holes, Δl is the end correction, and ε is the porosity of the cover plate.

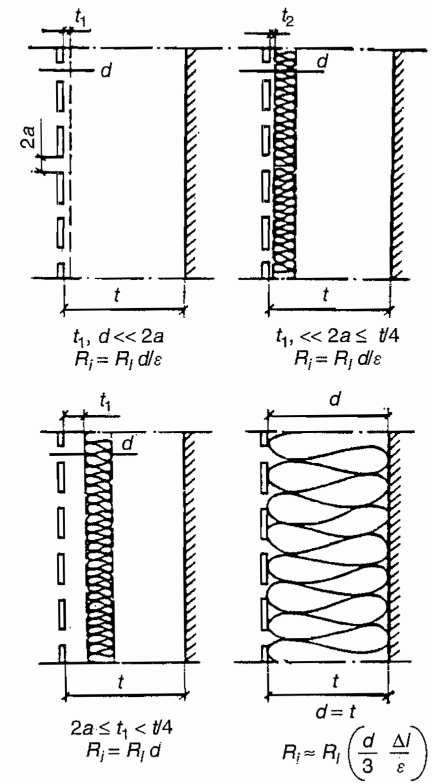

FIGURE 8.21 Methods to increase resonator resistance and the achieved specific acoustical resistance R_i (R_1 = flow resistivity of porous material, d is its thickness, and $\Delta l = 16a/3\pi$).

[a] L_p is octave-band SPL in dB re 20 μPa at the peak of the spectrum.

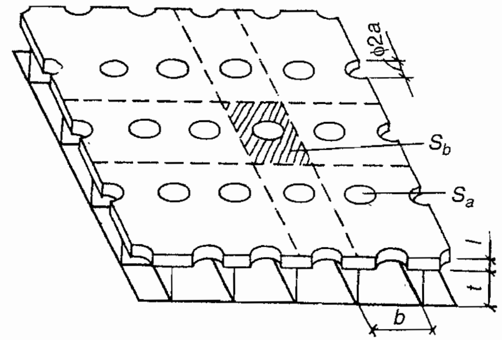

FIGURE 8.22 Resonators arranged on a raster to form a surface array.

Placing of flow-resistive materials in or behind the resonator opening reduces nonlinearity and sensitivity to grazing flow.

Spatial Average Impedance of Resonator Arrays

Locally reacting absorbers such as resonators are frequently used in the form of a surface array, shown in Fig. 8.22, where the individual resonators are arranged periodically. If the dimension b or $\sqrt{S_b}$ in Fig. 8.22 is much smaller than the acoustical wavelength, it is not necessary to take into account the interaction of the individual elements (resonators) with the sound field. To characterize the absorber, it is sufficient in this case to compute the spatial average wall impedance Z_1:

$$Z_1 = \frac{\langle p \rangle}{\langle v \rangle} = \frac{S_b}{S_a}\frac{p_a}{v_a} = \frac{S_b}{S_a} Z_R = \frac{Z_R}{\varepsilon} \quad \mathrm{N \cdot s/m^3} \tag{8.65}$$

where Z_R is the impedance of the resonator as given in Eqs. (8.55) "measured" in the orifice of the resonator and $\varepsilon = S_a/S_b$ is the surface porosity. The effective wall impedance Z_1 is then used in Eq. (8.37) to determine the absorption coefficient. The impedances Z_m in Table 8.8 are effective impedances averaged over the plate surface (resonator mass impedance divided by porosity).

8.8 PLATE AND FOIL ABSORBERS

Plate absorbers are used in absorbing low-frequency tonal noise in situations where Helmholtz resonators are not feasible. The resonator consists of the mass of a thin plate and usually the stiffness of the air space between the plate and the elastic mounting at the perimeter of the plate. Foils are a special case of a thin limp plate.

Limp Thin Plate or Foil Absorber

The resonance frequency of a foil absorber is

$$f_0 = \frac{\sqrt{\rho_0 c_0^2 / m'' t}}{2\pi} \tag{8.66}$$

where t is the depth of the partitioned air space in meters and m'' is the mass per unit area of the limp foil in kilograms per square meter. If the air space depth is not small ($t > \frac{1}{8}\lambda$), there will be many resonance frequencies ω_n ($n = 0, 1, 2, \ldots$) given by

$$\frac{\omega_n t}{c_0} \tan \frac{\omega_n t}{c_0} = \frac{\rho_0 t}{m''} \tag{8.67}$$

For an unpartitioned air space behind the foil the resonance frequency depends on the angle of sound incidence θ_0. In this case t must be replaced in Eqs. (8.66) and (8.67) by $t \cos \theta_0$. If the air space is filled (without obstructing the movement of the foil) with a porous sound-absorbing material, then $(t/c_0)\Gamma_a''$ is used instead of t/c_0 in Eq. (8.67).

Foil-Wrapped Porous Absorber

Sound absorbers consisting of a protective layer of thin foil, a porous layer, and an air space behind are frequently used where the porous material must be protected from dust, dirt, and water. The effect of the thin foil can be taken into account by a series impedance $Z_s = j\omega m''$ that is added to the surface impedance Z_1 [see Eq. (8.37)]. It is essential that the foil is not stretched so that its inertia and not its membrane stress controls its response. Inserting a large-mesh (≥ 1 cm) wire cloth between the porous sound-absorbing material and the protective foil is a practical way to assure this.

Elastically Supported Stiff Plate

A form of resonant plate absorber that can be easily treated analytically is the elastically supported stiff plate. The elastic support may be localized by discrete points to occur along the perimeter in the form of a resilient gasket strip. The effective stiffness of such a resonator is

$$s'' = \frac{s_e}{S_p} + \frac{\rho_0 c_0^2}{t} \quad \text{N/m}^3$$

and the resonance frequency is

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{s''}{m''}} = \frac{1}{2\pi}\sqrt{\frac{s_e/S_p + \rho_0 c_0^2/t}{m''}} \quad \text{Hz} \tag{8.68}$$

where $s_e = S_p \, \Delta p / \Delta x$ is the dynamic stiffness of resilient plate mounting and S_p is the surface area of the plate. Note that the elastic mounting increases the

resonance frequency (compared with that obtainable with a limp foil of the same m''). This can be compensated for by an appropriate increase of m''. However, an increase of m'' increases the Q of the resonator ($Q = \sqrt{s''/m''}/R$) resulting in a narrower bandwidth.

Elastic Foil Absorber

Elastic foil absorbers consist of small air volumes enclosed in thin (200–400-μm) foil coffers. The coffers have typical dimensions of a few centimeters. A typical

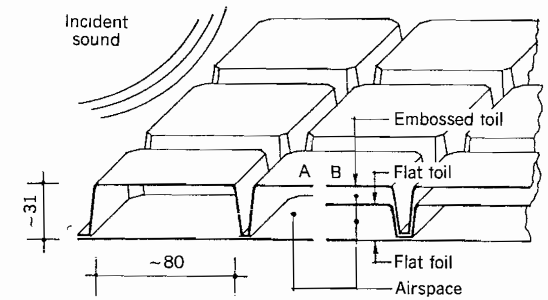

FIGURE 8.23 Construction of a foil absorber made of cold-drawn PVC foil.

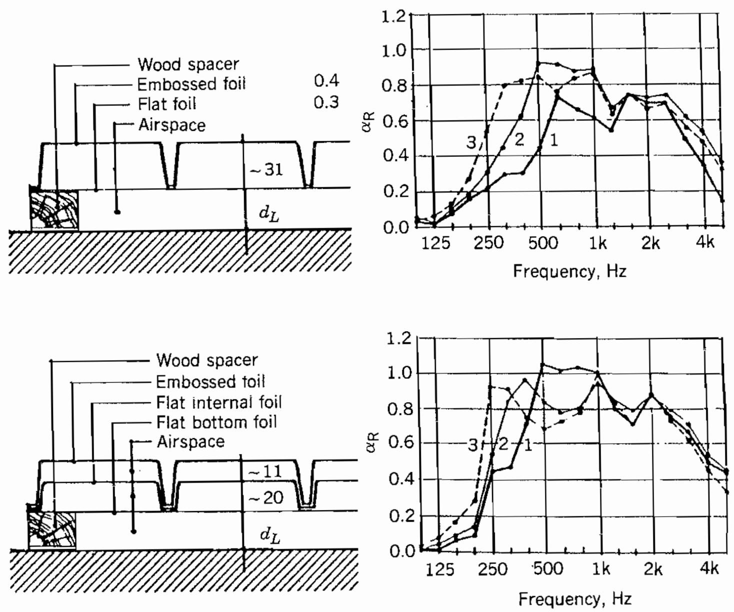

FIGURE 8.24 Random-incidence sound absorption coefficient α_R of absorbers made of cold-drawn PVC foil: (1) $d_L = 0$; (2) $d_L = 25$ mm; (3) $d_L = 50$ mm.

foil absorber is shown in Fig. 8.23. The wavelength of the incident sound is large compared with the typical dimensions of the coffers. Consequently, the incident sound periodically compresses the air in the individual coffers by exiting all of the volume-displacing modes of vibration of the various coffer walls. Because of the small thickness of the coffer walls, these resonances fall into the frequency range of 200–3150 Hz, which is of primary interest in building applications.[49] The foil material can be plastic (PVC) or metal. It is beneficial to emboss the foil because this leads to a more even distribution of the resonance frequencies. Figure 8.24 shows the measured random-incidence sound absorption coefficient obtained with two different foil absorber configurations, indicating that significant broadband sound absorption is achievable.

The key advantage of these foil absorbers is that they are nonporous, do not support bacterial growth, are lightweight, and can be made light transparent. Their main application is in breweries, packaging plants, hospitals, and computer chip manufacturing areas, where high emphasis is placed on hygiene and dust cannot be tolerated. They also lend themselves as sound absorbers in high-moisture environments such as swimming pools and as muffler baffles in cooling towers. Their light transparency is a distinct advantage in industrial halls. Considerable experience has been gained in such applications in Europe.[49]

9.1 INTRODUCTION

Chapter Organization

This chapter is organized in seven sections. The present section reviews some of the significant milestones in silencer design, citing relevant references. Section 9.2 reviews the acoustical criteria commonly used to determine silencer performance. Section 9.3 discusses the decomposition of a silencer into basic acoustical transmission elements, presents transmission matrix expressions for some elements used in the Section 9.4 examples, and provides references for additional elements not explicitly covered in this chapter. Section 9.4 discusses the predicted performance of several silencer designs and provides selected examples of designs aimed at achieving specific acoustical goals. Section 9.5 provides a more qualitative discussion of perforated-element mufflers along with a few muffler design examples. Section 9.6 considers dissipative silencers most widely used to attenuate broadband noise in ducts with gas flow with a minimum of pressure drop across the silencer. Section 9.7 discusses designs that combine reactive silencer low-frequency tonal performance with passive silencer high-frequency broadband performance. A reader solely interested in designing a silencer for a specific application may proceed directly to Sections 9.3–9.7.

Background Information

The noise generated by air/gas handling/consuming equipment, such as fans, blowers, and internal combustion engines, is controlled through the use of two types of devices: (1) passive silencers and lined ducts whose performance is a function of the geometric and sound-absorbing properties of their components and (2) active noise control silencers whose noise cancellation features are controlled by various electromechanical feed-forward and feedback techniques. This chapter focuses on passive silencers while active noise control is discussed in Chapter 17 and lined ducts are covered in Chapter 16.

In the remainder of this chapter, the term *silencer* is often used generically to refer to any type of passive noise control device. Specific names are introduced primarily in cases where the use of "silencer" may lead to ambiguities.

Over the last four decades silencers have been the focus of many research programs that improved the understanding of the basic phenomena and resulted in more accurate design methods. The groundwork for the behavior of lined ducts with no flow was laid even earlier by Morse[1] and Cremer,[2] and the first systematic evaluation of mufflers with no flow was conducted by Davis et al.[3] Those works were followed by numerous theoretical and experimental investigations which addressed additional important issues such as uniform flow, temperature gradient, and the behavior of new silencer components that are common in modern applications. Reviews of the major accomplishments in this area have been presented periodically in the form of individual articles in professional journals, chapters in engineering handbooks,[4–7] and, more recently, books by Munjal[8,9] solely devoted to mufflers.

The analytical work on this subject benefited substantially from the early adaptation of the transfer matrix approach to silencer modeling. This method, which was promoted for the description of mechanical systems early on,[10] was used along with electrical analogs to describe the behavior of basic silencer components[11] for plane-wave sound propagation in the absence of flow. Subsequent investigations began addressing the effects of flow on the response of elements consisting of area discontinuities[12,13] and generating transfer matrix models for silencer elements. The predicted performance of various reactive silencers using transfer matrices with convective and dissipative effects in the presence of flow agreed well with measured data.[14]

Concurrently, systematic studies were initiated on the behavior of perforated plates (perforates) to take advantage of their dissipative properties[15–17] for general applications in the transportation industry. Such perforates are used in automotive applications as part of the two- and three-pipe elements featuring one and two perforated pipes, respectively, contained within a larger diameter rigid-wall cylindrical cavity. Such configurations were investigated[18–23] by combining an orifice model with the transfer matrices of the axially segmented perforated tube or tubes and the unpartitioned cavity.

At higher frequencies or for large mufflers, three-dimensional effects become significant. The approaches used in three-dimensional silencer analysis include the finite-element, boundary-element, and acoustical-wave finite-element methods. Each has some inherent advantages at higher frequencies where higher order modes will start propagating, but on the average they are much more complex and time consuming to implement. Therefore, the plane-wave transfer matrix

method is presently the most widely used approach, particularly for synthesis of an initial configuration of a passive silencer.[24–26]

Experimental work conducted in parallel with the analysis validated the developed models and pointed out areas requiring further investigation. Methods for the direct measurement of transfer matrices were developed[27–31] to validate/modify the models of existing silencer elements. Substantial attention was also paid to the source impedance, which was expected to influence the insertion loss of a silencer and the net radiated acoustical power of the system. The source impedance of a six-cylinder engine was measured with an impedance tube using pure tones,[32,33] and the impedance of electroacoustical drivers and multicylinder engines was subsequently measured[34–37] using the much quicker two-microphone methods.[38–40] More recent indirect methods characterized the source impedance through measurements using two, three, or four different acoustical loads.[41–46]

The research performed and the knowledge developed in the field of passive silencers are very extensive and cannot be adequately covered in a single chapter. Accordingly, this chapter reviews the basic background information, summarizes the methodologies for silencer design, demonstrates these approaches through selected examples, and discusses additional topics and references useful to general applications. A reader wishing to acquire more information on internal combustion engine silencers is urged to review references 47–50 for a summary of a general automotive silencer development approach and of typical predicted and measured results, references 51 and 52 for condensed qualitative reviews of the accomplishments in this field, and references 8 and 9 for an extensive bibliography on and a detailed discussion of most silencer-related topics.

9.2 SILENCER PERFORMANCE METRICS

The majority of noise sources have an intake and an exhaust and, generally, they require both intake and exhaust silencers. The two cases are characterized by different flow direction, back pressure, average gas temperature, and average sound pressure levels, but the corresponding hardware is developed using the same principles and design methods. The following discussion is tailored to exhaust silencers but it is equally applicable to intake silencers.

Silencer Selection Factors

The use of a silencer is prompted by the need to reduce the radiated noise of a source but, in most applications, the final selection is based on trade-offs between the predicted acoustical performance, mechanical performance, volume/weight, and cost of the resulting system.

During development, the acoustical performance (insertion loss) of a candidate silencer is determined from the free-field sound pressure levels measured at the same relative locations with respect to the noise outlet of the unsilenced and silenced sources. If the noise outlet is inserted into a reverberant space, then the difference can be measured anywhere within the reverberant field, and the difference sound pressure level represents the power-based insertion loss.

The impact of the silencer on the mechanical performance of the source is determined from the change in the silencer back pressure. For a continuous-flow source, such as a fan or a gas turbine, the impact is determined from the increase in the average back pressure; by contrast, for an intermittent-flow source, such as a reciprocating engine, the impact is a function of the increase in the exhaust manifold pressure when an exhaust valve is open.

Most silencers are subject to volume/weight constraints, which also influence the silencer design process. In addition, the initial purchase/installation cost and the periodic maintenance cost are other important factors that influence the silencer selection process.

Since noise is the root cause of silencer design, the remainder of this chapter focuses on the prediction of a silencer's acoustical performance and also on the estimation of back pressure. The additional performance criteria associated with hardware volume, weight, and cost are trade-off parameters to be determined separately for each application.

Factors Influencing Acoustical Performance

Reactive and Dissipative Silencers. The net change ΔW in the acoustical power radiated from a source can be expressed as

$$\Delta W = W_1 - W_2 = W_1 - (W_1' - W_d) = (W_1 - W_1') + W_d \quad \text{N} \cdot \text{m/s} \qquad (9.1)$$

where W_1 and W_2 correspond to the unsilenced and silenced sources (Fig. 9.1), $W_1 - W_1'$ is the net change in the acoustical power output of the source resulting from changes in the silencer's reflection coefficient, and W_d is attributable to the dissipative properties of the silencer.

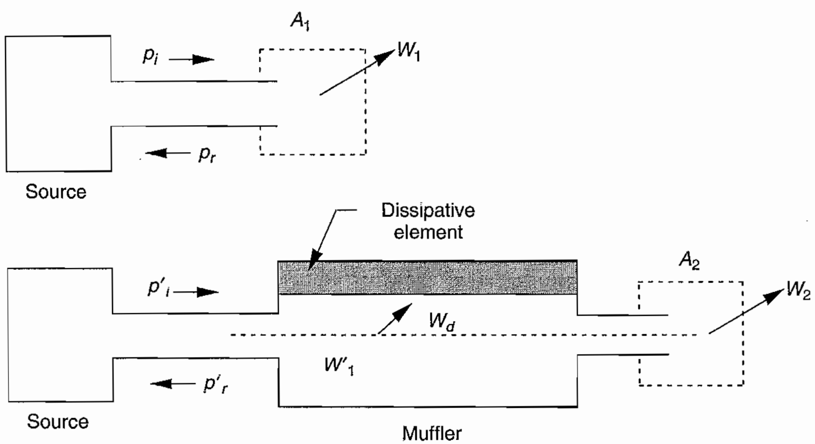

FIGURE 9.1 Radiated noise reduction mechanisms of a silencer.

The reflection coefficient is manipulated primarily by introducing cross-sectional discontinuities in the piping system, and the dissipated part W_d depends largely on the dissipative properties of the silencer elements. In practice, all silencer elements reflect and dissipate acoustical energy to some extent. However, traditionally, they have been categorized into reactive and dissipative silencers when their insertion loss is dominated by reflective and dissipative mechanisms, respectively. This convention has also been adopted in this chapter, but the reader should be aware that most common applications involve various degrees of overlap between the two extremes.

Flanking Paths and Secondary Source Mechanisms. The acoustical power radiated from a silenced source, such as an engine, includes airborne noise (W_{EX}) from the exhaust pipe outlet, silencer shell noise (W_{SH}) radiated from the vibrating walls of the silencer and exhaust line pipes, and a contribution (W_{AD}) from additional sources, such as source shell and source intake, located upstream of the silencer.

The shell noise results from the excitation of silencer components by the vibrating engine, by the intense internal acoustical pressure fields, and by aerodynamic forces. These contributions can be reduced substantially through various methods, but they cannot be totally eliminated and, eventually, they set the limit for the achievable insertion loss for high-performance silencers.

The acoustical power contributions W_{SH} and W_{AD} are excluded from further consideration in the remainder of the chapter; that is, the discussion is focused on the impact of silencers on the airborne noise contributions W_{EX}. However, one should be aware of their existence and significance, particularly in experimental applications where limited resources may lead to the measurement of W_{EX} in the presence of W_{SH} and W_{AD}.

Silencer System Modeling

Silencer Component Representation. The basic components of a typical silencer system comprise the noise source, silencer, connecting pipes, and surrounding medium (Fig. 9.2*a*). The pipe connecting the source to the silencer is treated as part of the source. Figure 9.2*b* shows the corresponding electrical analog of the acoustical system, which is widely used to facilitate the representation and handling of acoustical transmission lines. This analog model, which uses acoustical pressure p and mass velocity $\rho_0 S u$ in kg/s, instead of voltage and current, represents the noise source with a source pressure p_s and an internal impedance Z_s, the silencer and pipe segment with four-pole elements (T_{ij} and D_{ij}), and the surrounding medium with a termination (or radiation load) impedance Z_T. Analytical expressions for the transfer matrices of pipes and selected silencer elements are presented in references 8 and 9. Some of them are given later in Section 9.3.

Let p_i, u_i, $i = 1, 2, 3$, designate the acoustical pressure and particle velocity at the interfaces of acoustical components of the source–silencer–load system illustrated in Fig. 9.2*b*. These quantities may be obtained by solving the system

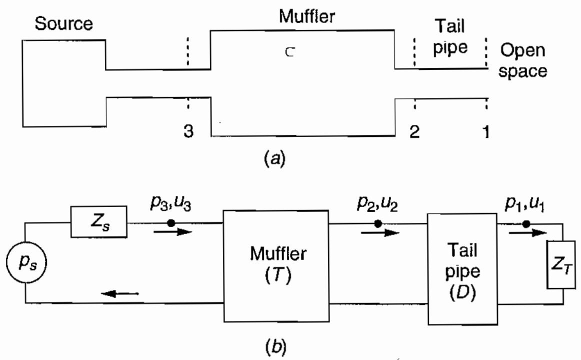

FIGURE 9.2 (*a*) Acoustical and (*b*) electrical analog components of a silencer.

of equations describing the response of the components depicted in Fig. 9.2*b*, namely,

$$p_s = p_3 + \rho_0 Z_s S_3 u_3 \tag{9.2}$$

$$\begin{bmatrix} p_3 \\ \rho_0 S_3 u_3 \end{bmatrix} = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \begin{bmatrix} p_2 \\ \rho_0 S_2 u_2 \end{bmatrix} \tag{9.3}$$

$$\begin{bmatrix} p_2 \\ \rho_0 S_2 u_2 \end{bmatrix} = \begin{bmatrix} D_{11} & D_{12} \\ D_{21} & D_{22} \end{bmatrix} \begin{bmatrix} p_1 \\ \rho_0 S_1 u_1 \end{bmatrix} \tag{9.4}$$

$$p_1 = Z_T \rho_0 S_1 u_1 \tag{9.5}$$

where ρ_0 is the mean gas density and S_i is the duct cross-sectional area at the ith location. The calculated quantities p_i, $\rho_0 S_i u_i$, $i = 1, 2, \ldots$, can then be combined with the selected performance criterion to determine the effectiveness of the silencer.

Acoustical Performance Criteria. The most frequently used performance criteria are the insertion loss (IL), noise reduction (NR), and transmission loss (TL). All three use a sound-pressure-level difference as a performance indicator; therefore, they require no explicit knowledge of the source strength p_s, of Eq. (9.2). The number of required system parameters (source impedance Z_s, transfer matrix elements D_{ij}, and termination impedance Z_T*) other than the silencer matrix T_{ij} can be further reduced by the specific choice of the performance criterion.

The IL is defined as the change in the radiated sound pressure level resulting from the insertion of the muffler, that is, the replacement of a pipe segment of length l_1 (Fig. 9.3*a*) located downstream from the source by the silencer and a new tail-pipe segment of length l_2 (Fig. 9.3*b*). Insertion loss is expressed as

$$\mathrm{IL} = L_b - L_a = 20 \log \left| \frac{p_b}{p_a} \right| \tag{9.6}$$

*The impedance Z in this chapter is defined as $p_i/(\rho_0 S_i u_i)$.

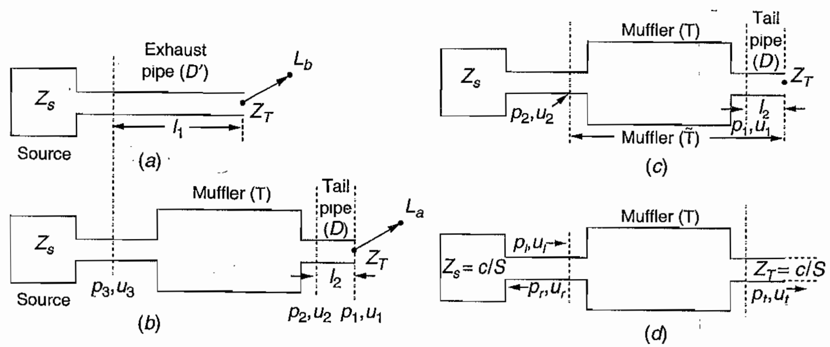

FIGURE 9.3 Quantities use for the determination of (*a,b*) insertion loss, (*c*) noise reduction, and (*d*) transmission loss.

where p_b, p_a and L_b, L_a are the measured sound pressures and sound pressure levels at the same relative location (distance and orientation) with respect to the exhaust outlet (Fig. 9.3*a*) before and after the installation of the muffler and "log" refers to a logarithm with respect to the base 10. Mathematically,

$$\mathrm{IL} = 20 \log \left| \frac{\tilde{T}_{11} Z_T + \tilde{T}_{12} + \tilde{T}_{21} Z_s Z_T + \tilde{T}_{22} Z_s}{D_{11} Z_T + D_{12} + D_{21} Z_s Z_T + D_{22} Z_s} \right| \tag{9.7}$$

where $\tilde{T}_{ij}$ is the combined transfer matrix element of the silencer and its tail pipe ($\tilde{T} = TD$), and D'_{ij} is the transfer matrix element of the replaced exhaust pipe segment. If the silencer is simply added to the end of the source ($l_1 = l_2 = 0$ in Figs. 9.3*a* and *b*), then both D' and D are identity matrices (see Transfer Matrices for Reactive Elements in Section 9.3) and Eq. (9.7) is reduced to

$$\mathrm{IL}(l_1 = l_2 = 0) = 20 \log \left| \frac{T_{11} Z_r + T_{12} + T_{21} Z_r Z_s + T_{22} Z_s}{Z_T + Z_s} \right| \tag{9.8}$$

The noise reduction is given by

$$\mathrm{NR} = L_2 - L_1 = 20 \log \left| \frac{p_2}{p_1} \right| \tag{9.9}$$

that is, it is the difference between the sound pressure levels measured at two points 1 and 2 (Fig. 9.3*c*) of the silenced system located upstream and downstream of the silencer, respectively. If D_{ij} and $\tilde{T}_{ij}$ represent the transfer matrix elements for the silencer portions downstream of points 1 and 2, respectively, the noise reduction is given by

$$\mathrm{NR} = 20 \log \left| \frac{\tilde{T}_{11} Z_T + \tilde{T}_{12}}{D_{11} Z_T + D_{12}} \right| \tag{9.10}$$

The TL is the acoustical power-level difference between the incident and transmitted waves of an anechoically terminated silencer (see Fig. 9.3d). In terms of the corresponding transfer matrix, the transmission loss is given by

$$\mathrm{TL} = 20\ \log\left|\frac{T_{11} + (S/c)T_{12} + (c/S)T_{21} + T_{22}}{2}\right| \tag{9.11}$$

where c is the speed of sound at design temperature and S is the cross-sectional area of the reference pipe.

This expression assumes that (a) the area of cross section of the exhaust pipe upstream of the silencer is the same as that of the tailpipe, that is, S; (b) the silencer is simply added at the end of the source ($l_1 = l_2 = 0$); and (c) the tail pipe end (or radiation end) is anechoic ($Z_T = c/S$).

The IL is the most appropriate indicator of a silencer's performance because it is the level difference of the acoustical power radiated from the unsilenced and silenced systems. It is easy to quantify from pre- and postsilencing data, but it is hard to predict because it depends on Z_s and Z_T, which vary from one application to another. By contrast, the TL is easy to predict but is only an approximation of the silencer's actual performance because it does not account for the source impedance and it models all silencer outlets with anechoic terminations. Equations (9.7) and (9.11) show that the TL and IL of a silencer become identical when the noise source and silencer termination are anechoic, that is, $Z_s = Z_T = c/S$. Similarly, it can readily be shown[8] that for a constant-pressure source ($Z_s = 0$), the NR and IL become identical, provided the cross-sectional area of the exhaust pipe upstream of the silencer is the same as that of the tailpipe.

The ultimate selection of an evaluation criterion is based on trade-offs between the desired accuracy in the predictions and the amount of available resources. For example, Z_s, required for IL predictions, can be determined experimentally through various methods,[32–46] but the procedure is too costly for the majority of applications. As a result, the silencer design is, generally, based on predicted TL, with a clear understanding of the associated approximations, while the final evaluation of the hardware during field tests is based on the measured IL.

9.3 REACTIVE SILENCER COMPONENTS AND MODELS

Reactive silencers consist typically of several pipe segments that interconnect a number of larger diameter chambers. These silencers reduce the radiated acoustical power primarily through impedance mismatch, that is, through the use of acoustical impedance discontinuities to reflect sound back toward the source. In essence, the more pronounced the discontinuities, the higher the amount of reflected power. Acoustical impedance discontinuities are commonly achieved through (a) sudden cross-sectional changes (i.e., expansions or contractions), (b) wall property changes (i.e., transition from a rigid-wall pipe to an equal-diameter absorbing wall pipe), or (c) any combination thereof.

Silencer Representation by Basic Silencer Elements

Every silencer can be divided into a number of segments or elements each represented by a transfer matrix. The transfer matrices can then be combined to obtain the system matrix, which may then be substituted into Eqs. (9.7), (9.10), or (9.11) to predict the corresponding acoustical performance for the silencer system.

The procedure is illustrated by considering the silencer of Fig. 9.4, which is divided into the basic elements, labeled 1–9, indicated by the dashed lines. Elements 1, 3, 5, 7, and 9 are simple pipes of constant cross section. Element 2 is a simple area expansion, element 4 is an area contraction with an extended outlet pipe, element 6 is an area expansion with an extended inlet pipe, and element 8 is a simple area contraction. The nine elements are characterized by the transfer matrices $T^{(1)}$ through $T^{(9)}$; therefore, the system matrix $T^{(S)}$ for the entire silencer is obtained from

$$T^{(S)} = T^{(1)} \cdot T^{(2)} \cdot \cdots \cdot T^{(9)} \tag{9.12}$$

through matrix multiplication. The matrices for each of the above elements may be derived from the formulas presented later in this section.

A few of the most common reactive muffler elements are discussed in this section and some are used in illustrative design examples. Additional elements that were the subject of previous investigations include gradually varying area ducts (such as horns), uniform-area compliant-wall ducts (such as hoses), Quincke tubes, inline cavities, inline bellows, catalytic converter elements, branch sub systems, side inlets/outlets, cavity-backed resistive-wall elements, and perforated-duct elements with and without mean flow through the perforations. Transfer matrices for each of these elements have been derived over the last three decades by different researchers,[53–70] and explicit expressions for their four-pole parameters are given in detail in references 8 and 9.

The variety of silencer elements and the multitude of elements per silencer result in numerous silencer configurations; therefore, a comprehensive study of all possible silencer applications is beyond the scope of this work. For this

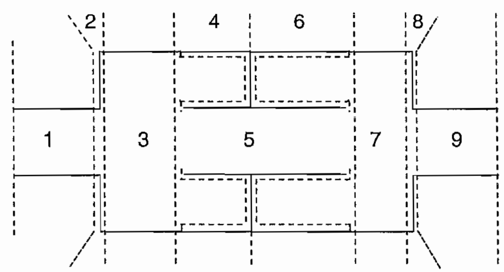

FIGURE 9.4 Decomposition of a silencer into basic elements.

reason, the remainder of this chapter uses selected silencer configurations to demonstrate

(a) the typical process for modeling a basic silencer element with a (four-pole parameter) transmission matrix,
(b) the process for predicting the acoustical performance of a given silencer configuration from the properties (transmission matrices) of its constituent elements, and
(c) the process for selecting a silencer design to achieve approximately a specified acoustical performance.

Furthermore, Section 9.5 provides additional information and sketches for perforated-tube elements and analyzes the performance of selected perforated-tube muffler configurations. The reader could also apply the demonstrated design process to any other silencer configurations by obtaining and utilizing the relevant transmission matrix information from the corresponding references 8, 9, 53–69.

Transfer Matrices for Reactive Elements

The transfer matrix of a silencer element is a function of the element geometry, state variables of the medium, mean flow velocity, and properties of duct liners, if any. The results presented below correspond to the linear sound propagation of a plane wave in the presence of superimposed flow. In certain cases, the matrix may also be influenced by nonlinear effects, higher order modes, and temperature gradients; these latter effects, which can be included in special cases, are discussed qualitatively later in this section, but they are excluded from the analytical procedure described below. The following is a list of variables and parameters that appear in most transfer matrix relations of reactive elements:

p_i = acoustical pressure at ith location of element
u_i = particle velocity at ith location of element
ρ_0 = mean density of gas, kg/m^3
c = sound speed m/s, $= 331\sqrt{\theta/273}$
θ = absolute temperature, K = °C + 273
S_i = cross section of element at ith location, m^2
$Y_i = c/S_i$
A, B = amplitudes of right- and left-bound fields
$k_c = k_0/(1 - M^2)$ assuming negligible frictional energy loss along straight pipe segments
$k_0 = \omega/c = 2\pi f/c$
$\omega = 2\pi f$
f = frequency, Hz
$M = V/c$
V = mean flow velocity through S
T_{ij} = (ij)th element of transmission matrix or transfer matrix

Symbols without subscripts, such as V, c, and M, describe quantities associated with the reference duct.

Pipe with Uniform Cross Section. The acoustical pressure and mass velocity fields p, $\rho_0 Su$ in a pipe with uniform cross section S and a mean flow V_0 are given by

$$p(x) = (Ae^{-jk_c x} + Be^{jk_c x})e^{j(Mk_c x+\omega t)} \tag{9.13a}$$

$$\rho_0 Su(x) = (Ae^{-jk_c x} - Be^{jk_c x})\frac{e^{j(Mk_c x+\omega t)}}{Y} \tag{9.13b}$$

where S is the cross section of the pipe. Equations (9.13a) and (9.13b) can be evaluated at $x = 0$ and $x = l$ to obtain the corresponding fields p_2, $\rho_0 Su_2$ and p_1, $\rho_0 Su_1$, respectively. Upon elimination of the constants A and B, one obtains[8,13]

$$\begin{bmatrix} p_2 \\ \rho_0 Su_2 \end{bmatrix} = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \begin{bmatrix} p_1 \\ \rho_0 Su_1 \end{bmatrix} \tag{9.14}$$

where the transmission matrix T_{pipe} is given by

$$T_{\text{pipe}} = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix}_{\text{pipe}} = e^{-jMk_c l} \begin{bmatrix} \cos k_c l & jY_0 \sin k_c l \\ \frac{j}{Y} \sin k_c l & \cos k_c l \end{bmatrix} \tag{9.15}$$

In the transfer matrix of Eq. (9.15) the acoustical energy dissipation that may result from friction between the gas and the rigid wall as well as from turbulence is neglected. These effects, which would result in a slightly different matrix,[8] may be noticeable in very long exhaust systems but they are negligible for most silencer applications.

Cross-Sectional Discontinuities. The transition elements used to model most cross-sectional discontinuities are shown in Figs. 9.5*b,c,e,f* and in the first column of Table 9.1. Using decreasing element-subscript values with distance from the noise source, the cross-sectional areas upstream, at, and downstream of the transition (S_3, S_2, and S_1) are related through[8]

$$C_1 S_1 + C_2 S_2 + S_3 = 0 \tag{9.16}$$

where the constants C_1 and C_2 (Table 9.1) are selected so as to satisfy the compatibility of the cross-sectional areas across the transition.

For each configuration, Table 9.1 also shows the pressure loss coefficient K, which accounts for the conversion of some mean-flow energy and acoustical field energy into heat at the discontinuities. As indicated, $K \le 0.5$ for area contractions, while $K \to (S_1/S_3)^2$ for area expansions at large values of S_1/S_3.

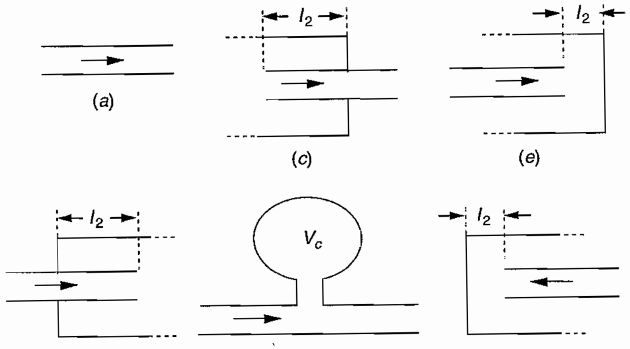

FIGURE 9.5 Basic silencer element: (*a*) plain pipe; (*b,c*) extended tube inlet/outlet; (*d*) resonator; (*e,f*) reversal expansion/contraction.

TABLE 9.1 Parameter Values of Transition Elements

Element Type	C_1	C_2	K
	-1	-1	$\dfrac{1-S_1/S_3}{2}$
	-1	1	$\left(\dfrac{S_1}{S_3}-1\right)^2$
	1	-1	$\left(\dfrac{S_1}{S_3}\right)^2$
	1	-1	0.5

Transfer matrices for cross-sectional discontinuities (csd) in the presence of mean flow that include terms proportional up to the fourth power (M^4) of the Mach number are presented in reference 8. However, in most silencer design applications, $M \ll 1$; therefore, terms of the form $1+M^n, n \geq 2$, are set to unity. This simplification reduces the matrix T_{csd}, which relates the upstream and

downstream acoustical fields p_3, $\rho S u_3$ and p_1, $\rho S u_1$ through

$$\begin{bmatrix} p_3 \\ \rho_0 S_3 u_3 \end{bmatrix}_{\text{upstream}} = T_{\text{csd}} \begin{bmatrix} p_1 \\ \rho_0 S_1 u_1 \end{bmatrix}_{\text{downstream}} \tag{9.17}$$

to

$$[T_{\text{csd}}] = \begin{bmatrix} 1 & \dfrac{kM_1Y_1}{C_2S_2Z_2 - M_1Y_1(C_1S_1+S_3K)} \\ \dfrac{C_2S_2}{C_1S_2Z_2+S_2M_3Y_3} & \dfrac{C_2S_2Z_2+S_3M_3Y_3}{} \end{bmatrix} \tag{9.18}$$

where $Z_2 = -j(c/S_2)\cot k_0 l_2$

l_2 = length of extended inlet/outlet pipe, m (9.19)

Letting length l_2 tend to zero (as in the case of sudden expansion and contraction shown in Fig. 9.5) yields the transfer matrix

$$\begin{bmatrix} 1 & KM_1Y_1 \\ 0 & 1 \end{bmatrix} \tag{9.20}$$

Resonators. A resonator is a cavity-backed opening in the sidewall of a pipe Fig. (9.5*d*). The opening may consist of a single hole on the pipe wall (Fig. 9.6*a*) or a closely distributed group of holes (Fig. 9.6*b*). The volume behind this opening can comprise a throat of length l_t and cross section S_n terminated by a straight pipe of cross-sectional area S_c and depth l_c (Fig. 9.6*c*), a concentric cylinder extending a length l_u and l_d upstream and downstream of the opening (Fig. 9.6*d*), an odd-shaped chamber of total volume V_c (Fig. 9.6*e*), or an extended-tube (quarter-wave) resonator of length l_2 (Figs. 9.5*b,c,e,f*).

The resonator opening in the wall of the main duct is assumed to be well localized; that is, the axial dimension of the perforated section is much smaller than the wavelength and typically smaller than a duct diameter. This requirement ensures that the duct–cavity interaction is in phase over the entire surface of the connecting opening. Transmission matrices for multihole openings with substantial axial dimensions requiring modeling by perforated-tube elements may be found in references 8 and 9.

The transfer matrix for a resonator for a stationary medium is given by[9]

$$T_r = \begin{bmatrix} 1 & 0 \\ \dfrac{1}{Z_r} & 1 \end{bmatrix} \tag{9.21}$$

where $Z_r = Z_t + Z_c$, Z_t is the impedance of the throat connecting the pipe to the cavity, and Z_c is the impedance of the cavity. Here, Z_c is independent of the flow in the main duct and is given by one of the following expressions:

$$Z_c = \begin{cases} Z_{tt} = -j\dfrac{c}{S_c}\cot k_0 l_c \\ Z_{cc} = -j\dfrac{c}{S_c}\dfrac{1}{\tan k_0 l_u + \tan k_0 l_d} & (\text{m} \cdot \text{s})^{-1} \\ z_{gv} = -j\dfrac{c}{k_0 V_c} \end{cases} \tag{9.22}$$

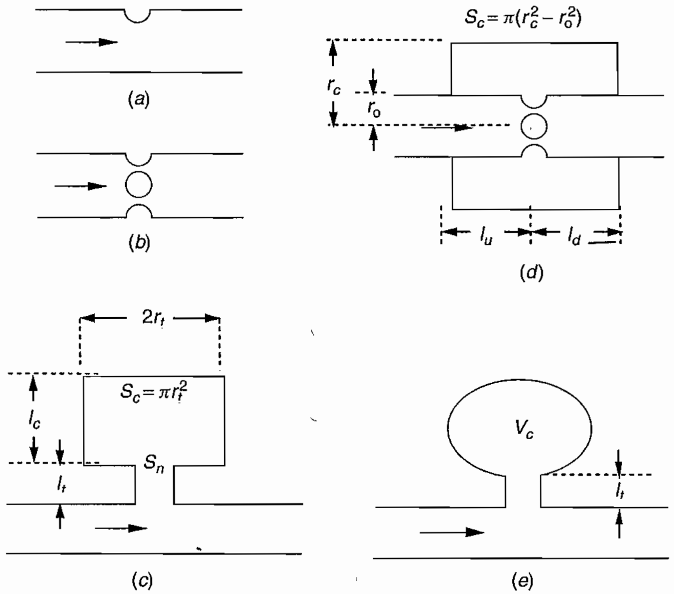

FIGURE 9.6 Resonator components and configurations.

where the subscripts tt, cc, and gv refer to the transverse-tube (quarter-wave resonator), concentric-cylinder, and general-volume cavities. These quantities and the lengths l_u, l_d, and l_c, the cross section S_c, and the volume V_c are illustrated in Fig. 9.6. It should be noted that at low frequencies ($k_0 l_c \ll 1$ and $k_0 l_u$, $k_0 l_d \ll 1$) both Z_{tt} and Z_{cc} are reduced to the expression of Z_{gv}.

The impedance Z_t of the throat connecting the duct to the cavity changes dramatically with grazing flow; therefore, it is characterized by two sets of values. For $M = 0$, this quantity is given by

$$Z_t^{[M=0]} = \frac{1}{n_h}\left(\frac{ck_0^2}{\pi} + j\frac{ck_0(l_t + 1.7r_0)}{S_0}\right) \quad (\mathrm{m \cdot s})^{-1}, \qquad (9.23)$$

where l_t is the length of the connecting throat, r_o the orifice radius, S_o the area of a single orifice, and n_h the total number of perforated holes. In the absence of mean flow, this expression has yielded good agreement between predicted and measured results for single-hole and well-localized multihole resonators.

The presence of grazing flow ($M \neq 0$ in the duct) has a strong effect on the impedance Z_t of the resonator throat. Measurements conducted using single- and multihole throats[15,57] have led to the empirical expression

$$Z_t^{[M\neq 0]} = \frac{c}{\sigma S_0}[7.3 \times 10^{-3}(1 + 72M) + j2.2$$
$$\times 10^{-5}(1 + 51l_t)(1 + 408r_0)f] \quad (\mathrm{m \cdot s})^{-1} \qquad (9.24)$$

where the parameters l_t and r_o in Eq. (9.23) are in meters and σ is the porosity. The expression of Eq. (9.24) is more appropriate for predictions in the presence of grazing flow.

Transmission Matrices for Other Elements. The mass and momentum conservation laws used to derive the transmission matrices for a pipe segment, area discontinuities, and resonators can be similarly deployed to obtain similar expressions for other elements. The reader may find additional information on transmission matrices in references 8, 9, and 53–69.

9.4 PERFORMANCE PREDICTION AND DESIGN EXAMPLES FOR EXPANSION CHAMBER MUFFLERS

Simple Expansion Chamber Muffler (SECM)

This silencer consists of an exhaust pipe, an expansion chamber, and a tail pipe of different transverse dimensions as shown in Fig. 9.7. The TL for this simple configuration may be obtained by substituting into Eq. (9.11) the transmission matrices for these elements obtained from Eqs. (9.15) and (9.18).

In a simplified case, where the flow is or is assumed to be insignificant, the product of the three matrices is reduced to the expression

$$\mathrm{TL} = 10 \log \left[1 + 0.25\left(N - \frac{1}{N}\right)^2 \sin^2 kL\right] \quad \mathrm{dB} \qquad (9.25)$$

where k is the wavenumber, L is the chamber length, and N is the area ratio given by $N = S_2/S_1$, where S_2 is the area of cross section of the chamber and S_1 that of the tail pipe or exhaust pipe (assumed to be equal).

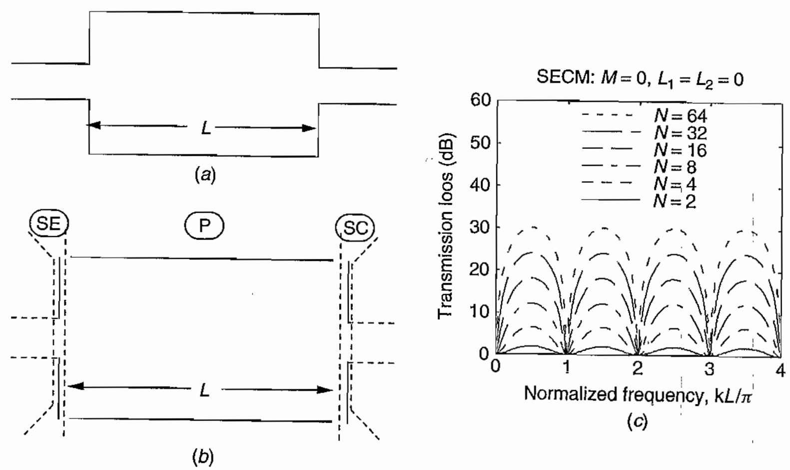

FIGURE 9.7 Simple expansion chamber muffler: (*a*) typical cross section; (*b*) muffler elements; (*c*) predicted transmission loss for different area ratios.

The predicted TL is presented in Fig. 9.7*c* for a few values of the area ratio N and displayed versus the dimensionless quantity $q = kL/\pi$. The troughs of the TL curve occur at $kL/\pi = n$, while the peaks occur at $kL/\pi = (2n-1)/2$, where $k = \omega/c$ is the wave number and n is an integer.

Example 9.1. The predicted curves of Fig. 9.7*c* can be used to develop a starting design of a SECM with a given performance goal. For example, assume that we need a 10-dB reduction for a 180-Hz tone generated by the exhaust of a small engine venting through a pipe with a diameter $d = 2$ in. (5.1 cm) at a temperature of 50°C and at a negligible flow speed.

The typical design process aligns the 180-Hz tone with one of the predicted acoustical performance peaks. Generally, alignment with a peak on a low-area-ratio (S_2/S_1) curve will minimize the muffler diameter and alignment with a peak at a low value of kL/π will minimize the length of the resulting muffler. In the present example, the design may proceed along the following steps:

- Step 1: The 180-Hz tone is aligned with the predicted 12-dB peak of the $S_2/S_1 = 8$ curve at $kL/\pi = 0.5$ (Fig. 9.7*c*).
- Step 2: At 50°C (323 K), the sound speed $c = 331$ radical $\sqrt{323/273} =$ 360 m/s.
- Step 3: The corresponding wavenumber $k = 2\pi f/c = 2\pi \times 180/360 =$ 3.14 rad/m.
- Step 4: The required muffler length L (given by $kL/\pi = 0.5) = 0.5\pi/k =$ $0.5\pi/3.14 = 0.5$.
- Step 5: The required muffler diameter $D = d\sqrt{S_2/S_1} = 5.1\sqrt{8} = 14.4$ cm.

One important implication of antilog addition and subtraction is that raising the trough levels of the IL (or, for that matter, the TL) by an amount DL has a more favorable impact than raising the peaks by the same amount DL. Therefore, it is desirable to try to raise the troughs (particularly, the first few at the lower end frequency range) through design adjustments, even at the expense of some reduction in the peaks of the revised muffler configuration.

A major disadvantage of the simple expansion chamber silencer is that in certain applications time-varying tones and their harmonics may align simultaneously with the periodic troughs and cause a severe deterioration in acoustical performance. This problem may be resolved to varying degrees by using extended-tube (inlet and/or outlet) elements.

Extended-Outlet Mufflers

An extended-outlet muffler (Fig. 9.8*a*) represents the first incremental step toward improving the performance of a single-chamber muffler. This configuration is decomposed into the three basic elements illustrated in Fig. 9.8*b*:

- a sudden expansion element (SE) at the inlet, flush with the left wall of the chamber;

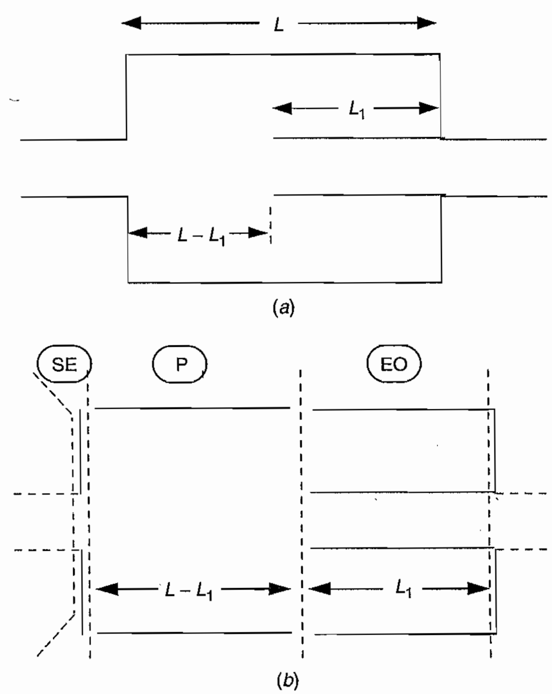

FIGURE 9.8 Extended-outlet expansion chamber: (*a*) typical configuration; (*b*) constituent muffler elements.

- a pipe element (P); and
- an extended-outlet element (EO) at the right end of the chamber.

The extended-outlet muffler design introduces a new length, L_1, which increases by 1 the number of dimensionless parameters (L/d, S_2/S_1, and L_1/L) that can be used to optimize the muffler's TL.

Transmission matrices for the silencer elements shown in Fig. 9.8*b* are obtained from Eq. (9.15) (for the pipe element P), Eq. (9.18) (extended-outlet element EO), and Eq. (9.20) (sudden expansion element SE).

It should be noted that at certain frequencies the impedance Z_2, introduced by the transmission matrix of Eq. (9.19) for the extended-outlet element, would approach zero, and the branch element would generate a pressure release condition. Under these conditions, the incident wave would appear to interact with a closed-end cavity, and no acoustical power would be transmitted downstream. For rigid end plates, this condition would occur when $\cot(kL_1) = 0$, corresponding to $kL_1/\pi = (2n-1)/2$. Accordingly, a dominant peak in the source spectrum can be reduced significantly by proper selection of the tube length extended into the chamber.

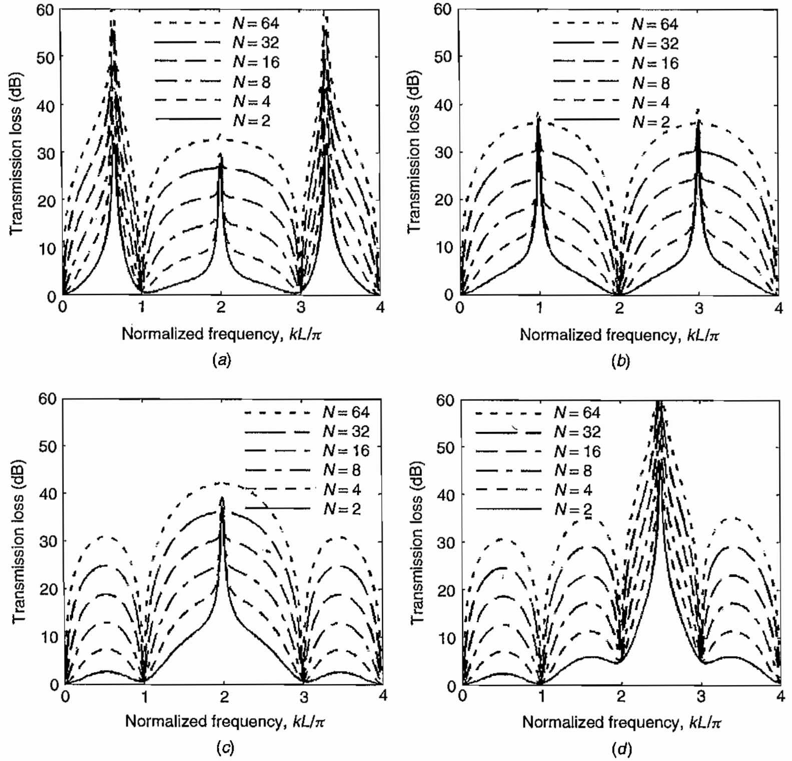

FIGURE 9.9 Transmission loss of extended-outlet muffler for different outlet pipe lengths: $M = 0$; L_1/L equals (*a*) 0.75, (*b*) 0.5, (*c*) 0.25, and (*d*) 0.2.

Figures 9.9*a*–9.9*d* illustrate the variation of the TL for an extended-outlet expansion chamber for four values of the dimensionless parameter L_1/L. As expected, the maximum peak of TL shifts toward higher frequencies as L_1/L decreases. Furthermore, a suitable choice of L_1/L, resulting in $kL_1/\pi = (2n-1)/2$, n being an integer, relocates some performance peaks so as to eliminate some of the troughs that would otherwise occur at $kL = n\pi$ (Fig. 9.7*c*) for the simple expansion chamber muffler. This behavior is exploited in the following two design examples.

Example 9.2. Consider the application requiring a 15-dB reduction of a steady 120-Hz tone generated by the exhaust of a small engine venting through a pipe with a diameter $d = 1.5$ in. (3.8 cm) at a temperature of 100°C and at a negligible flow speed.

Since the tone is steady, that is, its does not vary appreciably versus time, we can consider aligning it with one of the sharp peaks in the predicted TL. This

suggests selection of the Fig. 9.9*a* configuration, characterized by $L_1/L = 0.75$, which has a family of relatively sharp peaks at $kL/\pi = 0.75$.

In the present example, the design may proceed along the following steps:

- Step 1: The 120-Hz tone is aligned with the predicted >12-dB peak of the $S_2/S_1 = 8$ curve at $kL/\pi = 0.75$ (Fig. 9.9*a*).
- Step 2: At 100°C (373 K), the sound speed $c = 331\sqrt{373/273} = 387$ m/s.
- Step 3: The corresponding wavenumber $k = 2\pi f/c = 2\pi \times 120/387 = 1.95$ rad/m.
- Step 4: The required muffler length (given by $kL/\pi = 0.75$) $L = 0.75\pi/1.95 = 1.2$ m.
- Step 5: The required muffler diameter $D = d\sqrt{S_2/S_1} = 3.8\sqrt{8} = 10.8$ cm.

Example 9.3. Consider the application requiring a 10-dB reduction of a time-varying 150-Hz tone generated by the exhaust of a small engine venting through a pipe with diameter $d = 2.5$ in. (6.3 cm) at a temperature of 80°C and at a negligible flow speed. Furthermore, assume that the a variable load in the engine causes its frequency to vary ±15%, that is, operating anywhere in the $127 < f < 172$-Hz range.

Since the frequency of the tone is unsteady, we can consider aligning it with one of the "broad" peaks in the predicted TL. This suggests selection of the Fig. 9.9*b* configuration, characterized by $L_1/L = 0.5$, which has a family of relatively "broad hill peaks" around the spikes occurring at $kL/\pi = 1$.

All curves with $S_2/S_1 \geq 4$ appear to have TL > 10 dB within 15% of $kL/\pi = 1$. For a conservative result, we select the curve with $S_2/S_1 = 8$ and complete the muffler design using the following steps:

- Step 1: The 150-Hz tone is aligned with the predicted >10-dB peak of the $S_2/S_1 = 8$ curve at $kL/\pi = 1$ (Fig. 9.9b).
- Step 2: At 80°C (353 K), the sound speed $c = 331\sqrt{353/273} = 376$ m/s.
- Step 3: The corresponding wavenumber $k = 2\pi f/c = 2\pi \times 150/376 = 2.5$ rad/m.
- Step 4: The required muffler length (given by $kL/\pi = 1$) $L = 1.0\pi/2.5 = 1.25$ m.
- Step 5: The required muffler diameter $D = d\sqrt{S_2/S_1} = 6.3\sqrt{8} = 18$ cm.

The TL for extended-inlet silencers can be derived in a similar manner. For negligible values of flow, their acoustical performance is similar to that of the extended-outlet silencers; in other words, for negligible inflow, either side of the muffler can be used as the inlet with no appreciable change in the TL.

Double-Tuned Expansion Chamber (DTEC)

The "filling up" of the troughs achieved through the extended-outlet muffler can be further enhanced through the simultaneous deployment of an extended-inlet pipe of length L_2 (double tuning). An extended inlet introduces an additional parameter, L_2/L, which used in conjunction with the extended-outlet parameter L_1/L can fill up additional troughs and further improve the achievable TL over a broader frequency range. For optimum results, L_1 and L_2 are selected so as to neutralize different sets of troughs to the extent possible.

The new double-tuned expansion chamber (DTEC) silencer design (Fig. 9.10*a*) is decomposed into three basic elements (Fig. 9.10*b*):

- an extended-inlet element (EI) at the left end of the chamber,
- a pipe element (P), and
- an extended-outlet element (EO) at the right end of the chamber

Thus, the introduction of the new length, L_2, for the extended inlet enhances the optimization of the DTEC's transmission loss through an increased number of dimensionless parameters, which now include d/L, S_2/S_1, L_1/L, and L_2/L.

Transmission matrices for the Fig. 9.10*b* silencer elements are obtained from Eq. (9.15) (for the pipe element P) and from Eq. (9.18) (extended-inlet and extended-outlet elements EI and EO).

Of the infinite number of $(L_2/L,\ L_1/L)$ combinations, a selection of $L_1 = L/2$ and $L_2 = L/4$ leads to a particularly favorable TL. Specifically, since the extended-inlet element includes a term proportional to $\cot(kL_2)$ [see Eqs. 9.18 and 9.19], it produces stop bands at $kL_2 = (2n-1)\pi/2$ or, equivalently, at $kL = 2(2n-1)\pi$, filling up the troughs at $kL/\pi = 2, 6, 10, \ldots$. Similarly, since the EO element includes a term proportional to $\cot(kL_1)$, it produces stop bands at

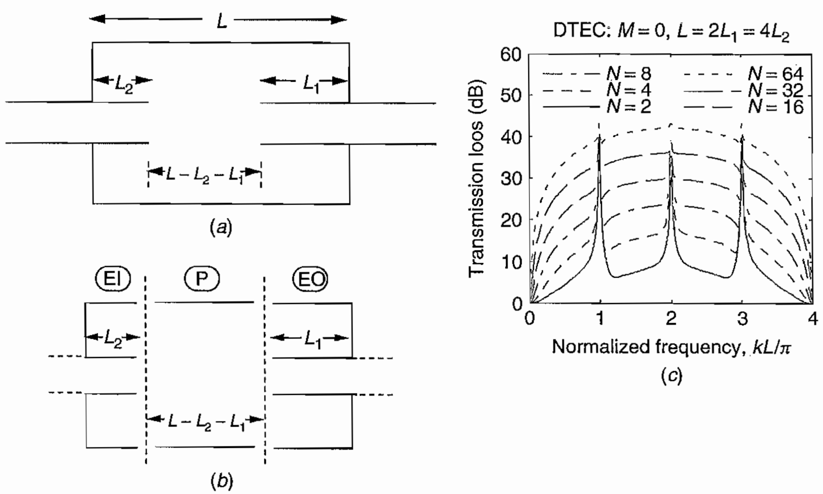

FIGURE 9.10 Double-tuned expansion chamber: (*a*) typical configuration; (*b*) constituent elements; (*c*) predicted TL for $L_2 = L/4$, $L_1 = L/2$.

$kL_1 = (2n-1)\pi/2$ or, equivalently, at $kL = (2n-1)\pi$, filling up the troughs at $kL/\pi = 1, 3, 5, \ldots$. In other words, this design features troughs only at $kL/\pi = 0, 4, 8, 12, \ldots$.

The corresponding predicted TL for a few area ratio values is shown in Fig. 9.10*c*. Its most prominent feature is the lack of troughs at locations other than at $kL/\pi = 4n$, n being an integer. Accordingly, this design offers a better solution for broadband performance than any of the previous configurations. High reduction limited to a narrow band (like Fig. 9.9*a*) can be achieved by adjusting the inlet/outlet lengths away from their $(L_1/L, L_2/L) = (\frac{1}{2}, \frac{1}{4})$ values.

Example 9.4. Consider the application requiring a 10-dB reduction of 200–600-Hz broadband noise generated by a noise source venting through a pipe with diameter $d = 2$ in. (5.1 cm) at a temperature of 120°C and at a negligible flow speed. Because of the broadband requirements, a DTEC muffler design is selected through the following steps:

- Step 1: The 400-Hz center of the subject frequency band is aligned with the center, $kL/\pi = 2$ of the broad TL peaks of Fig. 9.10*c*; this places the upper and lower frequency bounds (200 and 600 Hz) at kL/π values of 1 and 3, respectively.
- Step 2: The $S_2/S_1 = 4$ curve (Fig. 9.10*c*) is selected because it provides > 10 dB TL in the $1 < kL/\pi < 3$ range.
- Step 3: The required muffler diameter $D = d\sqrt{S_2/S_1} = 5.1\sqrt{4} = 10.1$ cm.
- Step 4: At 120°C (393 K), the sound speed $c = 331\sqrt{393/273} = 397$ m/s.
- Step 5: Given that $kL/\pi = 1$ corresponds to 200 Hz, the required muffler length $L = k = \pi c/(2\pi f) = 397/(2 \times 200) = 0.99$ m, $L_1 = L/2 = 0.495$ m and $L_2 = L/4 = 0.247$ m.

General Design Guidelines for Expansion Chamber Mufflers

Transmission loss curves with higher levels and fewer or less pronounced troughs can be obtained with more complex muffler configurations. Specifically, one can cascade two or more DTECs to further optimize performance through an increased number of system parameters. However, an increasing system complexity is not without limits, since muffler size and weight are important design parameters in practical applications. For example, increasing the number of elements reduces the average length/diameter of individual elements, which reduces low-frequency performance, and increases the number of partitions, which increases weight. These competing factors improve certain features while degrading others and lead to design trade-offs that are specific to each application.

A close examination of a number of designs (not detailed here) featuring one to three DTECs leads to the following observations or design considerations:

- The TL of a SECM features nulls (troughs) at $kL/\pi = 1, 2, 3, 4, 5$.

- If an SECM is augmented with an extended-inlet (or outlet, for that matter) pipe equal in length to half the chamber length, then the troughs corresponding to $kL/\pi = 1, 3, 5, 7, 9, \ldots$ are eliminated.
- If an SECM is augmented with an extended-inlet (or outlet, for that matter) pipe equal in length to quarter the chamber length, then the troughs corresponding to $kL/\pi = 2, 6, 10, 14, \ldots$ are eliminated.
- If an SECM is augmented with extended-inlet and extended-outlet pipes equal in length to half and quarter the chamber length, respectively (DTEC), then the TL retains troughs only at $kL/\pi = 4, 8, 12, 16, \ldots$.
- The TL of two identical cascaded DTECs occupying the same envelope as a single DTEC features less pronounced troughs and generally higher levels, except at low frequencies ($kL/\pi < 0.5$), where some degradation is observed.
- The TL of two unequal cascaded DTECs can be further improved over the TL of two identical cascaded DTECs occupying the same envelope.

Additional TL improvements can be achieved through the use of three or more cascaded DTECs occupying the same total envelope as one DTEC. However, such improvements lead to further degradation of low-frequency performance; therefore, commercial application mufflers generally include no more than two or three cascaded DTEC chambers. Nevertheless, a designer who is forced to use a larger number of chambers by the needs of a specific application may recover low-frequency performance through the use of other types of elements, as discussed in the next section.

9.5 REVIEW OF PERFORATED-ELEMENT MUFFLERS

Perforated-element silencers have long been known to be acoustically more efficient than the corresponding simple tubular-element silencers. However, a systematic aeroacoustical analysis of perforated elements began only in late 1970s, when Sullivan introduced his segmentation model.[18–20] This was followed by the distributed-parameter model of Munjal et al., which produced experimentally verified four-pole parameters for perforated elements, namely, concentric-tube resonators (Fig. 9.11*a*), plug chambers (Fig. 9.11*b*), and three-duct cross-flow (Fig. 9.11*c*) and reverse-flow chambers.[8,9,21–23].

This section conducts a parametric study on some perforated-element mufflers to identify representative trends and to develop basic design guidelines.[25] Again, TL has been selected as an appropriate performance index. Explicit expressions for the impedance and the transfer matrix parameters of perforated muffler elements in terms of the geometric and operating variables and formulas for TL and IL are given in Chapter 3 of reference 8.

Range of Variables

Perforated-tube mufflers share several parameters with the expansion chamber mufflers discussed earlier, but they also include additional parameters accounting

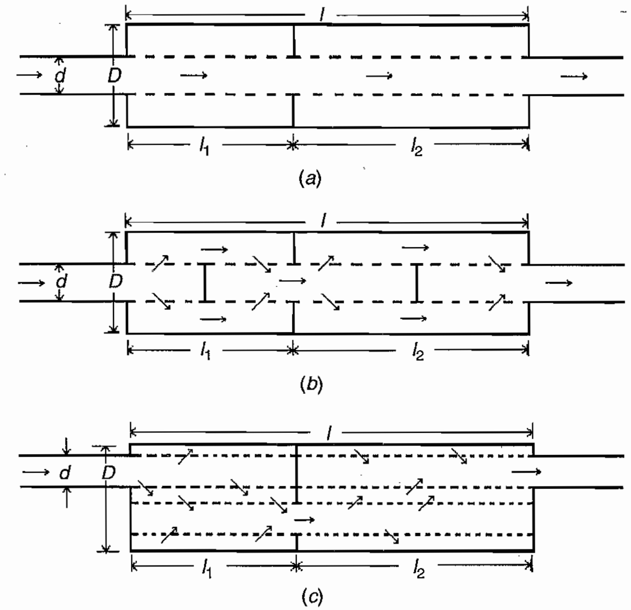

FIGURE 9.11 Schematic of the two-chamber configurations of three types of perforated-tube mufflers: (*a*) Concentric-tube resonator; (*b*) plug muffler; (*c*) three-duct cross-flow muffler.

for the additional features of the perforated tubes. Thus, the physical parameters influencing the performance of the Fig. 9.11 perforated mufflers include the following:

M = mean-flow Mach number in exhaust pipe
l = total length of muffler shell
D = internal diameter of muffler shell
d = internal diameter of exhaust pipe and tail pipe
d_h = diameter of perforated holes (Fig. 9.12)
C = center-to-center distance between consecutive holes (Fig. 9.12)
N_c = number of chambers within fixed-length muffler shell
t_w = wall thickness of perforated tube

Another parameter, often used instead of explicit values of d_h or C, is the porosity (or open-area ratio) of the perforated-tube wall, which is defined by

$$\sigma = \frac{\pi d_h^2}{4C^2} \tag{9.26}$$

Extensive simulations conducted for representative configurations encountered in most practical applications showed that the performance of perforated-tube

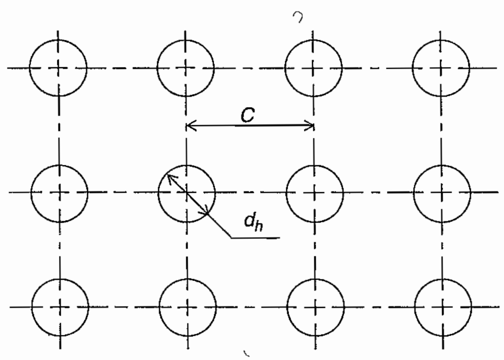

FIGURE 9.12 Parameters d_h and C of perforated-tube walls.

mufflers is relatively insensitive (within ±1 dB) to the hole diameter d_h and wall thickness t_w. For this reason, all of the following predictions have been conducted at the typically encountered values of $d_h = 4$ mm and $t_w = 1$ mm.

Furthermore, to reduce the simulations to a manageable number, the pipe diameter was fixed to a commonly encountered value of $d = 30$ mm for all cases considered in this section. This constraint does not influence the corresponding predicted TL curves, because they are invariant with respect to the specific value of d when plotted against the nondimensional frequency parameter kR ($R = D/2$ is the shell radius and $k = \omega/c$).

Despite the simplification resulting from the fixed values of d, d_h, and t_w, the number of perforated-tube muffler configurations is still too large for a comprehensive study. Under the circumstances, the influence of each parameter on muffler performance is demonstrated by selecting a reference (default) configuration and then by changing individual parameters (one at a time) about the default values. Table 9.2 shows the range of parameter values investigated including the default values (last column).

The TL was calculated as a function of the dimensionless frequency kR to extend the validity of the predictions over all geometrically similar hardware, that is, mufflers differing only by a length scale. The nondimensional frequency parameter kR was varied in steps of 0.025 from 0.025 to 3, which is well

TABLE 9.2 Parameter Values Used in Perforated Tube Muffler Performance Predictions

Parameter Name	Description	Range	Default
M	Mach number	0.05, 0.1, 0.15, 0.2	0.15
D/d	Expansion ratio	2, 3, 4	3
C/d_h	Center-to-center distance	3, 4, 5, 6	4
N_c	Number of chambers	1, 2, 3	2
L_2/L	Chamber size	$1, \frac{1}{2}, \frac{1}{3}$	$\frac{1}{2}$
L/d	Muffler length–pipe diameter	15, 20, 25	20

within the plane-wave cutoff limit of 3.83 for the axisymmetric mufflers of Figs. 9.11*a*,*b*. By comparison, the cutoff limit of kR for the asymmetric configuration of Fig. 9.11*c* is 1.84.

Acoustical Performance

Figures 9.13–9.17 show the computed TL for the Fig. 9.11 mufflers as a function of the normalized frequency kR. The three plots (a, b, and c) in each figure display the TL of a concentric-tube resonator muffler, plug muffler, and three-duct cross-flow muffler, respectively, and the different traces within each plot correspond to different combinations of muffler parameter values listed in Table 9.2.

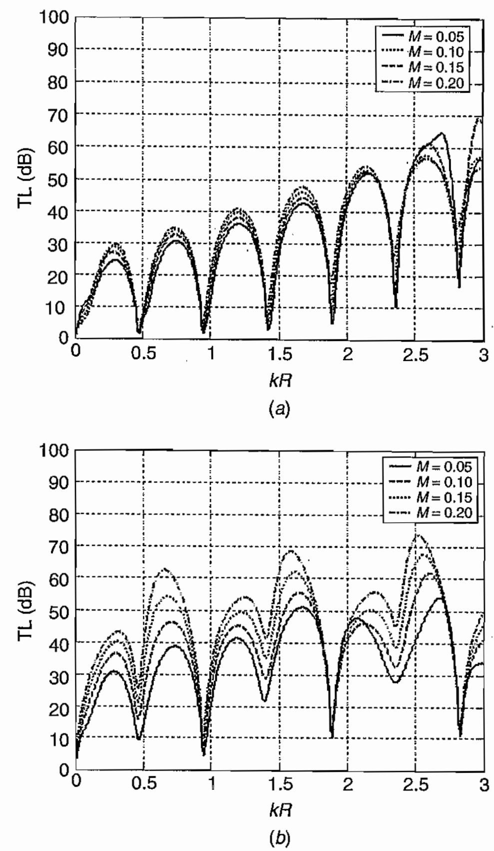

FIGURE 9.13 Effect three of mean flow Mach number on TL of (a) CTR, (b) plug muffler, and (c) duct muffler: (—) $M = 0.05$; (- - -) $M = 0.1$; (. . .) $M = 0.15$; (-·-·-) $M = 0.2$.

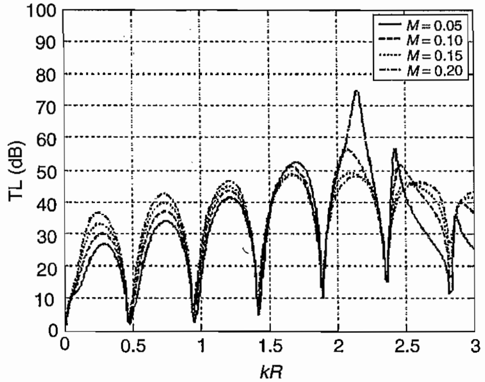


(c)

FIGURE 9.13 *(continued)*

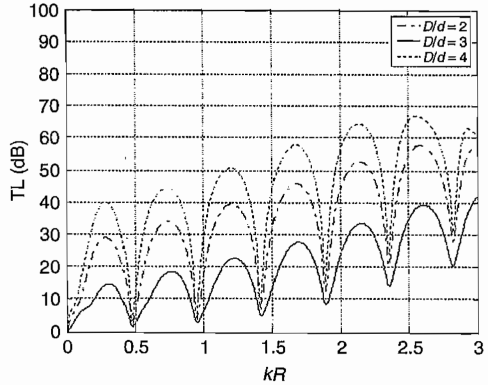
Figure 9.13 shows the effect of the mean-flow Mach number on the acoustical performance of three perforated-element muffler designs. These predictions show a general increase in TL when the mean-flow Mach number increases. The effect is minimum for the concentric-tube resonator (CTR) and maximum for the plug muffler; this is not surprising given that (because of their intrinsic geometric features) the former and latter configurations present the minimum and maximum "blockages," respectively, to the mean flow through the muffler.

Clearly, the choice of the Mach number is not in the designer's control, as it is determined by the engine displacement, speed, and exhaust pipe diameter. Nevertheless, the designer may combine the information in Fig. 9.13 with back-pressure information (discussed in the next section) in the selection of a muffler design appropriate for the specific application.

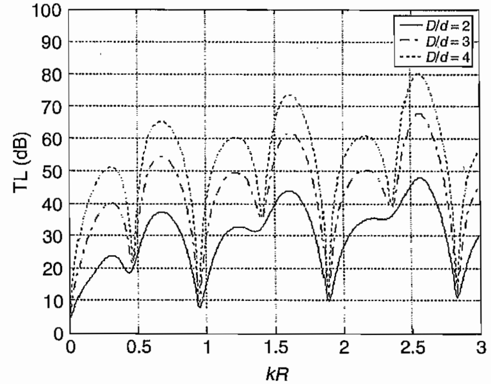
The effect of the expansion ratio, or the diameter ratio D/d, is illustrated in Fig. 9.14. The TL of all three perforated-element mufflers improves considerably with higher diameter ratio.

In most practical applications, the shell diameter D is directly related to muffler volume, weight, and cost and influences the choice of the expansion ratio D/d and the type of muffler. The alternate troughs in the TL curves are higher for a plug muffler (Fig. 9.14*b*) than for the other two designs; therefore, when space is constrained, the plug muffler typically offers a higher acoustical performance. Unfortunately, it also leads to a typically higher back pressure, as discussed later. As a result, the final choice is usually based on a trade-off between acoustical and mechanical performance.

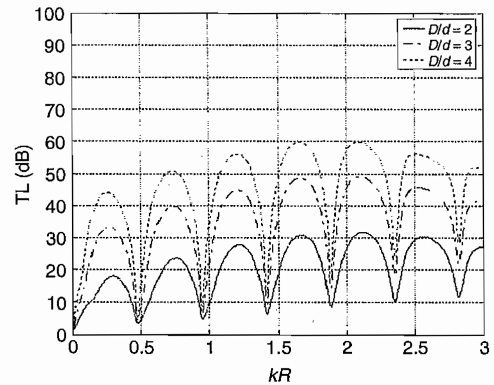
The effect of the center-to-center spacing between consecutive holes (which determines the porosity) on the TL of the mufflers is illustrated in Fig. 9.15. As can be seen, the performance of all perforated mufflers tends to that of the simple expansion chamber muffler for sufficiently high values of porosity ($\sigma > 0.1$) but is considerably better for lower values of porosity, particularly for the plug



(a)



(b)



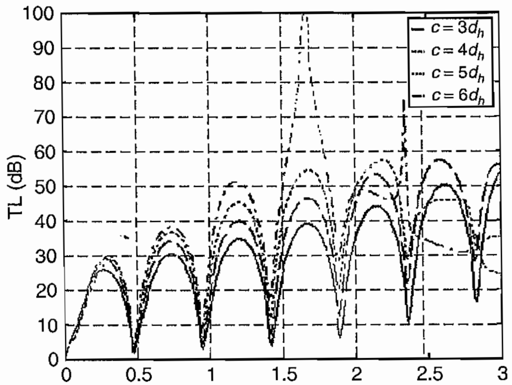
(c)

FIGURE 9.14 Effect of expansion ratio on TL of (*a*) CTR, (*b*) plug muffler, and (*c*) three-duct muffler: (—) $D/d = 2$; (- - -) $D/d = 3$; (. . .) $D/d = 4$.

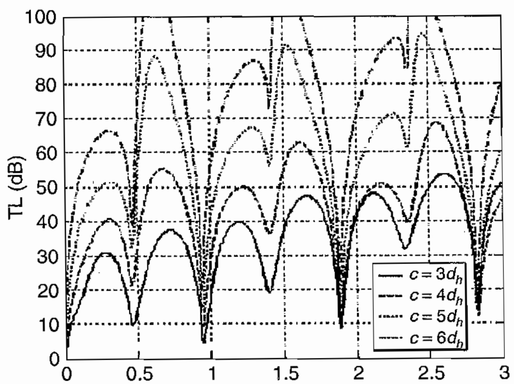
muffler and the three duct muffler configurations. On the other hand, a reduced porosity raises back pressure, except for the CTR, where the back pressure is nearly independent of porosity, as demonstrated later in this section. Consequently, the porosity provides another parameter that can be used to trade off between acoustical and mechanical performance.

Another, and perhaps more meaningful, parameter often used instead of the porosity is the open area ratio x, defined as

$$x = \frac{\text{total area of perforations}}{\text{cross-sectional area of pipe}} \tag{9.27}$$

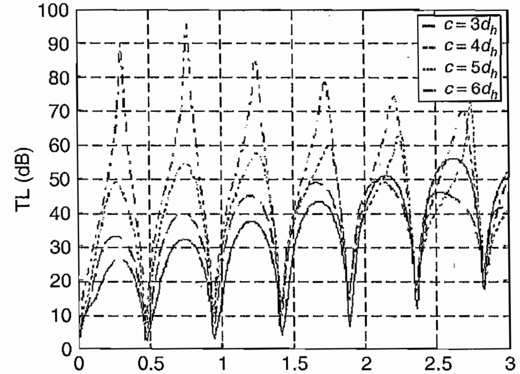


(a)



(b)

FIGURE 9.15 Effect of center-to-center distance between consecutive holes on TL of (*a*) CTR, (*b*) plug muffler, and (*c*) three-duct muffler: (—) $C = 3d_h$; (- - -) $C = 4d_h$; (. . .) $C = 5d_h$; (-·-·-) $C = 6d_h$.



(c)

FIGURE 9.15 (*continued*)

The denominator refers to the inlet/outlet pipe cross section that accommodates the entire mean flow. For example, the CTR (Fig. 9.15*a*) and three-duct muffler (Fig. 9.15*c*), may be described in terms of either the porosity associated with the indicated $C = 3d_h, 4d_h, 5d_h, 6d_h$ or in terms of the corresponding open-area ratio values of 3.49, 1.78, 1.25, and 0.87, respectively. The corresponding values of x for the plug muffler (Fig 9.15*b*) are half as much.

The plot in Fig. 9.16 shows the effect of multiple equal partitioning of a muffler of overall length l on the TL. The normalized frequency spacing between the consecutive troughs is proportional to the number of partitions and, as in the case of the simple expansion chamber mufflers, the troughs occur at frequencies given by

$$\sin kl_{1,2} = 0 \qquad kl_{1,2} = n\pi \qquad n = 1, 2, 3 \ldots \tag{9.28}$$

In general, the partitioning improves the TL of all three mufflers, except at the low-frequency end of the CTR curves, where the TL decreases. An increased number of partitions N_c would be particularly desirable for a CTR, where an increase in partitions would not increase the back pressure. However, the back pressure will be proportional to the cube of the number of chambers for the other two types of mufflers. Therefore, increased partitioning must be closely considered with an increased porosity to optimize acoustical performance while maintaining the back pressure within acceptable levels.

Figure 9.17 illustrates the effect of unequal partitioning of a muffler of overall length l on the TL by comparing the results of an equally and an unequally partitioned muffler for each of the three designs. One can observe that unequal partitioning (a) has no significant impact on the envelope of the TL peaks, (b) influences significantly the location of individual peaks and troughs, and (c) raises noticeably the level of each alternate trough. On average, the additional

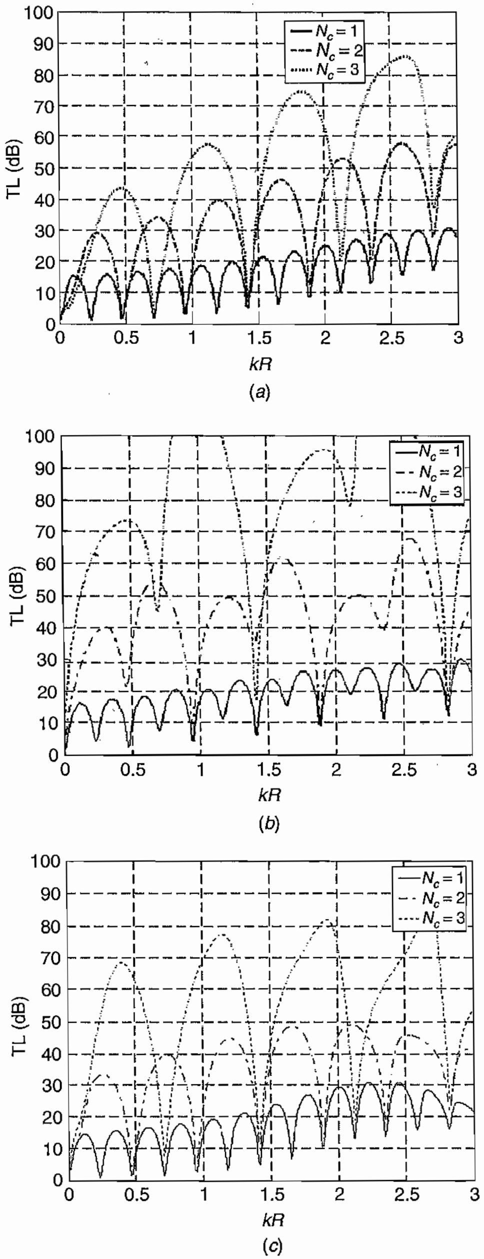


FIGURE 9.16 Effect of number of chambers within the same overall length on TL of (*a*) CTR, (*b*) plug muffler, and (*c*) three-duct muffler: (—) $N_c = 1$; (- - -) $N_c = 2$; (. . .) $N_c = 3$.

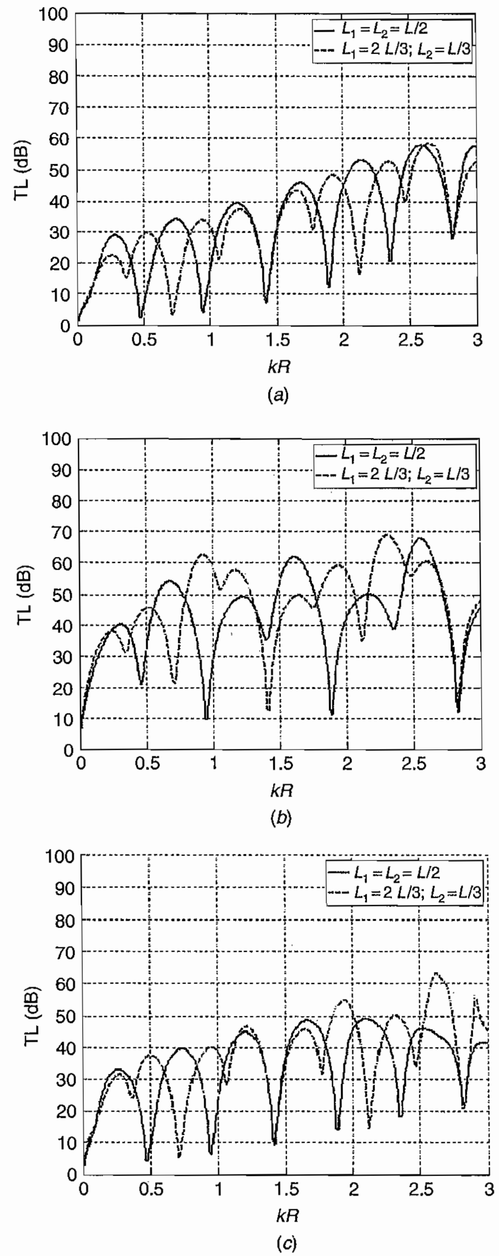

FIGURE 9.17 Effect of unequal partitioning of (*a*) CTR, (*b*) plug muffler, and (*c*) three-duct muffler: (—) $l_1 = l_2 = \frac{1}{2}$; (- - -) $l_1 = 2l/3$; $l_2 = l_3$.

tuning enabled by the unequal partitioning will enhance the overall acoustical performance of mufflers.

Back Pressure

The static pressure drop resulting from energy dissipation in sheared flow regions of the muffler elements results in a substantial back pressure on the piston of a reciprocating engine. This generally has an adverse effect on the volumetric efficiency, power, and specific fuel consumption of a multicylinder engine.

A systematic experimental study was undertaken[25] to derive empirical expressions for pressure drop or head loss across all the three types of perforated-element chambers of Fig. 9.11. The results were expressed as a coefficient that normalized the pressure drop with respect to the incoming dynamic head in the pipe, namely,

$$y \equiv \frac{\Delta p}{H} \qquad H = \tfrac{1}{2}\rho U^2 \tag{9.29}$$

The parameter y was dependent on the open-area ratio x of the perforate defined by Eq. (9.27), and its value was determined to vary as follows:

Concentric-tube resonator:

$$y_{\text{ctr}} = 0.06x \qquad 0.6 < x \tag{9.30}$$

Plug muffler:

$$y_{\text{pm}} = 5.6e^{-0.23x} + 67.3e^{-3.05x} \qquad 0.25 < x < 1.4 \tag{9.31}$$

Three-duct cross-flow chamber:

$$y_{\text{cfc}} = 4.2e^{-0.06x} + 16.7e^{-2.03x} \qquad 0.4 < x < 5.8 \tag{9.32}$$

During the measurements of the parameter y,[25] the desired variation in the open-area ratio x was achieved by varying the length l_2 (see Fig. 9.11). The measured y [Eqs. (9.30)–(9.32)] was found to be independent of the mean-flow velocity U (for Mach number $M \leq 0.2$) and very weakly dependent on the expansion ratio D/d and lengths l_1 and l_3 for values of x in the range indicated by Eqs. (9.30)–(9.32). However, the expressions for y in these equations are least-squares fits and therefore are not limited to the indicated range; they cover the entire practical range ($0.2 < x < 6.0$).

The back-pressure coefficient y_{ec} for the expansion chamber mufflers of Section 9.3 is analogously given by[8]

$$y_{\text{ec}} = (1-n)^2 + \tfrac{1}{2}(1-n) \qquad n = \left(\frac{d}{D}\right)^2 \tag{9.33}$$

Equations (9.30)–(9.32) show that the static pressure drop across a CTR, which involves no net flow through the perforated-tube walls, is much smaller than that across the corresponding plug muffler and the three-duct cross-flow chamber. Similarly, Equations (9.30) and (9.33) indicate that the pressure drop across a CTR is less than that across a simple expansion chamber of identical shell size and pipe diameter.

9.6 DISSIPATIVE SILENCERS

Dissipative silencers are the most widely used devices to attenuate the noise in ducts through which gas flows and in which the broadband sound attenuation must be achieved with a minimum of pressure drop across the silencer. They are frequently used in the intake and exhaust ducts of gas turbines, air conditioning and ventilation ducts connected to small and large industrial fans, cooling-tower installations, and the ventilation and access openings of acoustical enclosures, and they have an allowed pressure drop that typically ranges from 125 to 1500 Pa (0.5–6 in. H_2O). Unlike reactive silencers, which mostly reflect the incident sound wave toward the source, dissipative silencers attenuate sound by converting the acoustical energy propagating in the passages into heat caused by friction in the voids between the oscillating gas particles and the fibrous or porous sound-absorbing materials, as described in detail in Chapter 8.

The theories of dissipative silencers were developed long ago,[1,2,71–74] and they are highly complex. This chapter provides design information in a form that can be readily used by engineers not thoroughly trained in acoustics. Though there are a large variety of geometries used, the most common configurations include parallel-baffle silencers, round silencers, and lined ducts.

Lined Ducts

The sound attenuation of lined and unlined ducts and lined and unlined bends are treated in Chapter 16. The geometry of frequently used dissipative silencers is shown schematically in Fig. 9.18.

Figure 9.19 shows some of the baffle constructions that have been used in typical applications. Only the acoustically significant features are shown. Protective treatments such as perforated facing, fiberglass cloth, and porous screens are omitted. If the same concepts depicted in Figs. 9.19*a*–*i* are applied as a duct lining, one-half of the baffles depicted in Fig. 9.19 constitutes the lining.

Figure 9.19 illustrates the cross sections of frequently used silencer baffle configurations.

The full-depth porous baffle depicted in Fig. 9.19*a* is the most frequently used in parallel-baffle silencers. The other baffle configurations are used in special-purpose silencers custom deigned to yield high attenuation in specific

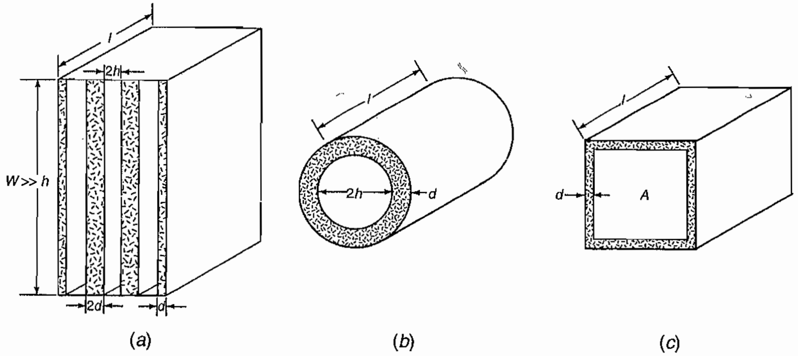

FIGURE 9.18 Geometry of frequently used silencer types: (*a*) parallel baffle; (*b*) round; (*c*) lined ducts.

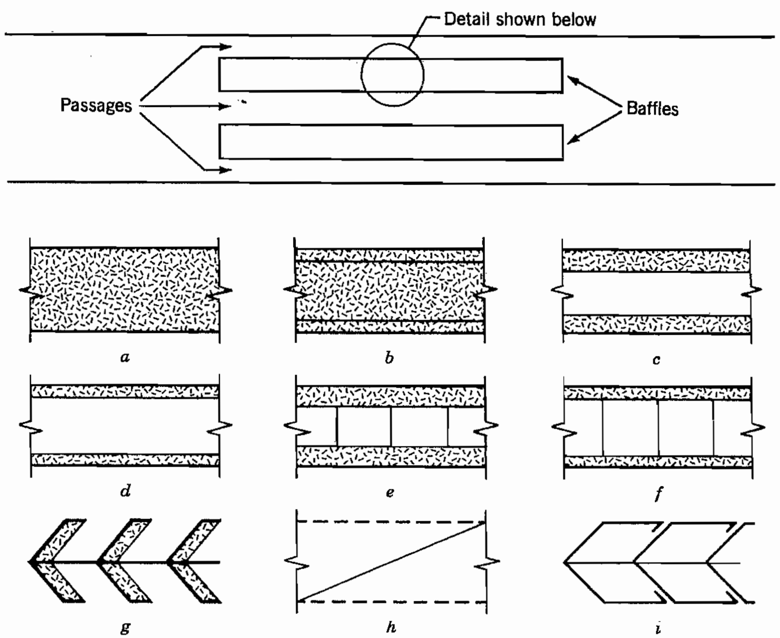

FIGURE 9.19 Cross section of frequently used silencer baffle configurations: (*a*) full-depth porous; (*b*) porous center layer with thin resistive facing on both sides; (*c*) thick porous surface layer with unpartitioned center air space; (*d*) thin porous surface layers with unpartitioned air space; (*e*) thick porous layer with partitioned center air space; (*f*) thin porous surface layers with partitioned center air space; (*g*) tuned cavity (Christmas tree), porous material in cavities protected from flow; (*h*) small percentage open-area perforated surface plates exposed to grazing flow, partitioned center air space; (*i*) Helmholtz resonators.

frequency ranges or to work in hostile environments of contaminated flow or high temperatures.

Key Performance Parameters

The key design parameters of silencers are acoustical insertion loss (IL), pressure drop (Δp), flow-generated noise, size cost, and life expectancy. The challenge of silencer design is to obtain the needed IL without exceeding the allowable pressure drop and size for a minimum of cost. These are frequently opposing requirements, and the optimal design represents a balance compromise between them.

Insertion Loss. The IL of a silencer is defined as

$$\mathrm{IL} = 10 \log \frac{W_0}{W_M} \tag{9.34}$$

where W_0 and W_M represent the sound power in the duct without and with the silencer, respectively. Provided that structure-borne flanking along the muffler casing and sound radiation from the casing is kept low, the sound power in the duct with the silencer in place is given by

$$W_M = W_0 \times 10^{-(\Delta L_l + \Delta L_{\mathrm{ENT}} + \Delta L_{\mathrm{EX}})/10} + W_{\mathrm{SG}} \tag{9.35}$$

where W is in watts (N·m/s); ΔL_l represents the attenuation of the silencer of length l; ΔL_{ENT} and ΔL_{EX} are the entrance and exit losses, respectively; and W_{SG} is the sound power generated by the flow exiting the silencer.

Combining Eqs. (9.34) and (9.35) yields

$$\mathrm{IL} = -10 \log \left(\frac{W_{\mathrm{SG}}}{W_0} + 10^{-(\Delta L_l + \Delta L_{\mathrm{ENT}} + \Delta L_{\mathrm{EX}})/10} \right) \tag{9.36}$$

In the extreme case of very high silencer attenuation, the second term on the right-hand side of Eq. (9.36) becomes comparable to the first, and the achievable IL is affected by the self-generated noise of the silencer, and in this case Eq. (9.36) is nonlinear. When the flow velocity in the silencer passages is sufficiently low, flow noise is negligible. In this case, Eq. (9.36) is linear and simplifies to

$$\mathrm{IL} \cong \Delta L_l + \Delta L_{\mathrm{ENT}} + \Delta L_{\mathrm{EX}} \quad \mathrm{dB} \tag{9.37}$$

Entrance Loss ΔL_{ENT}. In most dissipative silencers, the entrance losses ΔL_{ENT} are small if the incident sound energy is in the form of a plane wave normally incident on the silencer entrance. This is always the case for straight ducts at low frequencies. The small entrance loss should be considered as a safety factor.

However, if the cross dimensions of the duct are much larger than the wavelength, the incident sound field usually contains a very large number of higher order modes. The conversion of the semidiffuse sound field in the entrance duct into a plane-wave field in the narrow silencer passages typically results in an entrance loss of 3–6 dB. The engineer can also assign any entrance loss between 0 dB at low frequencies and up to 8 dB at high frequencies on the basis of prior experience with similar situations or on the basis of scale model measurements. If no such information is available, Fig. 9.20 can be used to estimate the entrance loss.

***Exit Loss* ΔL_{EX}.** Most exit losses ΔL_{EX} are generated when the silencer is located at the open end of a duct and the typical cross dimensions of the opening are small compared with the wavelength. In this case, the exit loss is predominantly determined by the end reflection. Exit losses for silencers inserted in ducts are usually small and can either be neglected or considered as part of the safety margin.

It should be noted that the relative importance of the entrance and exit losses diminishes as the silencer length increases because both quantities are independent of this length. Figure 9.21 shows qualitatively a typical sound pressure level versus distance recorded by a microphone traveling through the silencer and indicates the three components of IL.

***Silencer Attenuation* ΔL_l.** The silencer attenuation ΔL_l is proportional to its length (tail and nose of baffle not included) and to the lined perimeter of the passage, P, and inversely proportional to the cross-sectional area of the passage,

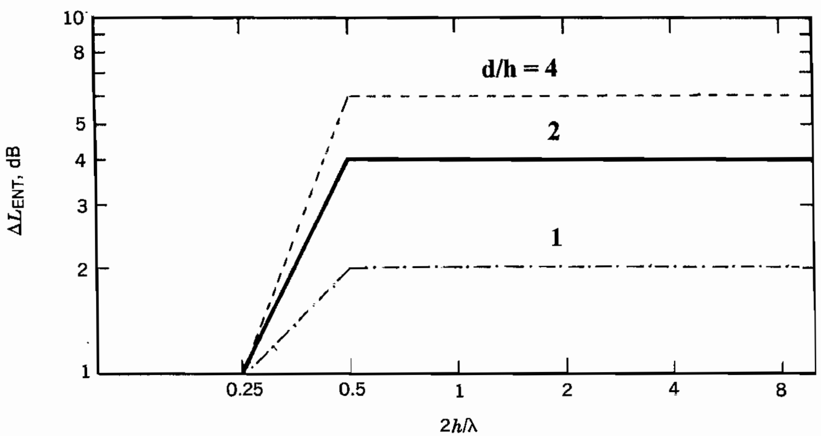

FIGURE 9.20 Acoustical entrance loss coefficient, ΔL_{ENT}, of silencers in a large duct with a semireverberant sound field in the entrance duct: $2h$ = silencer passage cross dimension.

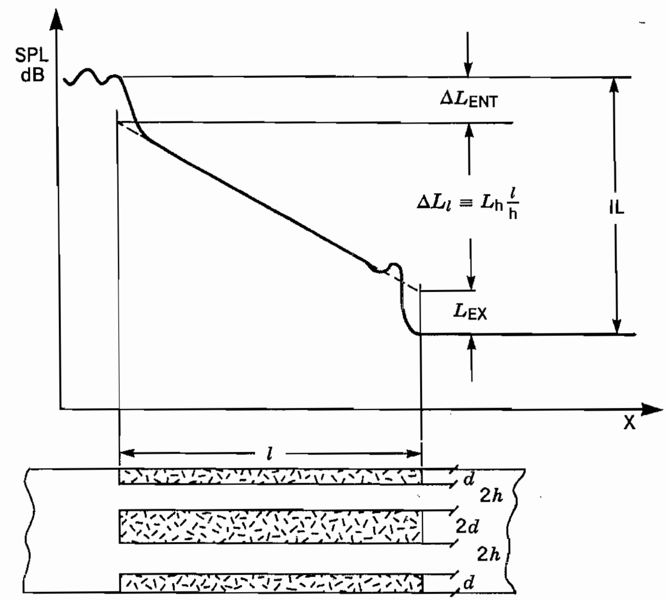

FIGURE 9.21 Typical SPL-versus-distance curve obtained when microphone traverses through a silencer.

A. It can be expressed as

$$\Delta L_l = \left(\frac{P}{A}\right) l L_h \tag{9.38}$$

where L_h is the parameter that depends in a complex manner on the geometry of the passage and the baffle, acoustical characteristics of the porous sound-absorbing material filling the baffles, frequency, and temperature. The quantity L_h, which also depends on the velocity of the flow in the passage, is usually referred to as the attenuation per channel height. The major part of this section is devoted to the determination of this important normalized sound attenuation parameter.

***Pressure Drop* Δp.** The total pressure drop Δp_T across a muffler is made up of entrance, exit, and friction losses:

$$\Delta p_T = 1/2\rho v_P^2 \left[K_{ENT} + K_{EX} + \left(\frac{P}{A}\right) l K_F\right] = \Delta p_{ENT} + \Delta p_{EX} + \Delta p_F \quad \text{N/m}^2 \tag{9.39}$$

where ρ is the density of the gas and v_P its face velocity in the passage of the silencer. The constants K_{ENT} and K_{EX} are the entrance and exit head loss coefficients, which depend only on the geometry of the baffle/passage configuration.

The third term on the right-hand side of Eq. (9.39) represents the friction losses, given by

$$\Delta p_F = \frac{P}{A} l (K_F \tfrac{1}{2} \rho v_P^2) \quad \mathrm{N/m^2} \tag{9.40}$$

Comparing Eq. (9.38) with Eq. (9.40), one notes that baffle configurations that tend to yield high acoustical attenuation ΔL_l also tend to yield high frictional pressure losses Δp_F. Both ΔL_l and Δp_F are proportional to $(P/A)l$, indicating that high silencer attenuation and low frictional pressure drop are contradictory requirements. This finding emphasizes the need to optimize L_h by beneficial choice of the acoustical parameters of the baffles before one resorts to obtaining increased sound attenuation by increasing the factor $(P/A)l$.

Parallel-Baffle Silencers

The parallel-baffle-type silencer shown in Fig. 9.18*a* is the most frequently used because of its good acoustical performance and low cost. The attenuation of such a silencer is proportional to the perimeter–area ratio P/A, the length l, and L_h. Therefore, it is maximized by maximizing $(P/A)L_h$. The largest perimeter–area ratio obtained for narrow passages is $1/h$. Allowing for entrance losses, Eq. (9.38) yields the following simple formula for silencer attenuation:

$$\Delta L_l = L_h \frac{l}{h} + \Delta L_{\mathrm{ENT}} \quad \mathrm{dB} \tag{9.41}$$

where ΔL_{ENT} can be approximated from Fig. 9.20. The following discussion shows how to obtain L_h from the geometric and acoustical parameters of the silencer.

Prediction of Attenuation. The sound energy traveling in the passages of a parallel-baffle silencer, depicted in Fig. 9.19, is attenuated effectively in a wide bandwidth if (1) the sound enters the porous sound-absorbing material in the baffles and (2) a substantial part of the energy of the sound wave entering the baffle is dissipated before it can reenter the passage. Formulas for wall impedance that yield maximum attenuation in a narrow-frequency band are given in reference 2.

Requirement 1 is fulfilled if the passage height is small compared with wavelength (i.e., $2h < \lambda$) and the porous sound-absorbing material is open enough and has sufficiently low flow resistivity so that the sound wave enters the baffle rather than being reflected at the interface. This requires a "fluffy" material of low flow resistivity. Requirement 2 is fulfilled by a porous material of moderate flow resistivity. The requirements of easy sound penetration and high dissipation are contradictory unless the baffle is very thick and is packed with porous sound-absorbing material of low flow resistivity. Consequently, the choice of baffle thickness and flow resistivity of the porous sound-absorbing material is always a compromise.

Generally, the silencer geometry is controlled by the shape of the attenuation-versus-frequency curve we aim to achieve. To provide reasonable attenuation at the low end of the frequency spectrum, the baffle thickness $2d$ must be on the order of one-eighth of the wavelength. To provide reasonable attenuation at the high end of the frequency spectrum, the passage height $2h$ must be not much larger than the wavelength. To allow reasonable penetration of the sound and yield the needed dissipation, the total flow resistance $R_1 d$ of a baffle of thickness $2d$ must be 2–6 times the characteristic impedance of the gas in the silencer passages at design temperature.

Quantitative Considerations. The normalized attenuation constant L_h is obtained by solving the coupled wave equation in the passage and in the porous material of the baffle and requiring that (1) the coupled wave, which propagates axially in both the passage and baffle, has a common propagation constant Γ_c and (2) both particle velocity and the sound pressure are continuous at the passage baffle interface.

The coupled wave equation[1,71–74] can be solved by numerical iteration methods to yield the common propagation constant Γ_c. The normalized attenuation L_h is then obtained from

$$L_h = 8.68h \; \mathrm{Re}\{\Gamma_c\} \quad \mathrm{dB/m} \tag{9.42}$$

where Γ_c depends on the characteristic impedance ρc of the gas in the passage, the characteristic impedance Z_a and the propagation constant Γ_c of the porous material in the baffle, and the geometry.

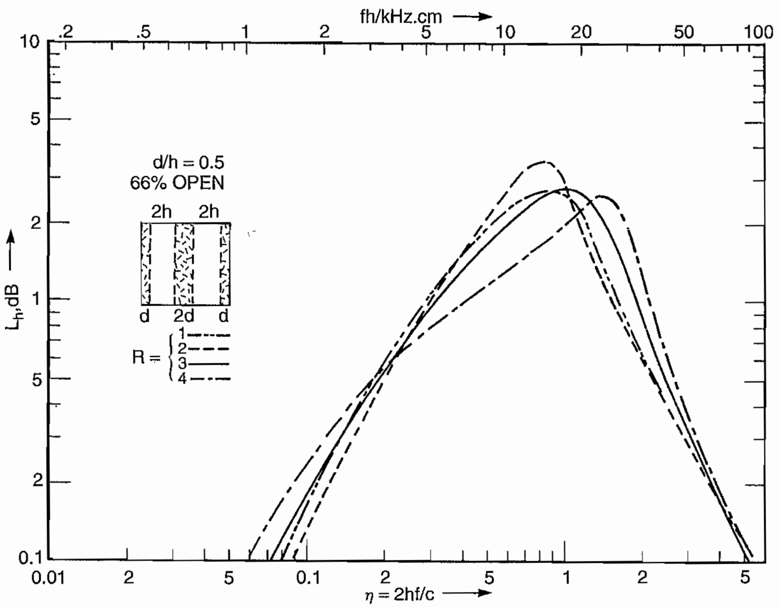
The characteristic impedance Z_a and the propagation constant Γ_c of the porous sound-absorbing materials (which are complex quantities and vary with frequency) are generally not available. As discussed in Chapter 8, one can approximate these important parameters with reasonable accuracy if the flow resistivity of the porous sound-absorbing material R_1 is known. For fibrous sound-absorbing materials the characteristic impedance Z_a and propagation constant Γ_a in the bulk porous material can be estimated using the empirical formulas presented in Chapter 8.

The most accurate characterization of the porous materials is achieved by measuring the characteristic impedance and propagation constant on a sufficiently large number of samples as a function of frequency at room temperature and by scaling these data to design temperature. Note that this attenuation, which is computed on the basis of the acoustical parameters of the porous material predicted from flow resistivity by employing the formulas given in Chapter 8, compares very well with experimental data if the porous sound-absorbing material is homogeneous.

Normalized Graphs to Predict Acoustical Performance of Parallel-Baffle Silencers. The normalized attenuation L_h has been computed for various percentages of open area of the silencer cross section (i.e., for various h/d) and for various values of the normalized flow resistance $R = R_1 d/\rho c$ of isotropic porous sound-absorbing material in the baffles. It is presented in Figs. 9.22*a–c* for open-area ratios of 66, 50, and 33%, respectively. The effect of nonisotropic material is covered in reference 72. The vertical axis in Fig 9.22 represents the normalized attenuation L_h in decibels on a logarithmic scale. The lower horizontal scale represents the normalized frequency parameter $\eta = 2h/c$. It is valid for all temperatures and gases provided that the speed of sound c is taken at the actual temperature. *The upper horizontal scale, which is valid only for air at room* temperature, represents the product of the half-passage height h in centimeters and the frequency f in kilohertz.

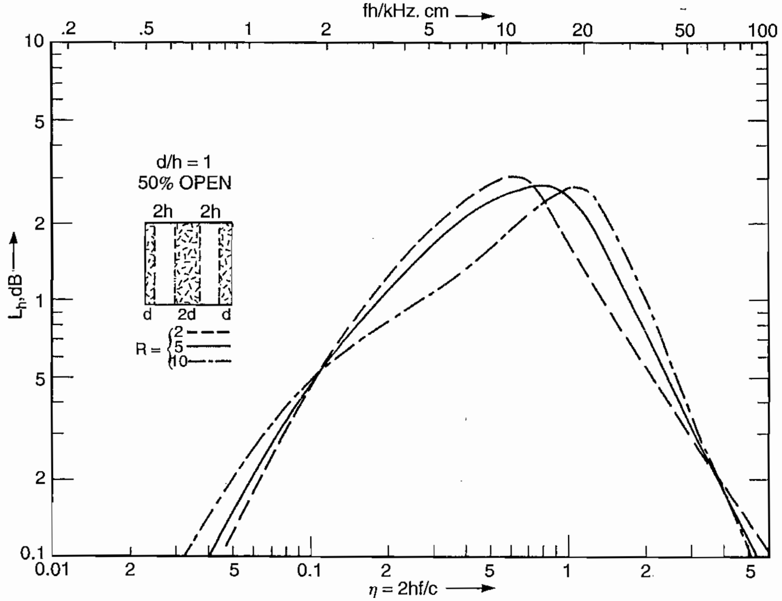
Figures 9.22*a*–*c* show that the attenuation starts to decrease rapidly above the frequency where the passage height $2h$ becomes large compared to the wavelength (i.e., $\eta > 1$). The attenuation in this frequency region can be increased by up to 10 dB by utilizing a two-stage silencer with staggered-baffle arrangement. Note that the bandwidth of appreciable attenuation increases with decreasing percentage of open area of the silencer cross section.

Figure 9.22 shows that in the range of $R = R_1 d/\rho c$ from 1 to 5, the attenuation does not depend strongly on the specific choice of the flow resistance; this coincidence is welcome because the present lack of adequate knowledge of and control over the material characteristics represents the weakest link in the prediction process. Note that if the normalized flow resistance becomes too large

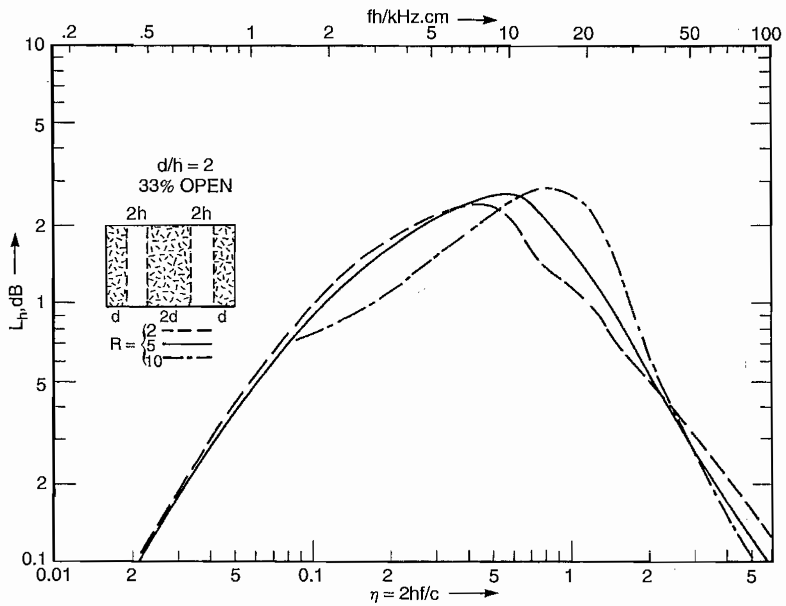


(*a*)

FIGURE 9.22 Normalized attenuation-versus-frequency curves for parallel-baffle silencers with normalized baffle flow resistance $R = R_1 d/\rho c$ as parameter: (*a*) 66% open; (*b*) 50% open; (*c*) 33% open.



(*b*)



(*c*)

FIGURE 9.22 (*continued*)

($R \geq 10$), a substantial decrease of attenuation occurs in the frequency region from $\eta = 0.2$ to $\eta = 1$ accompanied by a modest increase of attenuation at very low and at high frequencies.

The normalized attenuation-versus-frequency curves presented in Figs. 9.22*a*–*c* correspond to zero flow; corrections to account for flow are presented in a later section.

The use of the design information presented in Figs. 9.22*a*–*c* is illustrated by a few examples.

Example 9.5. Predict the attenuation-versus-frequency curve of a parallel-baffle silencer consisting of 200-mm- (8-in.-) thick parallel baffles 1 m (40 in.) long spaced 400 mm (16 in.) off center when the flow resistance of the baffle $R_1 d = 5\rho c$ and the duct carries a very low velocity air at 20°C; $h = 0.1$ m; $d = 0.1$ m; $L = 1$ m; $c = 340$ m/s; $\rho = 1.2$ kg/m^3; $R = R_1 d/\rho c = 5$.

Solution

1. Determine frequency f^*, which corresponds to $\eta = 1$:

$$f^* = \frac{c}{2h} = \frac{340 \text{ m/s}}{0.2 \text{ m}} = 1700 \text{ Hz}$$

2. Determine $1/h = 1$ m/0.1 m $= 10$.
3. Determine the applicable normalized attenuation-versus-frequency curve for $d/h = 1$ and $R = 5$; the solid curve in Fig. 9.22*b* is applicable.
4. Mark the frequency $f^* = 1700$ Hz on the horizontal scale of a sheet of transparent graph paper that has the same horizontal and vertical scales as Fig. 9.22*b* and align it with $\eta = 1$ in Fig 9.22*b*.
5. Shift the transparent graph paper vertically until the mark $L_h = 1$ in Fig. 9.22*b* corresponds to 10 ($1/h = 10$) on the transparent overlay.
6. Copy the solid curve in Fig. 9.22*b* that corresponds to $R = 5$ on the overlay.
7. The copied curve then corresponds to the attenuation-versus-frequency curve of the silencer according to $\Delta L_l = L_h(1/h)$; the above procedure is sketched in Fig. 9.23.

Example 9.6. Design a parallel-baffle silencer that yields the attenuation listed below:

f, Hz	100	200	500	1000	2000	4000
ΔL, dB	4	9	19	26	10	5

Design Steps

1. Find the graph in Figs. 9.22*a*–*c* that best matches the shape of the desired attenuation-versus-frequency curve plotted in Fig. 9.23. Overlay the transparent paper of Fig. 9.23 on the curve that yields the best match and shift the transparent overlay horizontally and vertically until all of the desired attenuation-versus-frequency points fall below the chosen normalized attenuation-versus-frequency curve. In this case, the solid curve in Fig. 9.22*c* gives the best match.

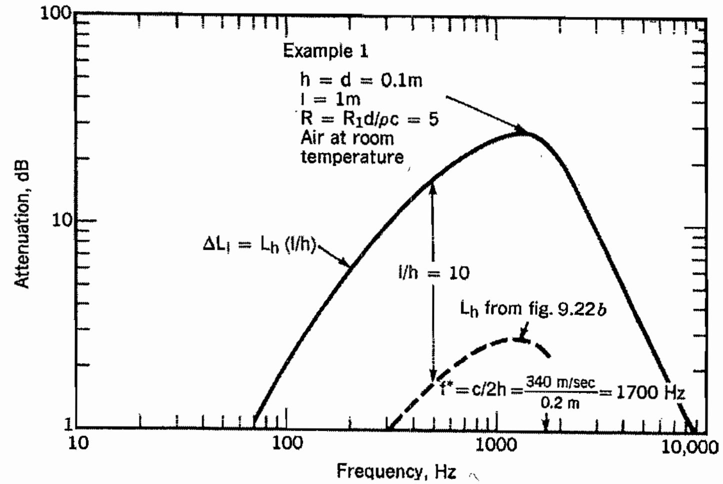


FIGURE 9.23 Attenuation prediction for parallel-baffle silencer, Example 9.5.

2. On the overlay, mark the frequency f^* that corresponds to $\eta = 1$ on the horizontal scale of the appropriate design curve under the overlay, and on the vertical scale, mark the attenuation ΔL^*, which corresponds to $L_h = 1$ on the design curve below the overlay, as shown in Fig. 9.24. In this case, these will be $f^* = 2000$ Hz and $\Delta L^* = 10$ dB.
3. From the design curve below the overlay, note the values of the parameters d/h and R that correspond to the curve that provides the best match. In this case, these are $d/h = 2$ and $R = R_1 d/\rho c = 5$.
4. On the basis of the information obtained in steps 3 and 4, one obtains the geometric and acoustical parameters of the silencer that will yield the specified attenuation as follows:
   - Passage height $2h$:

$$\eta = 1 = \frac{2hf^*}{c} \quad \text{yields} \quad 2h = \frac{340 \text{ m/s}}{2000 \text{ s}^{-1}} = 0.17 \text{ m}$$

   - Baffle thickness $2d$:

$$2d = 2(2h) = 2 \times 0.17 \text{ m} = 0.34 \text{ m}$$

   - Silencer length:

$$\Delta L^* = 10 = \frac{l}{h} \quad \text{yields} \quad l = \Delta L^* h = 10 \times \frac{0.17}{2} \text{ m} = 0.85 \text{ m}$$

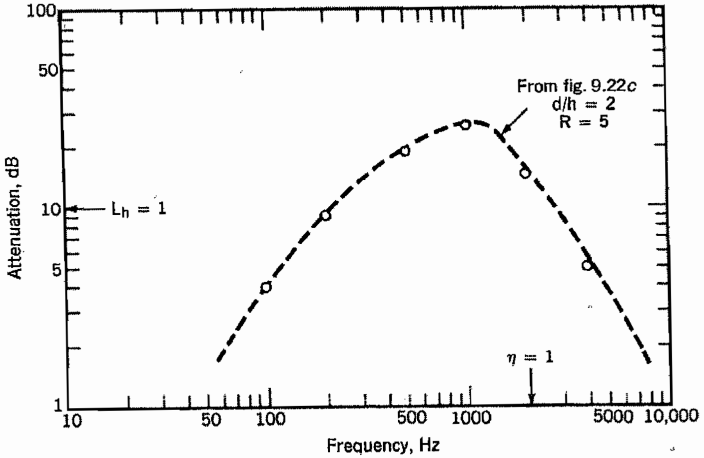

FIGURE 9.24 Acoustical design of a parallel-baffle silencer, Example 9.6: (o) design requirements; (- - - - - -) curve of matching attenuation versus frequency from Fig. 9.22*c*.

- Flow resistance per unit thickness of porous material:

$$\frac{R_1 d}{\rho c} = 5 \quad \text{yields} \quad R_1 = \frac{5\rho c}{d} = \frac{5}{0.17\ \text{m}}\rho c = 29.4\rho c/\text{m}$$

or

$$R_1 = 0.7\rho c/\text{in.} \quad \text{or} \quad R_1 = 1.2 \times 10^4\ \text{N} \cdot \text{s/m}^4$$

Cross-Sectional Area. The cross-sectional area of the muffler is determined by the maximum allowable pressure drop and self-generated noise as discussed later.

Effect of Temperature. The design temperature affects the acoustical and aerodynamic performance of the silencers because the following key parameters depend on the temperature: (1) speed of sound, (2) density of the gas, and (3) viscosity. The effects of temperature are taken into account as follows:

$$c(T) = c_0\sqrt{\frac{273+T}{293}} \quad \text{m/s} \tag{9.43}$$

$$\rho(T) = \rho_0 \frac{293}{273+T} \quad \text{kg/m}^3 \tag{9.44}$$

$$R(T) = R_0\left(\frac{273+T}{293}\right)^{1/2} \tag{9.45}$$

where T is the design temperature in degrees Celsius, c_0 is the speed of sound, ρ_0 is the density of the gas (usually air) at 20°C, and

$$R_0 = \frac{R_1(20^\circ\text{C})d}{\rho_0 c_0} \tag{9.46}$$

where $R_1(20^\circ\text{C})$ is the flow resistivity of the porous bulk material at 20°C. This material parameter is usually provided by the manufacturer or is measured.

Example 9.7. To illustrate how to account for the effect of temperature, let us predict the attenuation provided by the silencer of Example 9.5 at $T = 260^\circ\text{C}$ (500°F).

Solution The effect of temperature must be accounted for in the flow resistivity and in the speed of sound according to Eqs. (9.45) and (9.43), yielding $c(T) =$ 457 m/s and $R(T) = 10$. From now on, the solution proceeds according to the same steps followed in Example 9.5.

1. $f^* = c(T)/2h = (457\ \text{m/s})/0.2\ \text{m} = 2285\ \text{Hz}; l/h = (1\ \text{m}/0.1\ \text{m}) = 10.$
2. The applicable normalized attenuation curve that corresponds to $d/h = 1$ and $R = 10$ is the short/long-dashed curve in Fig. 9.22*b*.

This results in the attenuation-versus-frequency curve shown as the solid line in Fig. 9.25. The dashed curve in Fig. 9.25 is the attenuation of the same silencer at room temperature (20°C), as determined in Example 9.5.

Comparing the solid curve obtained for 260°C with the dashed curve obtained for 20°C, one notes a shift in the attenuation-versus-frequency curve toward higher frequencies with increasing temperature. This shift is mainly due to the increase of propagation speed of sound with increasing temperature. In addition, one also observes distortion in the shape of the attenuation-versus-frequency curve. This is caused by the increase in the flow resistivity of the porous material,

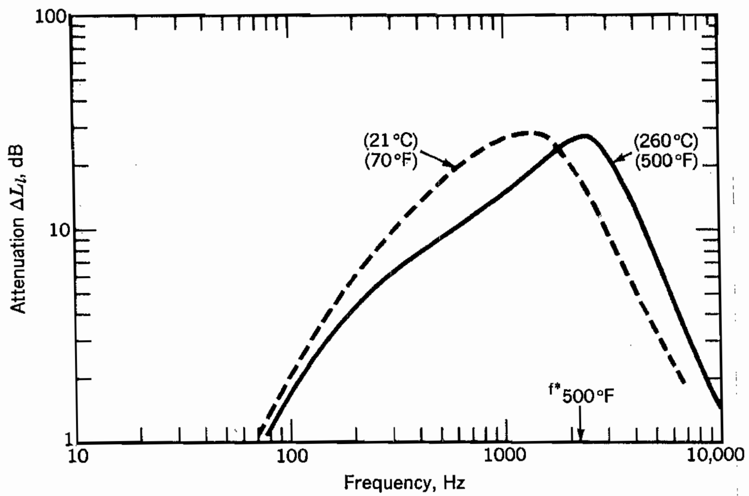

FIGURE 9.25 Attenuation of silencer of Example 9.5 at 260°C (500°F), Example 9.7.

which in turn is due to the increasing viscosity with increasing temperature. This effect has also been predicted by Mechel.[75]

Baffle Thickness Considerations. A particular percentage of open area of a silencer can be accomplished either by a small number of thick baffles or by a large number of thin baffles. Figure 9.26 shows the attenuation-versus-frequency curves computed for a 2-m- (6.5-ft-) long silencer of 50% open area with baffle thickness $2d = 2h$ of 152 mm (5 in.), 203 mm (8 in.), 254 mm (10 in.), and 305 mm (12 in.). The baffles are filled with a fibrous sound-absorbing material that has a flow resistivity $R_1 = 51,500$ N · s/m^4 at 500°C ($1\rho c$/in. at 20°C). The outstanding feature of the data presented in Fig. 9.26 is that in the midfrequency region, the sound attenuation decreases with increasing baffle thickness. At 500 Hz, the 152-mm- (6-in.-) thick baffles yield 25 dB attenuation while the 305-mm- (12-in.) thick baffles yield only 11 dB. This is because the sound does not fully penetrate into the fibrous sound-absorbing material in the thick baffles. Consequently, the material and the space in the center of the thick baffles are wasted.

Figure 9.27 shows the predicted sound attenuation of a silencer of the same geometry as that in Fig. 9.26, but the baffles in this case are filled with fibrous sound-absorbing material of low flow resistivity such that the total normalized flow resistance of each baffle was $R = R_1 d/\rho c = 2$, which allows full penetration of the sound into even the thickest baffle. Consequently, the sound attenuation at

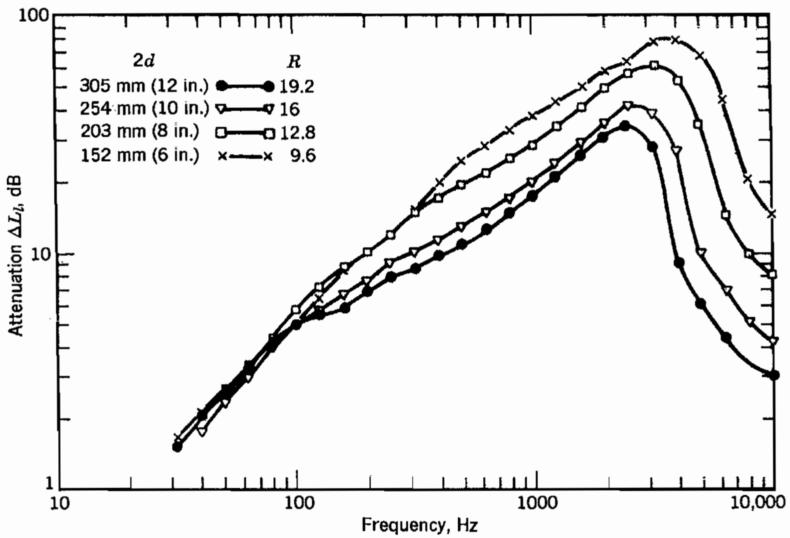

FIGURE 9.26 Computed attenuation-versus-frequency curves for a 2-m- (6.6-ft-) long parallel-baffle silencer of 50% open area with baffle thickness $2d$ as parameter.

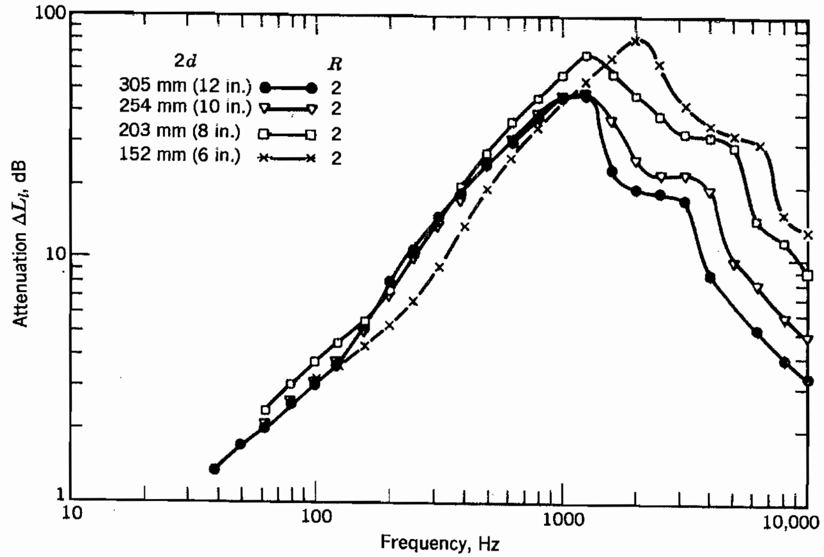

FIGURE 9.27 Computed attenuation-versus-frequency curves of the same silencer as Fig. 9.26 but fibrous fill is chosen to yield $R = R_1 d/\rho c = 2$ for all baffle thicknesses.

low and midfrequencies depends only slightly on the baffle thickness. Comparing Figs. 9.26 and 9.27 reveals that using a few thick baffles (which is more economical than using many thinner baffles) results in decreased sound attenuation at midfrequencies unless the baffles are filled with a sound-absorbing material of low enough resistivity so that the normalized baffle flow resistance at design temperature, $R = R_1 d/\rho c$, is much less than 10. Fibrous sound-absorbing materials that fulfill this requirement for thick baffles used in elevated temperatures may not be readily available. Consequently, silencer baffles of traditional design in high-temperature applications should be kept at a thickness that seldom exceeds $2d = 200$ mm (8 in.).

Note that the attenuation-versus-frequency curve of parallel-baffle silencers increases monotonically up to a frequency $f = c/2d$, where the passage width corresponds to a wavelength, and decreases sharply above it.

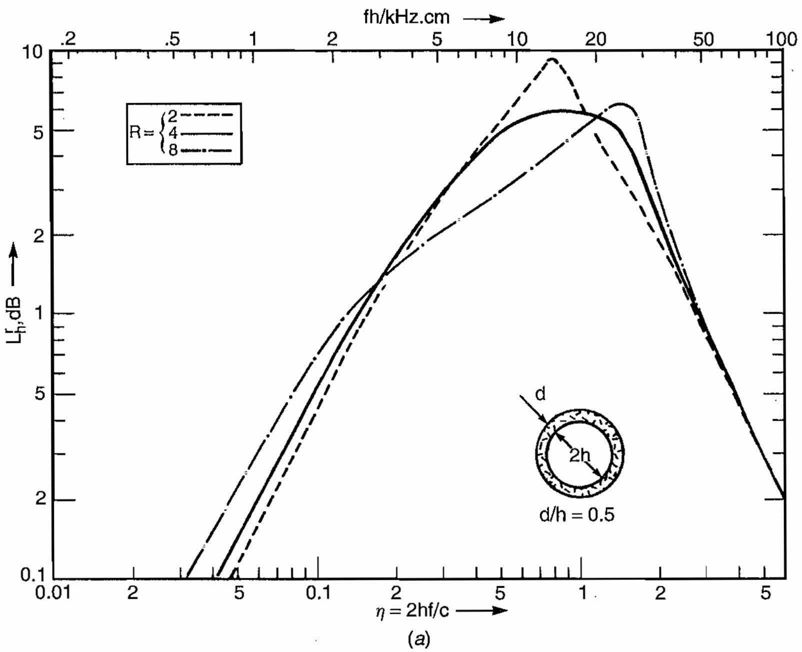
Round Silencers

Round silencers, as depicted in Fig. 9.18b, are used in connection with round ducts. The curvature of the duct casing results in a high form stiffness that yields high sound transmission loss of the silencer wall at low frequencies. The acoustical performance of round silencers with respect to normalized attenuation L_h is very similar to that of parallel-baffle silencers. The diameter of the round passage, $2h$, and the thickness of the homogeneous isotropic lining, d, resemble the passage width $2h$ and the half-baffle thickness d of a parallel-baffle silencer. The silencer attenuation $\Delta L^r(l)$ of a round muffler of length l is obtained from

$$\Delta L^r(l) = L_h^r \frac{l}{h} \tag{9.47}$$

The sound attenuation in round ducts has been studied by Scott[71] and Mechel.[74] Their work forms the theoretical foundations for computing their performance.

Figure 9.28 shows curves of normalized attenuation L_h^r versus normalized frequency $\eta = 2hf/c$ for round silencers with homogeneous isotropic lining for thickness–passage radius ratios d/h of 0.5, 1, and 2, respectively, with the normalized lining flow resistance $R = R_1 d/\rho c$ as parameter. The lower horizontal scale is valid for all temperatures, while the upper scale is valid only for air at room temperature. Figure 9.28 shows that the normalized attenuation increases monotonically with frequency until the wavelength corresponds to the diameter of the passage ($\eta = 2hf/c = 2h/\lambda = 1$). Above this frequency the attenuation decreases rapidly with increasing frequency, as was the case for parallel-baffle silencers. Note that the maximum normalized attenuation is about $L_{h,\max}^r \approx 6$ dB



(a)

FIGURE 9.28 Curves of normalized attenuation L_h^r versus frequency for round silencers with normalized lining flow resistance $R = R_1 d/\rho c$ as parameter: (a) $d/h = 0.5$; (b) $d/h = 1$; (c) $d/h = 2$.

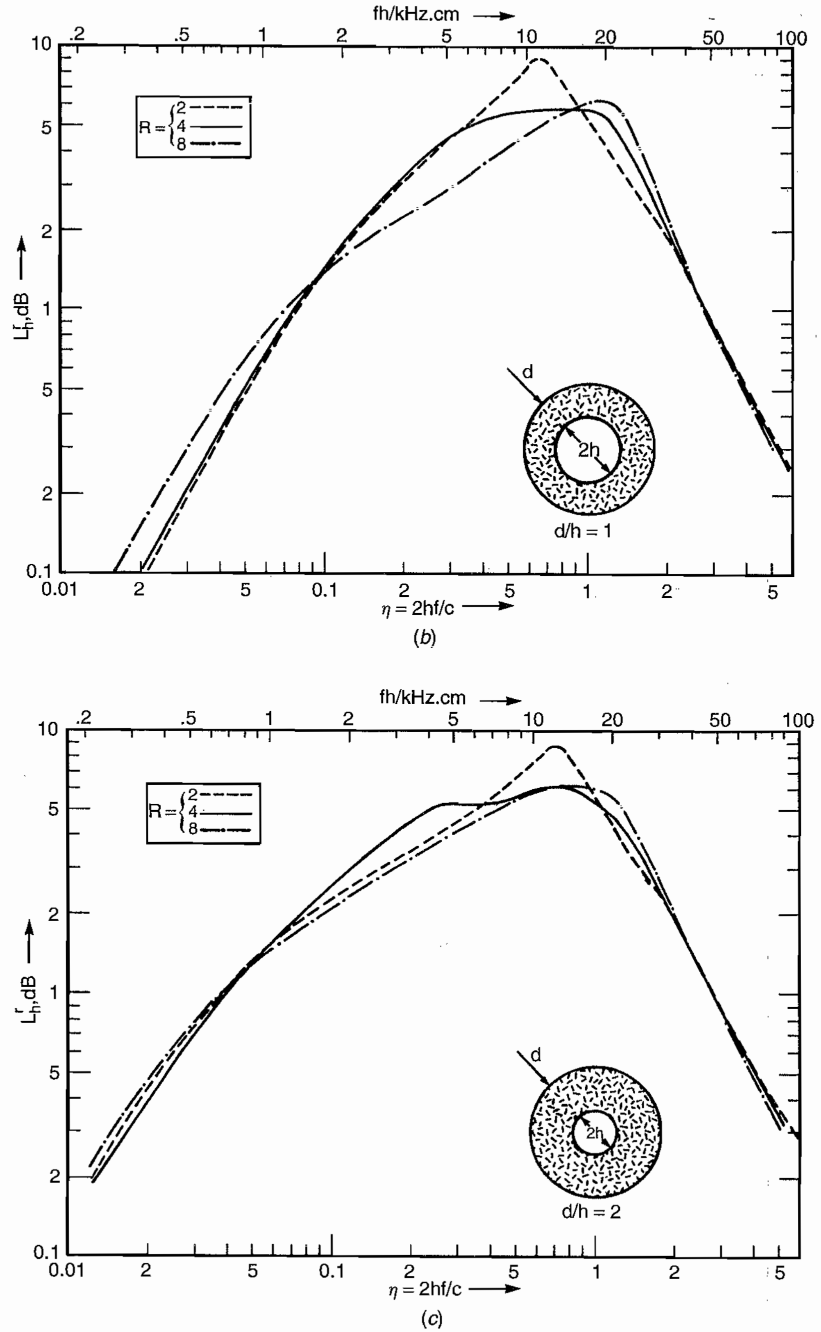


FIGURE 9.28 *(continued)*

for round silencers compared to $L^r_{h,\max} \approx 3$ dB for parallel-baffle silencers. This is because a round passage has twice as high perimeter–area ratio $(2/h)$ than a narrow passage of a parallel-baffle silencer $(1/h)$. As expected, the attenuation bandwidth increases toward low frequencies with increasing lining thickness d. The curves presented in Fig. 9.28 are used in the same way as the corresponding curves for parallel-baffle silencers by applying the design steps listed earlier in the Examples 9.5 and 9.7. Incidentally, similar curves and trends have been predicted by Mechel.[75]

Pod Silencers

Round silencers have a generic disadvantage of providing poor high-frequency performance when the passage diameter is large compared with the wavelength. This disadvantage can be overcome by inserting a center body or pod into the passage[76]. With the center body in place, the round silencer has a narrow annular passage, just like a parallel-baffle silencer, and the attenuation will continue to increase monotonically until the wavelength of the sound becomes equal to the width of the narrow annular passage, as illustrated in the example of Fig. 9.29. Both the rigid and absorbing center bodies result in a modest increase in attenuation at low and midfrequencies, which is mostly due to reduction of the passage cross-sectional area. The attenuation of this silencer without center body

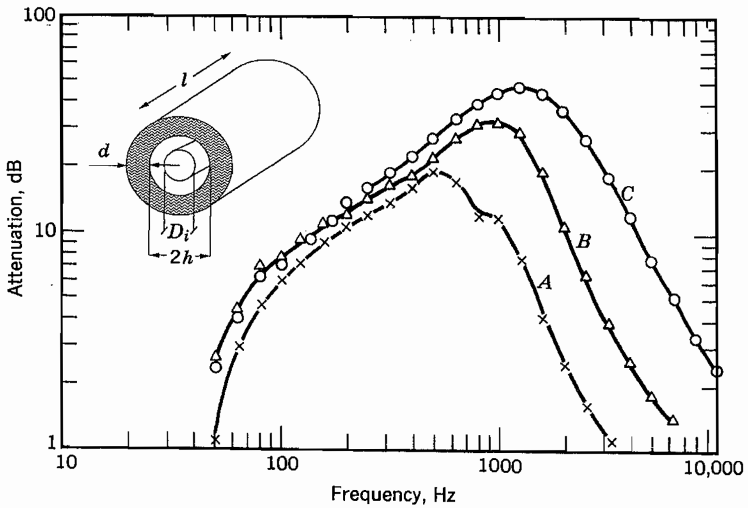

FIGURE 9.29 Effect of center body on the attenuation-versus-frequency curve of a round silencer, passage diameter $2h = 0.6$ m (24 in.), center body diameter $D_i = 0.3$ m (12 in.), lining thickness $d = 0.2$ m (8 in.), length $l = 1.2$ m (48 in.), $T = 20°$C (68°F), $R_1 = 16{,}000$ N · s/m^4 (1ρc/in.): A, no center body; B, rigid center body; C, absorbing center body.

decreases sharply above 560 Hz, the frequency where the wavelength equals the diameter of the passage. With the rigid center body the attenuation continues to increase up to 1130 Hz and with the porous center body up to 2260 Hz.

If center bodies are impractical, the high-frequency attenuation of round silencers can also be increased by inserting parallel baffles into the round passage. Similarly, the high-frequency attenuation of silencers with rectangular cross section can be increased by inserting parallel baffles (oriented perpendicular to the plane of the thick, low-frequency liner, or side branches on the sidewalls) into the rectangular passage. As described in detail by Kurze and Ver[77], the inserted parallel baffles also increase the low-frequency attenuation by a beneficial interaction with the low-frequency part of the silencer located at the walls. The mechanism of this interaction is that the reduction of the wave speed owing to the structure factor of the parallel baffles increases the attenuation performance of the low-frequency liner on the sidewalls. Similarly, the structure factor of the low-frequency liner on the sidewalls increases the attenuation of the parallel baffles. Consequently, the beneficial interaction results in increased sound attenuation at both low and high frequencies. This type of insert silencer also has the benefit of requiring substantially less total silencer length than the traditional series combination of a low- and high-frequency silencer section.

Effect of Flow on Silencer Attenuation

The flow affects the attenuation of sound in silencers in three ways:

1. It changes slightly the effective propagation speed of the sound.
2. By creating a velocity gradient near the passage boundaries, it refracts the sound propagating in the passage toward the lining if the propagation is in the flow direction (exhaust silencers) and "focuses" the sound toward the middle of the passage if the propagation is opposite to the flow direction (intake silencers).
3. It increases the effective flow resistance of the baffle.

Figure 9.30*a* shows the effect of flow on the attenuation performance of an exhaust silencer when the flow direction coincides with the direction of sound propagation. Note that the attenuation is decreased at low frequencies and is increased slightly at high frequencies. In most cases, a Mach number $M > 0.1$ is not permissible because of material deterioration or self-noise.

Figure 9.30*b* shows what happens when the sound propagates against the flow. In this case the attenuation at low frequencies increases because it takes the sound a longer time to traverse through the *muffler* passage. The high-frequency attenuation decreases because the velocity gradients in the passage "channel" the sound toward the center of the passage. The effect of flow on attenuation can be approximated by appropriate shift of the attenuation-versus-frequency curve obtained without flow $(M = 0)$.

The attenuation in the presence of flow is obtained by shifting the no-flow $(M = 0)$ attenuation curve as illustrated in Fig. 9.31*a* when the direction of sound

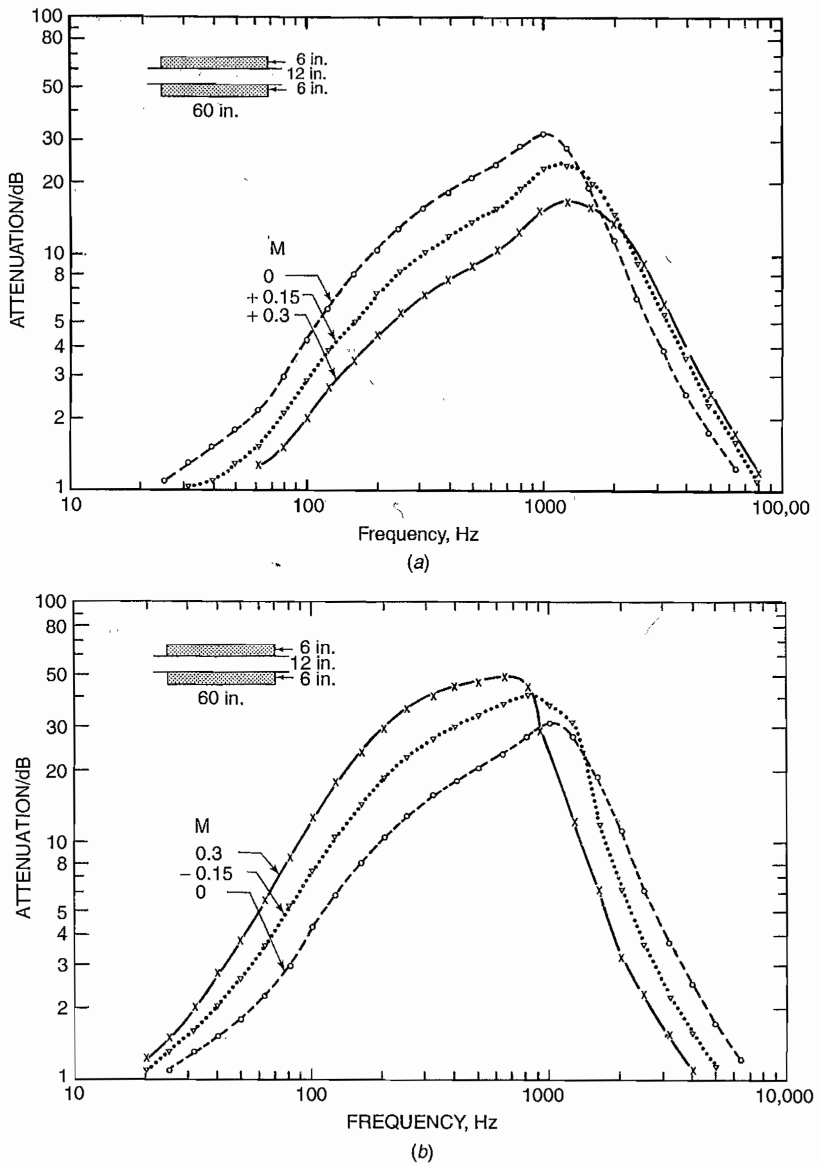

FIGURE 9.30 Effect of flow on sound attenuation for Mach numbers $M = 0$, 0.15, 0.3: sound propagation (*a*) in flow direction and (*b*) against flow direction.

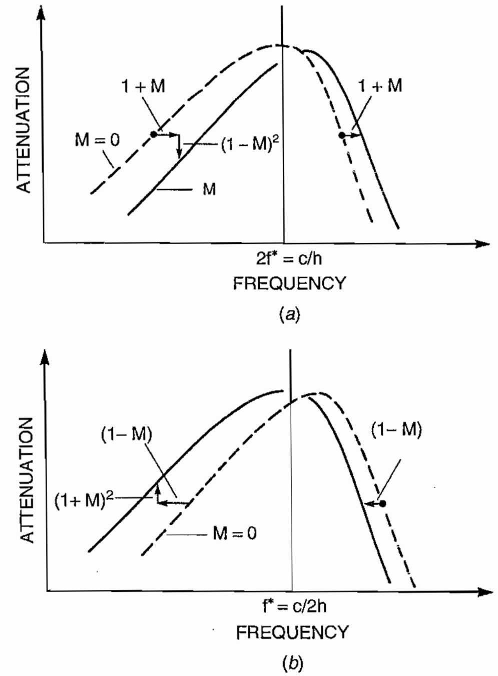

FIGURE 9.31 Rules for shifting the no-flow ($M = 0$) attenuation-versus-frequency curve to account for flow effects: sound propagation (*a*) in flow direction and (*b*) against flow direction.

propagation and the gas flow are the same and in Fig. 9.31*b* when they are opposite.

Figure 9.32 shows the attenuation-versus-frequency curve of a silencer with $M = 0.15$ flow in the direction of sound propagation. The values represented by the crosses are those directly computed for $M = +0.15$ (dotted line in Fig. 9.30*a*) and those represented by the open circles were obtained by shifting the $M = 0$ curve in Fig. 9.30*a* according to the guidelines discussed in conjunction with Fig. 9.31 The agreement between the curve obtained by shifting and by computations (which takes into account flow effects in the wave equation) is good.

The empirical flow correction procedure illustrated in Fig. 9.31 is based on experience with parallel-baffle silencers. We have no experience at present to gauge its applicability and accuracy for other silencer geometries.

Flow-Generated Noise

At present there is no universally accepted method for predicting the flow-generated noise of silencers. Information provided by silencer manufacturers shall be used wherever available. The empirical predictive scheme presented here

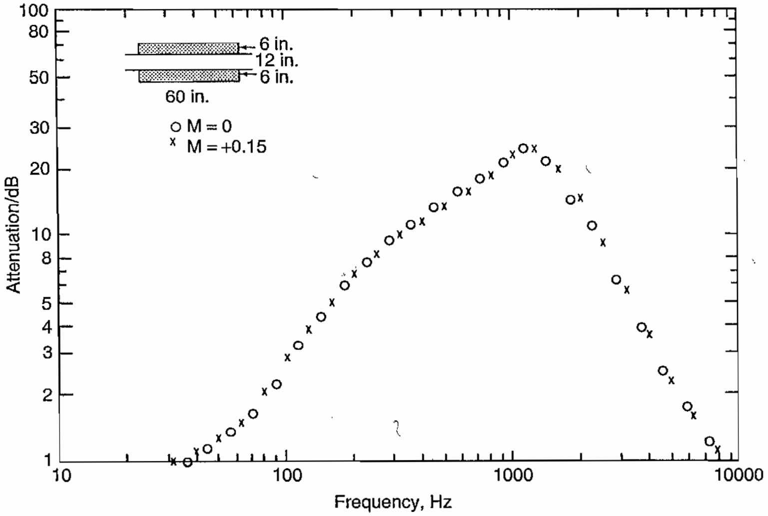

FIGURE 9.32 Attenuation-versus-frequency curve of a silencer for sound propagation in flow direction, $M = +0.15$: (×) computed; (○) obtained by shifting the $M = 0$ curve according to Fig. 9.31*a*.

is based on a broad range of experimental data on flow-generated noise of duct silencers and is reproduced from ISO 14163:1998(E).[78]

An estimate for the octave-band sound power level of regenerated sound can be obtained from Eq. (9.48):

$$L_{W,\text{oct}} = B + \left\{ 10 \lg \frac{PcSn}{W_0} + 60 \lg \text{Ma} + 10 \lg \left[1 + \left(\frac{c}{2fH} \right)^2 \right] - 10 \lg \left[1 + \left(\frac{f\delta}{v} \right)^2 \right] \right\} \quad (9.48)$$

where B = a value depending on type of silencer and frequency, dB
v = flow velocity in narrowest cross section of silencer, m/s
c = speed of sound in medium, m/s
Ma = Mach number (Ma = v/c)
P = static pressure in duct, Pa
S = area of narrowest cross section of passage, m^2
n = number of passages
f = octave-band center frequency, Hz
H = maximum dimension of duct perpendicular to baffles, m
δ = length scale characterizing high-frequency spectral content of regenerated noise, m
$W_0 = 1$ W $= 1$ N · m/s

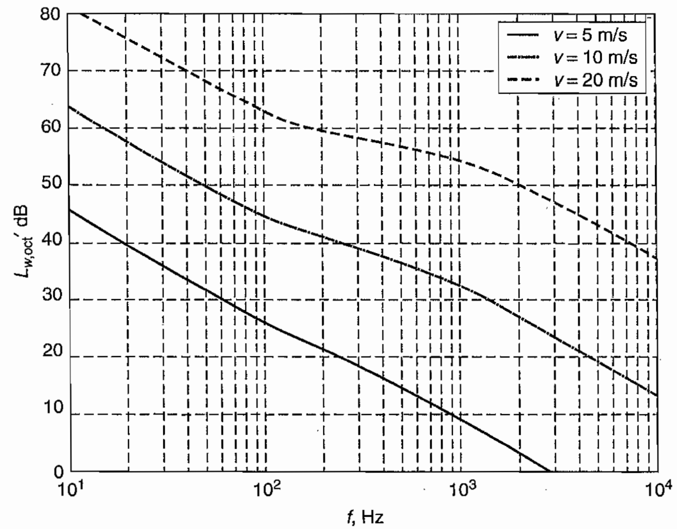

FIGURE 9.33 Octave-band sound power level $L_{W,\text{oct}}$ of regenerated sound versus frequency f for air under ambient conditions in a ducted silencer with narrowest cross section $S = 0.5\ \text{m}^2$, maximum transverse dimension $H = 1$ m, and different flow velocities v.

The sound power level of regenerated sound will vary with the temperature T approximately with $-25 \lg(T/T_0)$ decibels. For smooth-walled dissipative splitter silencers used in heating, ventilation, and air-conditioning equipment, an approximation is given by $B = 58$ and $\delta = 0.02$ m. For this case, a graph of Eq. (9.48) is shown in Fig. 9.33, and the A-weighted sound power level of a duct cross section of 1 m^2 is then calculated from

$$L_{WA} = \left(-23 + 67 \lg \left[\frac{v}{v_0} \right] \right) \quad \text{dB} \quad (9.49)$$

where $v_0 = 1$ m/s. For other types of silencers, particularly for resonator silencers, B may be larger in certain frequency bands. However, no general information can be given on the values of B and δ.

Prediction of Silencer Pressure Drop

The maximum permissible pressure drop at design flow rates and at design temperatures, together with the flow-generated noise, determines the cross-sectional dimensions of a silencer. It is important that the silencer designer makes good use of all the available pressure drop, though with an adequate factor of safety. The maximum permissible pressure drop $\Delta p_{\max}$ must be carefully allocated among the pressure drop of transition ducts (Δp_{trans}) and the total pressure drop of the silencer, Δp_{tot}:

$$\Delta p_{\max} \geq F_s(\Delta p_{\text{trans}} + \Delta p_{\text{tot}}) \quad \text{N/m}^2 \quad (9.50)$$

The specific choice of the safety factor ($F_s > 1$) is influenced by the degree of inhomogeneity of the inflow and by guaranty obligations regarding pressure drop performance of the silencer system. The silencer system usually includes the transition ducts both upstream and downstream of the silencer.

Detailed information on how to predict the pressure drop of inlet and exit transitions has been compiled by Idel'chik.[79] The silencer pressure losses are expressed as a product of the dynamic head in the muffler passage, $0.5\rho v_p^2$, and a loss coefficient. The terms K_{ENT}, K_F, and K_{EX} represent the entrance, friction, and exit loss coefficients. They are predicted according to the formulas given in Table 9.3

The required silencer face area is determined by an iteration process. First, Eq. (9.39) is solved for the passage velocity v_p. The initial face area A'_F is obtained as

$$A'_F = \frac{Q}{v_p}\left(\frac{100}{\mathrm{POA}}\right) \quad \mathrm{m}^2 \tag{9.51}$$

TABLE 9.3 Pressure Loss Coefficient for Parallel Baffle Silencers

Geometry	Loss Coefficient
Square-edge nose 	$K_{\mathrm{ENT}} = \dfrac{0.5}{1 + h/d}$
Rounded nose 	$K_{\mathrm{ENT}} \simeq \dfrac{0.05}{1 + h/d}$
Typical perforated metal facing 	$K_F \simeq 0.0125$ ℓ = baffle length, tail and nose not included
Square tail 	$K_{\mathrm{EX}} = \left(\dfrac{1}{1 + h/d}\right)^2$
Rounded tail 	$K_{\mathrm{EX}} = 0.7\left(\dfrac{1}{1 + h/d}\right)^2$
Faired tail, 7.5° 	$K_{\mathrm{EX}} = 0.6\left(\dfrac{1}{1 + h/d}\right)^2$

where Q is the volume flow rate through the silencer (in cubic meters per second) v_p is the passage velocity (in meters per second), and POA is the percentage of open area of the silencer cross section (e.g., for parallel-baffle muflers POA = 50 means that $h/d = 1$; the passage height is the same as the baffle thickness). Based on this initial value of $A_F = A'_F$, the pressure loss of the inlet and exit transitions is calculated and added to the muffler pressure drop. The total $F_s(\Delta p_{\mathrm{trans}} + \Delta p_T)$ is compared with maximum permissible pressure drop $\Delta p_{\max}$ according to Eq. (9.50). If $F_s(\Delta p_{\mathrm{trans}} + \Delta p_T) > \Delta p_{\max}$, the face area of the silencer must be increased. This results in a decrease of Δp_T and a relatively smaller increase in $\Delta p_{\mathrm{trans}}$, and the iteration is continued until the inequality, expressed in Eq. (9.50), is satisfied.

Economic Considerations

For large silencers such as used in electric power plants, the product of the pressure drop and volume flow rate, $Q\Delta p$, represents a substantial power that is lost (converted to heat). The cost to produce this power during the entire design life of the installation usually far exceeds the purchase cost of the silencer. Therefore, it is important to specify a silencer pressure drop that yields the lowest total cost. The total cost includes the present worth of revenue requirements to purchase and install the silencer (which decreases with increasing pressure drop allowance) and the present worth of revenue requirements of the energy cost caused by operating the silencer (which increases with increasing pressure drop allowance). The optimal pressure drop is that which yields the lowest total cost. Information on how to predict the optimal silencer pressure drop is given in reference 80.

9.7 COMBINATION MUFFLERS

It is clear from Sections 9.1–9.3 that the TL of reactive mufflers is generally characterized by several troughs that limit the overall value of TL notwithstanding the peaks, owing to the arithmetic of antilog summation. The acoustically lined ducts and parallel-baffle mufflers (or splitter silencers) do not suffer from this characteristic; they are characterized by a wide-band TL curve. However, they have rather poor performance (attenuation) at low frequencies where the reactive mufflers have a relative edge. One way out of these limitations is to combine reflective or reactive elements and dissipative elements into a combination muffler (or hybrid muffler). An acoustically lined plenum chamber is one obvious example of a combination muffler. Figures 9.34–9.37 illustrate the concept and present some design guidelines in the process.[81]

Figure 9.34a is an unlined simple axisymmetric expansion chamber. Figures 9.34b,c show the chamber with lining (with resistivity of 5000 Pa · s/m^2) of 18.2 and 36.4 mm thickness, respectively. The plots in Fig. 9.34 compare the computed values of their axial transmission loss TL$_a$ (assuming rigid shell). Clearly, the role of lining is to raise and even out the troughs, particularly at the medium and high frequencies.

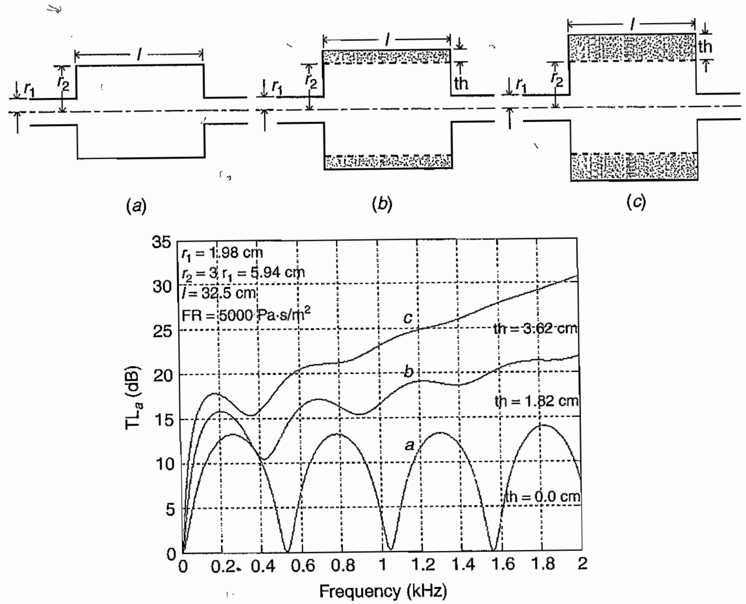

FIGURE 9.34 Use of acoustical lining in combination with a simple expansion chamber or plenum; th = lining thickness in centimeters.

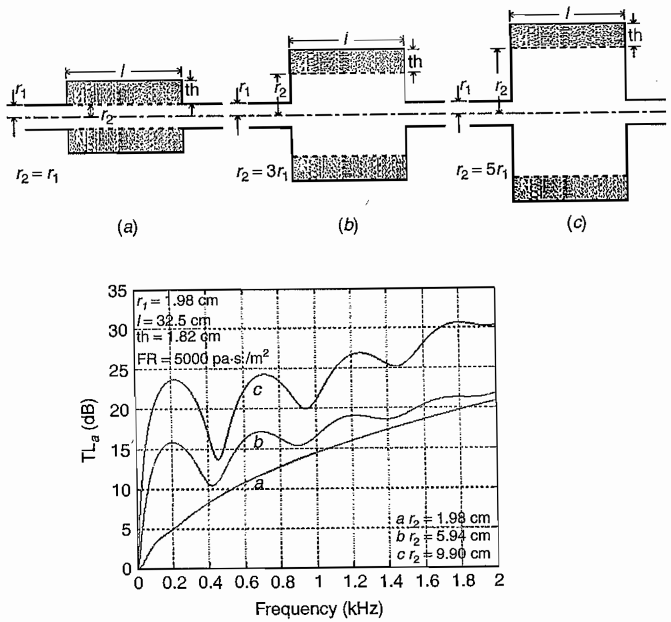

FIGURE 9.35 Use of sudden area discontinuities in combination with lined duct.

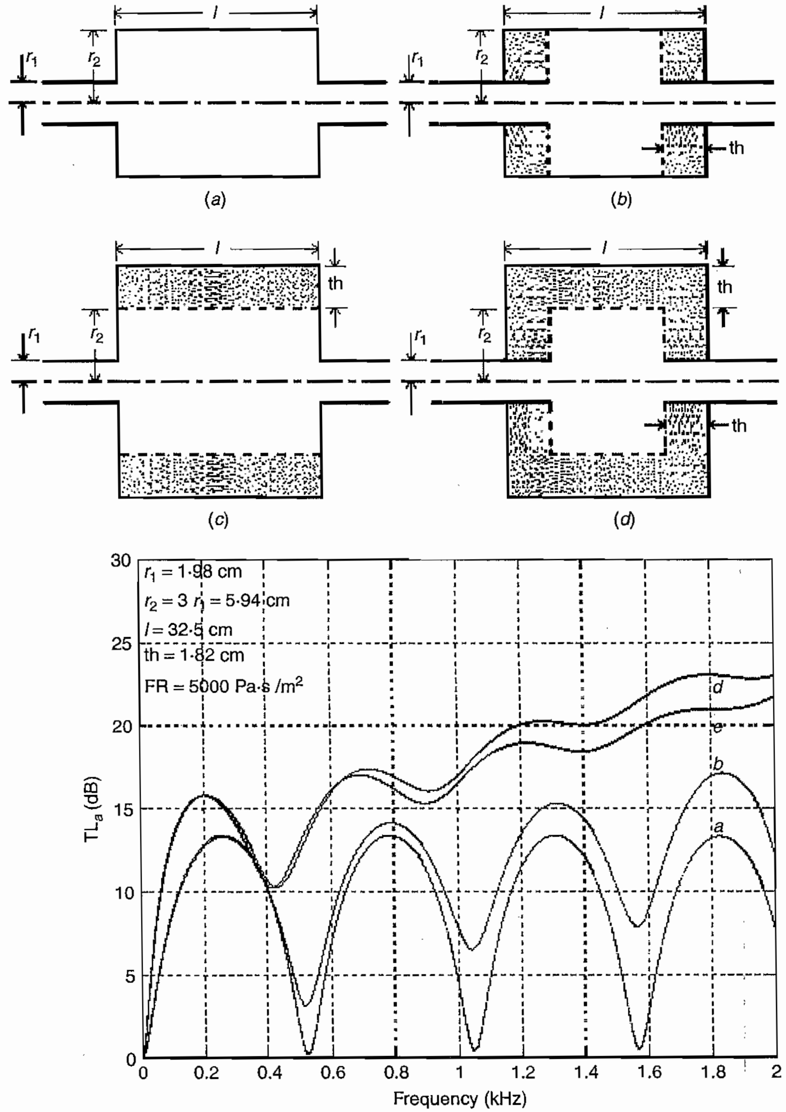

FIGURE 9.36 Effect of lined walls and lined shell.

Figure 9.35 shows the effect of building a sudden expansion and contraction into an acoustically lined circular duct, keeping the radial thickness of the lining constant. As can be noticed, the area discontinuities (sudden impedance mismatch) increase TL, particularly at the low frequencies ($\leq$ 400 Hz).

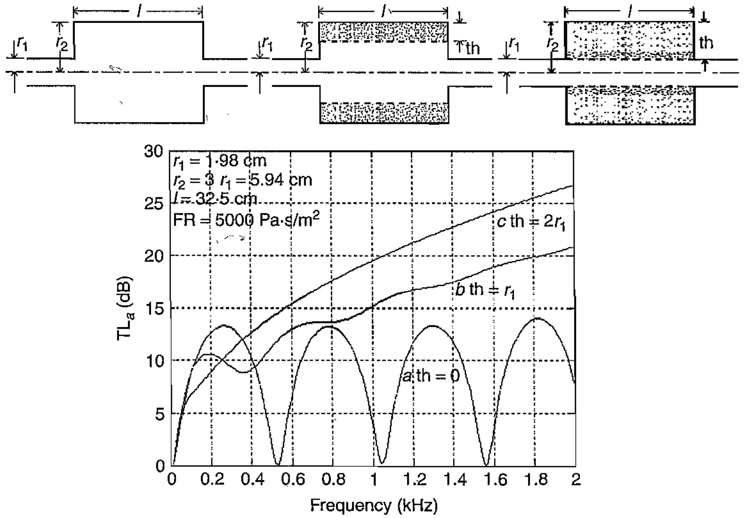

FIGURE 9.37 Reactive elements versus dissipative elements within the same overall shell radius.

A plenum chamber has lining not only on the shell but also on the sidewalls/plates. Figure 9.36 shows (a) a simple expansion chamber (plenum), (b) one with lined sidewalls, (c) one with lined shell only, and (d) one with lined shell as well as lined sidewalls (or end plates). It may be noticed that while the sidewall lining has considerable effect (in raising the troughs), the effect of shell lining is much more pronounced. In fact, a comparison of curves *b* and *c* of Fig. 9.36 shows that the relative effect of sidewall lining is only marginal.

In all the three foregoing figures, provision of lining has increased the overall radius of the muffler shell. Sometimes, it may not be feasible or advisable to increase the shell radius. Then, the internal lining of the shell would decrease the ratio of sudden expansion and sudden contraction. Figure 9.37 shows the effect of this compromise (between reaction and dissipation), keeping the overall shell radius constant. It may be observed that the performance of lined ducts is relatively poor at very low frequencies, when a simple unlined chamber has an edge. The two can supplement each other in a combination muffler (configuration *b* in Fig. 9.37).

CHAPTER 10

Sound Generation

ISTVÁN L. VÉR

Consultant in Acoustics, Noise, and Vibration Control
Stow, Massachusetts

Acoustical engineers can be grouped into two categories: those who try to *minimize* the efficiency of sound radiation and are called *noise control engineers* and those who try to *maximize* it and are called *audio engineers*. This book addresses the first group exclusively.

The main duty of noise control engineers is to know how to reduce, in a cost-effective manner, the noise produced by equipment at the location of an observer. The noise reduction can be achieved (1) *at the source*; (2) *along the propagation path* by building extensive barriers between the source and receiver, installing silencers, and so on, as discussed in Chapters 5 and 9; and (3) *at the receiver* by enclosing it, as discussed in Chapter 12, or by creating a limited "zone of silence" around it by active noise control, as described in Chapter 18.

The most effective, and by far the least expensive, noise control can be achieved at the source by reducing its sound radiation efficiency. A reduction of the efficiency of noise generation of the source results in a commensurate *reduction of the noise at all observer locations*. In comparison, the erection of barriers, enclosing the receiver, and creating a localized "zone of silence" at the receiver are *effective only in limited spatial regions*. Putting silencers on the noisy equipment is cumbersome and usually increases the size and weight and reduces the mechanical efficiency of the equipment. The last two measures are often referred to as the *brute-force* methods.

The reduction of the efficiency of noise radiation at the source can be achieved passively by changing the shape of the body if its vibration velocity is given and by changing both the shape and mass of the body if the vibratory force acting on it is given. Reducing the efficiency of sound radiation by active means is generally accomplished by placing a secondary sound source of the same volume displacement magnitude but opposite phase in the immediate vicinity of the body, as discussed in detail in Chapter 18, or by a combination of these passive and active measures.

If constructional changes are possible, always the passive measures should be implemented first, even if the needed additional reduction will be achieved by active means. Even if they do not achieve all the needed noise reduction, passive noise control measures reduce the demand on the power-handling capability of the noise-canceling loudspeakers. In addition, passive noise control measures remain effective in case the active control fails. The most desirable, but also the most difficult to achieve, passive noise control measures are those which require constructional changes of the equipment. Not infrequently, the same constructional changes that reduce the efficiency of sound radiation also may improve the mechanical efficiency of the equipment. The primary purpose of every machine is to perform a specific, usually mechanical, function. The noise is an unwanted by-product. The reduction of the efficiency of sound radiation at the source must always be accomplished without interfering with the primary function of the equipment. As we will show later, the reduction in the efficiency of sound radiation of any noise source is always achieved by reducing the force or forces that act on the surrounding fluid.

10.1 BASICS OF SOUND RADIATION

This chapter deals with the sound radiation of small pulsating and oscillating rigid bodies. Throughout this chapter the adjective *small* means that the dimensions of the body are small *compared with the acoustical wavelength*. Sound radiation of large bodies is treated in Chapter 11. An exhaustive treatment of the sound radiation of all types of bodies is given in reference 1.

Historical Overview

Technical acoustics is a branch of applied physics. All acoustical phenomena can be derived from Newton's basic laws. During the early part of the last century the science of technical acoustics has been developed mainly by physicists with a strong background in electromagnetism or by electronics engineers. The reason for this is that only they had the mathematical background to deal with dynamic phenomena in general and, most importantly, with the wave equation. In those days, the education of mechanical engineers was almost exclusively in static deformation of structures and *slow* phenomena in hydrodynamics. Physicists often describe the acoustical phenomena by mathematical formalisms that facilitate the mathematical analyses. Unfortunately, these formalisms, such as *monopoles, dipoles, quadrupoles, "equivalent electric circuits," and "short circuiting,"* were often not familiar to mechanical engineers. This built artificial barriers for the mechanical engineers which have been overcome only in the last few decades due to the dramatic increase in the education of mechanical engineers in dynamic phenomena.

This chapter attempts to explain the important phenomena of sound generation in a form, the author believes, that might have been done if the theory of sound generation had been developed by mechanical engineers. As we will show in the remainder of the chapter, the sound radiation phenomena can be fully described without knowing anything about monopoles, dipoles, quadrupoles, and equivalent electric circuits.

The added advantage of characterizing the sound sources by the force and the moment they exert on the fluid rather than assigning abstract descriptors such as *equivalent point sound source, dipole strength,* and *quadrupole strength* means that such characterization gives a better understanding of the physical phenomena involved and identifies the actual physical parameters that control all types of sound generation processes.

Qualitative Description of Sound Radiation of Small Rigid Bodies

Small rigid bodies oscillating in an unbounded fluid experience three types of reaction forces; (1) inertia force needed to accelerate the fluid to move out of the way of the body, (2) force to compress the fluid, (3) friction forces owing to the viscosity of the fluid.

The inertia force, which is by far the largest of them, is 90° out of phase with the velocity of the body. The compressive force is in phase with the velocity and is much smaller than the inertia force. However, it has to be considered because it determines the sound radiation. The friction force is usually small enough compared with the two other components that it can be neglected by assuming that the fluid has no viscosity.

Sound is generated by phenomena that cause a localized compression of the fluid (gases or liquids). This chapter deals with the most common sources of sound generated by pulsation and oscillatory motion of small rigid bodies and by pointlike forces and moments acting on the fluid.

Anyone who has operated a bicycle pump can attest to it that it takes considerable force to maintain a repetitive pumping motion of the piston when the valve is closed. The compression of the air in the closed cavity generates a large reaction force that opposes the motion of the piston. The opposing force depends only on the magnitude of the stroke and does not depend on the rapidity of the pumping.

It takes considerably less force to perform the same repetitive pumping motion when the valve is open and the hose is not connected to the tire. The force that resists the stroke in this case is the inertia force needed to push the air mass (stroke times surface area of the piston times the density of the air) through the open valve. The inertia force is proportional to the acceleration (i.e., the rapidity of the pumping motion) of this mass. The reaction force is very small if the rate of repetition is low and increases with increasing repetition rate. At sufficiently high repetition rate it becomes harder to accelerate the air mass that must be pushed through the open valve during increasingly shorter time periods than to compress the air in the pump's cavity. In this case the force needed to operate the leaky pump approaches that needed to operate the pump with the valve closed.

As we will see, similar behavior is observed in the sound radiation of small rigid bodies where the surrounding fluid is compressed in earnest only when the force needed to move the fluid in the vicinity of the pulsating or oscillating body out of the way becomes the same order of magnitude as that required to compress it.

Pulsating Small Rigid Bodies. If a small body, exemplified by a pulsating sphere, operates at low frequencies where the wavelength of the sound is large compared with the acoustical wavelength, the pressure has two components. One is 90° out of phase with the velocity of the pulsating surface and a much smaller component is in phase with it. The former component is owing to the inertia of the surrounding fluid that is pushed into a larger spherical area during the outward motion of the pulsating surface and pulled back during the inward movement without much compression. The latter component of the pressure, which is in phase with the surface velocity, is owing to the compression of the surrounding fluid.

The force needed to overcome the inertia of this back-and-forth sloshing fluid volume increases with increasing frequency and so does the in-phase component of the surface pressure. Above a frequency where the wavelength becomes smaller than six times the radius of the sphere, it becomes easier to compress the fluid than to accelerate the fluid volume and the pulsating sphere becomes an efficient radiator of sound. Both the in-phase and 90° out-of-phase components of the pressure are evenly distributed over the surface of the sphere and the pulsating sphere radiates sound omnidirectionally.

At low frequencies not only the pulsating sphere but also all pulsating small bodies have an omnidirectional sound-radiating pattern and both the far-field sound pressure and radiated sound power depend only on the net volume flux and the frequency irrespective of how the vibration pattern is distributed over their surface. Because of these unique properties, pulsating small bodies are referred to as monopoles.

Oscillating Small Rigid Bodies. In the case of an oscillating rigid body, exemplified by an oscillating sphere, the fluid pushed aside by the forward-moving half of the sphere is "sucked in" by the void created by the receding half of the sphere. The fluid moves back and forth around the sphere between the two poles. The velocity of the fluid is highest near the surface of the sphere and decreases exponentially with increasing radial distance. This exponentially decreasing velocity field is referred to as the near field. The kinetic energy flux of the near field depends on the geometry of the body, the direction of the oscillatory motion, and the density of the fluid surrounding the body. The quantity *added mass/fluid density* is a property of the body and its motion. It is referred to in the acoustical literature as the *added volume*. In the hydrodynamic literature the *added mass coefficient* is defined as the ratio of the added volume, V_{ad}, and volume of the body, V_b.

Push–pull action between the poles (located in the direction of the oscillatory motion) makes it easy to move the fluid back and forth and the surface of the oscillating small rigid sphere, for the same surface velocity, experiences much smaller reaction pressure than the pulsating sphere and radiates substantially less sound. The magnitude of the reaction pressure on the surface of the oscillating sphere has its maxima at the poles where the radial velocity has its maxima and zero at the equator where the radial velocity is zero. Consequently, the sound radiation pattern is maximum in the direction of the oscillatory motion and zero in the direction perpendicular to it. This behavior is not restricted to the oscillating sphere but holds for small oscillating rigid bodies of any shape. In analogy to the similar radiation patter of the magnetic field caused by an oscillating charge, oscillating small rigid bodies are referred to as dipole sound sources.

The net oscillatory force exerted on the fluid is obtained by integrating the pressure distribution over the surface of the sphere. The force points in the direction of the oscillatory motion. As we will show later, with respect to sound radiation, a small, oscillating rigid body is equivalent to a pointlike force (i.e., pressure exerted by a small surface) acting on the fluid. The radiated sound power is obtained as the product of the body's velocity and the component of the net reaction force that is in phase with the velocity.

The distribution of the reaction pressure on the surface is known only for a few bodies. Consequently, the net oscillatory force they exert on the fluid (and consequently the radiated sound field) cannot be obtained directly. As we will show later, the force exerted on the fluid by such bodies—and consequently also their sound radiation pattern—can be predicted on the bases of the oscillatory velocity and geometry of the body and its added mass in the direction of the oscillatory motion. The latter can be found frequently in the hydrodynamic literature or can be determined experimentally by measuring the resonance frequency of the body supported on a spring; first in a vacuum then immersed in a fluid (preferably a liquid).

Moment Excitation: Lateral Quadrupole. Two closely spaced identical small rigid bodies oscillating in the same direction but 180° out of phase, or the equivalent two closely spaced parallel pointlike forces acting on the fluid 180° out of phase, are referred to as a *lateral quadrupole*. The forces constituting the moment are frequently due to shear strain. Both of these descriptions are helpful in understanding the sound radiation properties.

If we consider the representation of the two closely spaced small rigid bodies oscillating in opposite directions, it becomes apparent that the fluid pushed aside by the pole of one of the bodies does not need to be moved around to the opposite pole but is easily moved into the void created by the receding pole of the second body. The reaction pressure on the surface of each of the bodies, and consequently the sound field they produce, is substantially smaller than would result when only one of the bodies would oscillate.

If we consider the model of two parallel closely spaced pointlike forces, we realize that the lateral quadrupole represents excitation of the fluid by a moment.

The source strength is characterized by the moment, regardless of whether the moment is constituted by large forces spaced very close to each other or by smaller forces spaced at a larger distance apart, provided that the distance is still much smaller than the wavelength.

The sound radiation pattern of a lateral quadrupole is zero in two planes. The first of this is perpendicular to the plane defined by the two parallel forces and cuts the plane of the forces halfway between them. All points located in this plane have an equal distance from the two bodies moving in opposite directions and their contribution to the sound field cancels each other.[2] The second plane of zero sound pressure is perpendicular to the direction of the motion of the oscillating bodies and cuts through their center. The sound pressure is zero at all points on this plane because the two oscillating bodies constituting the lateral dipole have zero radial velocity in these directions.

The sound radiation pattern has maxima in two planes. Both of these planes cut the zero planes at 45° angles. In two dimensions the radiation pattern resembles an old-fashioned, four-bladed propeller where the four maxima are represented by the four blades and the minima by the void between the blades.

If the two opposing forces are of different magnitude, the sound radiation pattern is the superposition of the quadrupole radiation pattern associated with a moment constituted by two opposing forces having the same magnitude as the smaller force and a dipole pattern associated with a single pointlike force that equals the difference between the two forces.

Because the maxima of the dipole pattern "fill" the zero planes of the quadrupole pattern, the resulting radiation pattern has no zero value in any direction.

Sound Excitation by Two Opposing Forces Aligned Along a Line: Longitudinal Quadrupole. If two equal-magnitude but opposing dynamic forces are placed on a line a small distance apart (or the equivalent of two identical small rigid bodies are oscillating 180° out of phase), the sound radiation pattern resembles that of a single pointlike force. However, the two maximum lobes, pointing in the direction of the forces, are much narrower and the radiated sound power is much smaller than if only one of the forces acted on the fluid. In analogy to the directivity pattern of the magnetic field generated by two closely spaced charges oscillating in the opposite direction, this type of sound source is referred to as a longitudinal quadrupole. This type of radiation pattern occurs when a small rigid body oscillates in water near to and perpendicular to the water–air interface. In this case the mirror image represents the identical second body that oscillates 180° out of phase.

If the two opposing forces are not equal, then the resulting radiation pattern is the superposition of the pattern of a longitudinal quadrupole and a dipole. Because both radiation patterns have zero value in a plane that is perpendicular to the forces and cuts through the center of the force pair, the resulting radiation pattern has zero value in this plane. The contribution of the dipole component widens the two maximum lobes.

Radiated Sound Power. The sound power radiated by all of the above-discussed sound sources can also be determined by integrating the intensity $p^2_{\text{rms}}(r, \vartheta, \theta)/\rho_0 c_0$ over a large radius ($kr \gg 1$) sphere centered at the acoustical center of the source, where $p^2_{\text{rms}}(r)$ is the mean-square value of the sound pressure at distance r in the direction designated by the angles ϑ and θ.

Acoustical Parameters of Sound Radiation

This section contains a brief introductory discussion of the acoustical parameters of fluids, including the speed of sound, density, and plane-wave acoustical impedance.

Propagation Speed of Sound in Fluids. The molecules of fluids and gases in equilibrium undertake a random motion with equal probability of direction, c_t, and the propagating speed in a stationary fluid, c_0, given by[2]

$$c_0 = c_t\sqrt{\gamma} = \sqrt{\frac{\gamma RT}{M}} \quad \text{m/s} \tag{10.1}$$

where $\gamma = c_p/c_v$ is the specific heat ratio with $\gamma \approx 1.4$ for air and $\gamma \approx 1.3$ for steam, R is the universal gas constant ($R = 8.9$ J/K), T is the absolute temperature in degrees Kelvin (K), (0 K = −273°C), and M is the molar mass equal to 0.029 kg/mole for air and 0.018 kg/mole for steam. For air Eq. (10.1) yields

$$c_0 = 20.02\sqrt{T\,(\text{K})} = 342.6\sqrt{\frac{T\,(\text{K})}{293}} = 342.6\sqrt{\frac{T\,(^\circ\text{C}) + 273}{293}} \quad \text{m/s} \tag{10.2}$$

For air at 20°C = 68°F = 293 K the propagating speed is $c_0 = 342.6$ m/s, at which a sound wave travels in air. The individual molecules collide with each other in a random fashion exchanging momentum with each other. If they impinge on a solid impervious wall, they rebound back from it. Sound is generated when dynamic forces acting on the fluid superimpose a very small but organized dynamic velocity on the very large random velocity of the molecules. The word "organized" means that in the case of periodic motion the superimposed velocity has a specific direction and a specific frequency and in the case of random motion it has a direction and its frequency composition can be described either by its power spectrum or autocorrelation function, as described in Chapter 3. In a stationary fluid the kinetic energy of the molecules acquired through the excitation causes compression and the compression then accelerates the molecules. In a stationary fluid the kinetic energy and potential energy are in balance in any small volume of the fluid. If the sound source acts on a moving media, the kinetic energy depends on the velocity and the direction of the fluid movement. In this chapter we will deal with stationary media only. Sound radiation in moving media is covered in Chapter 15.

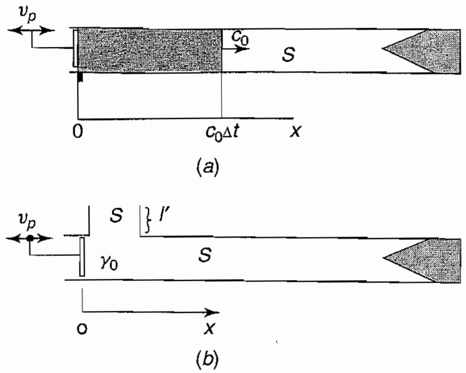

FIGURE 10.1 Oscillating plane rigid piston radiating sound into a small-diameter rigid pipe that is either infinitely long or anechoically terminated: (*a*) Hypothetical experiment to determine the plane wave impedance of fluids, No side branch; (*b*) open side branch of the same cross section area S as the face area of the piston and effective length l'.

The superimposed organized particle velocity of sound we experience is usually in the range 10^{-8} m/s (corresponding to a sound pressure level of 14 dB re 20 μPa) to 10^{-4} m/s (corresponding to 94 dB re 20 μPa).

Plane-Wave Impedance. The plane-wave impedance can be obtained by performing a hypothetical experiment similar to that suggested by Ingard,[2] as shown in Fig. 10.1*a*.

Hypothetical Experiment 1. Assume, as sketched in Fig. 10.1*a*, that a plane, rigid piston of surface area S is located on the left end of a small-diameter (much smaller than the wavelength), infinitely long or anechoically terminated tube with rigid walls filled with a fluid of density ρ_0 and speed of sound c_0. If the piston moves to the right with a constant speed of v_p, the face of the piston experiences a reaction pressure. To determine the plane-wave impedance defined as $Z_0 = p(x = 0)/v_p$, we need to find that particular pressure $p(x = 0)$ at the piston–fluid interface (at position $x = 0$) that results from the piston velocity v_p. At the time Δt, the shaded volume of the fluid on the left, $S_0 c_0 \,\Delta t$, has acquired the particle velocity v_0 and the rest of the fluid on the right is motionless. The momentum M acquired by the fluid during the time Δt is then $M = v_0 \rho S_0 c_0 \,\Delta t$. According to Newton's law the force on the interface is

$$F(x = 0) = Sp(x = 0) = \frac{d}{dt} M \,\Delta t = v_p \rho_0 S c_0 \quad \text{N} \qquad (10.3)$$

yielding the plane wave impedance Z_0,

$$Z_0 \equiv \frac{p(x = 0)}{v_p} = \rho_0 c_0 \quad \text{N} \cdot \text{s/m}^3 \qquad (10.4)$$

Performing the same thought experiment on a solid bar yields the plane-wave impedance of a solid as

$$Z_0 \approx \rho_M c_L \quad \text{N} \cdot \text{s/m}^3 \qquad (10.5)$$

where c_L = propagation speed of longitudinal waves in bar, $(E/\rho)^{1/2}$ m/s
ρ_M = density of solid material, kg/m^3
E = Young's modulus, N/m^2

If the piston oscillates with a velocity of the form $v_p\, e^{j\omega t}$, starting at $t = 0$, the sound pressure in the tube filled with a fluid (air) is

$$p(x, t) = v_p \rho_0 c_0 \, e^{-jkx} \, e^{j\omega t} \quad \text{N/m}^2 \qquad (10.6)$$

and the sound power radiated by the piston, W_{rad}, is

$$W_{\text{rad}} = \tfrac{1}{2} \hat{v}_p \,\text{Re}[\hat{p}_p(x = 0)]\, S \rho_0 c_0 \quad \text{N} \cdot \text{m/s} \qquad (10.7)$$

where in Eqs. (10.6) and (10.7) $\omega = 2\pi f$, f is the frequency in hertz, $k = \omega/c_0$ is the wavenumber, and the hat above the symbol signifies the peak value. Observing Eqs. (10.6) and (10.7), note that the higher is the product of density and speed of sound, the larger are the sound pressure and the radiated power that a given excitation velocity v will generate.

For example, when plane waves are generated in a column of air, water, and steel, an enforced velocity v = 1 mm/s = 10^{-3} m/s will produce the sound pressure p, sound pressure level SPL (in dB re 2×10^{-5} N/m^2) listed below. Assuming that the cross-sectional area is 10^{-4} m^2, we also can predict the radiated sound power W_{rad} in watts:

Material	ρ (kg/m^3)	c (m/s)	p (N/m^2)	SPL (dB)	W_{rad} (W)
Air inside rigid tube	1.21	344	0.42	86	4.2×10^{-8}
Water inside rigid tube	998	1481	1478	157	1.5×10^{-4}
Steel bar in air	7700	5050	3.9×10^4	186	3.9×10^{-3}

In plane waves all of the volume displacement produced by the vibratory excitation at the interface is converted into compression and the resulting sound pressure at the interface is in phase with the excitation velocity. In this case, the sound radiation is that which is the maximum achievable. In other situations, where the volume displaced by the vibratory excitation is mainly used for "pushing aside" rather compressing the fluid, the resulting sound pressure at the interface is much smaller. That is, the pressure has only a small component that is in phase with the vibration velocity of the excitation, which is the reason for the inefficient low-frequency sound radiation of small bodies. For such small sound sources, maintaining the same velocity with increasing frequency means that it is increasingly more difficult to push aside the fluid. When it becomes much easier to compress the fluid than to push it aside, the pressure produced at the interface reaches its maximum and is nearly in phase with the excitation velocity and the efficiency of sound radiation approaches that of a plane wave. The remaining very small but finite phase difference is essential because it determines the radius of curvature of the wave front.

Piston Generating Sound in Rigid Tube with Open Side Branch. To illustrate the effect in a quantitative manner that the efficiency of sound generation is decreased if it is easier to push the fluid aside than to compress it, consider the situation shown in Fig. 10.1*b*. It differs from the situation depicted in Fig. 10.1*a* by the addition of an open side branch to the pipe in the immediate vicinity of the piston. Let assume that the piston, the main pipe, and the side-branch pipe all have the same cross-sectional area S and that the effective length of the open-ended side branch is l'. The mass of the air in the side branch is $\rho_0 S l'$. The force needed to push this mass aside, $j\omega v_p \rho_0 S l'$, is smaller than the force $v_p \rho_0 c_0 S$ needed to compress the fluid, and the presence of the open side branch will reduce the ability of the piston to exert force on the fluid.

The sound pressure that the oscillating piston with peak velocity amplitude $\hat{v}_p$ produces is given by

$$\hat{p}(x=0) = \hat{v}_p \frac{1}{1/(j\omega\rho_0 l') + 1/(\rho_0 c_0)} \quad \text{N/m}^2 \tag{10.8}$$

Separating the real and imaginary parts in Eq. (10.7) yields

$$\hat{p}(x=0) = \hat{v}_p \frac{(\omega\rho_0 l')^2 \rho_0 c_0 + (j\omega\rho_0 l')(\rho_0 c_0)^2}{(\rho_0 c_0)^2 + (\omega\rho_0 l')^2} \quad \text{N/m}^2 \tag{10.9}$$

At low frequencies where $\omega\rho_0 l' \ll \rho_0 c_0$, Eq. (10.8) yields

$$\hat{p}(x=0) \approx \hat{v}_p(j\omega\rho_0 l') \quad \text{N/m}^2 \tag{10.10}$$

At high frequencies where $\omega\rho_0 l' \gg \rho_0 c_0$, Eq. (10.8) yields

$$\hat{p} \approx \hat{v}_p \rho_0 c_0 \quad \text{N/m}^2 \tag{10.11}$$

Inspecting Eqs. (10.9) and (10.10), note that the sound pressure produced by the piston is small, is nearly 90° out of phase of the velocity of the piston, and increases linearly the frequency ω. Using the vocabulary of electric engineers, the low impedance of the mass in the open side branch, $j\omega\rho_0 l'$, "shunts" $\rho_0 c_0$, the plane-wave impedance of the fluid in the tube.

More specifically at low frequencies most of the volume displaced by the oscillating piston flows into the open side branch, where it encounters little "resistance," and only a very small portion flows into the main tube. Consequently,

the magnitude of the reaction force exerted on the piston owing to the presence of both the side branch and the main pipe is only a minute amount larger than the small force needed to keep the fluid mass in the side branch oscillating. The same small force is exerted on the fluid in the main pipe. This force is substantially smaller than it would be if the entrance of the side branch were closed. Accordingly, the sound pressure in the main tube is also substantially smaller.

The sound power that the piston is radiating into the main tube is the product of the velocity of the piston and the small component of the reaction force that is in phase with the velocity and is given by

$$W_{\text{rad}} = \tfrac{1}{2}\hat{v}_p \operatorname{Re}[\hat{p}(x=0)]\, S = \tfrac{1}{2}\hat{v}_p^2 S \frac{\rho_0 c_0 (\omega\rho_0 l')^2}{(\rho_0 c_0)^2 + (\omega\rho_0 l')^2} \quad \text{N}\cdot\text{m/s} \tag{10.12}$$

The hat above the variables indicates peak amplitude. If the rms value of the piston' velocity were used, the factor $\frac{1}{2}$ would be omitted in Eq. (10.12).

Inspecting Eq. (10.12), note that at low frequencies where $\omega\rho_0 l' \ll \rho_0 c_0$, the radiated sound power approaches zero with decreasing frequency. At high frequencies where $\omega\rho_0 l' \gg \rho_0 c_0$, the radiated sounds power becomes independent of frequency and approaches that obtained in Eq. (10.7) for the pipe without an open side branch.

Pipe with Open Side Branch Representing Sound Radiation of Pulsating Sphere. Following the qualitative suggestion by Cremer and Hubert,[3] we are assigning the specific values for S and l' in Eqs. (10.9) and (10.12), namely, $S = 4\pi a^2$, $\hat{v}_p = \hat{v}_s$, and $l' = a$, and considering that the wavenumber $k = \omega/c_0$ and $\hat{v}_p S = \hat{v}_s 4\pi a^2 = \hat{q}$ is the peak volume velocity of our sound source, Eq. (10.9) yields the well-known[3] formula for the peak value of the sound pressure on the surface of the sphere:

$$\hat{p}(a) = \hat{v}_s \frac{j\omega\rho_0 a}{1 + jka} \quad \text{N/m}^2 \tag{10.13}$$

Also note that the volume of fluid in the side branch is $V_{\text{ad}} = 4\pi a^3$ and the added mass of the fluid is $M_{\text{ad}} = 4\pi a^3 \rho_0$. For a pulsating sphere the volume V_{ad} is three times the volume of the sphere and is called the *added volume* in the acoustical literature and in M_{ad} is called the *added mass*. The added mass plays a central role in the sound radiation of small pulsating and oscillating rigid bodies. The added mass is a measure of the ability of these bodies to exert a dynamic force on the surrounding fluid.

Substituting the same values into Eq. (10.12) yields the well-known formula[4] for the sound power radiated by the a pulsating sphere of radius a and peak surface velocity $\hat{v}_s$:

$$W_{\text{rad}} = \hat{v}_s^2 4\pi a^2 \left(\frac{\rho_0 c_0}{2}\right) \frac{(ka)^2}{1 + (ka)^2} = \hat{q}^2 \left(\frac{\rho_0 c_0}{2}\right) \frac{(ka)^2}{1 + (ka)^2} \quad \text{N/m}^2 \tag{10.14}$$

Sound Radiation by Volume-Displacing Sound Sources

To describe the sound radiation of small volume-displacing sound sources, we take the unusual approach of starting with the case where the source operates in the most restrained environment and then gradually weakening the restraints to arrive at the unrestrained case where the sound source operates in an undisturbed infinite fluid.

On the top of Figure 10.2 is shown the starting point where the volume-displacing sound source is represented by a piston that vibrates with an axial velocity v_p in the mouth of a rigid linear horn. The horn represents the restraint. The linear horn is a rigid hollow cone with the tip cut off. The cutoff end becomes the mouthpiece of the horn. The diameter of the cross-sectional area of the linear horn increases linearly with increasing distance r from the tip and its cross-sectional area increases with r^2. The cross-sectional area of the horn at its mouth, $l\theta$, is chosen to fit the mouth of a human speaker. The symbol θ is the solid angle (θ equals π for a quarter space, 2π for a half space, and 4π for a full space, as illustrated in Fig. 10.3).

The cross-sectional area at the large end of the horn is chosen to be $S_{\text{End}} \geq \lambda^2 \geq c_0^2/f_{\text{int}}^2$, where f_{int} is the lowest frequency of interest (usually 500 Hz for voice communication) so that practically no sound is reflected from the far end of the horn. If this condition is fulfilled, the use of the linear horn is equivalent to increasing the size of the mouth of the human speaker by the ratio of the end and mouthpiece cross-sectional areas of the horn, as illustrated by the lower sketch in Fig. 10.11.

The cross-sectional area of the horn can be expressed as

$$S(r) = \theta r^2 \quad \text{m}^2 \qquad (10.15)$$

According to Cremer and Hubert,[3] the sound pressure inside the horn as a function of distance from the tip can be expressed as

$$\tilde{p}(r) = \frac{\tilde{v}_p\,(l/r)}{1/(\rho_0 c_0) + 1/(j\omega\rho_0 l)} \quad \text{N/m}^2 \qquad (10.16)$$

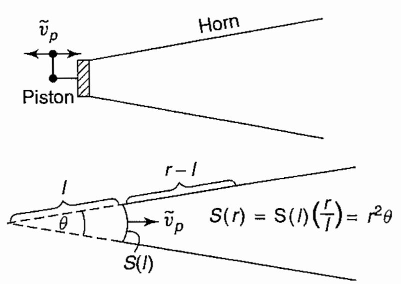

FIGURE 10.2 Vibrating piston sound source driving a linear acoustical horn (see text for explanation of symbols).

where v_p is the vibration velocity of the piston at the mouth of the horn and l is the radial length from the cutoff tip of the cone to the mouthpiece end, as illustrated in Fig. 10.2. Observing Eq. (10.16), note the following:

1. The term $j\omega\rho_0 l$ represents the added mass that is the consequence of the expansion of the cross section, which makes it possible to push the fluid off axis. In the extreme case when $\theta \to 0$ the horn turns into a rigid pipe and the added mass becomes infinite. This means that the near field in the pipe extends to infinity.
2. The sound propagates in the linear horn at all frequencies (which is not the case in an exponential horn, where no sound propagates below its cutoff frequency).
3. At low frequencies when $kl = (\omega/c_0)l \ll 1$ the sound pressure increases linearly with frequency as $p(r) \cong j\omega\rho_0(l^2/r)\tilde{v}_p$.
4. Above the frequency $\omega \geq c_0/l$ the linear horn works at full efficiency and the sound pressure as a function of distance becomes $p(r) \cong v_p(l/r)\rho_0 c_0$.

Considering that the volume velocity at the mouth of the horn is $q = v_p\theta l^2$, the radiated sound power takes the form

$$W_{\text{rad}} = q^2\rho_0 c_0\left(\frac{k^2}{\theta}\right)\frac{1}{1+(kl)^2} = q^2\frac{\rho_0\omega^2}{c_0\theta}\left[\frac{1}{1+\pi(S/\lambda^2)(4\pi/\theta)}\right] \quad \text{N}\cdot\text{m/s} \qquad (10.17)$$

Figure 10.3 shows what happens if we gradually weaken the restraint by increasing the solid angle θ from zero to 4π. In the extreme case, when the solid angle

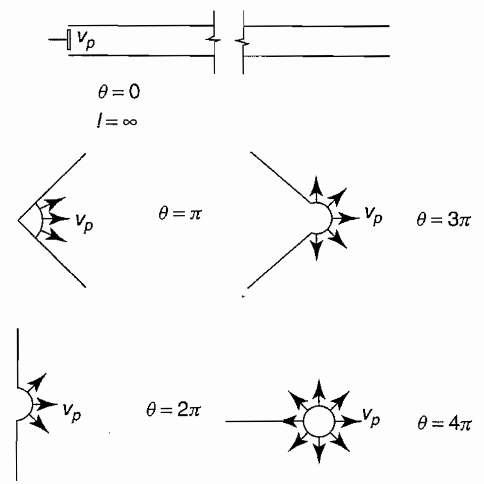

FIGURE 10.3 Increasing the solid angle θ of the horn; Top left: $\theta = 0$, pipe. Middle left: $\theta = \pi$, quarter space. Bottom left: $\theta = 2\pi$, half space. Middle right: $\theta = 3\pi$, three-quarter space. Bottom right: pulsating sphere in unbounded space.

of the horn θ is zero and tip length l approaches infinity, the horn becomes a cylindrical pipe, as shown in the top sketch. In this extreme case the sound pressure in the pipe is

$$p(r,t) = (q/S)\, e^{-jkr}\, e^{j\omega t} \quad \text{N/m}^2 \tag{10.18}$$

indicating that theoretically the amplitude of the sound pressure would not decrease with distance. A practical use of this attribute is shown on the left in Fig. 10.11.

Consider now the effect of increasing the solid angle of the horn from $\theta = 0$ by an infinitesimally small $\Delta\theta$. Consequence of this is a phenomenological change in the behavior of the sound field, namely the sound pressure approaches zero at an infinitely large axial distance while for the pipe it would remain just as high as on the surface of the piston. Such quantum jumps are not allowed in Newtonian physics. The change in the behavior of the sound field is rapid but continuous. In the constant cross-sectional area of the pipe the near field extends infinitely. In the linear horn with infinitesimally small solid angle the near field extends nearly infinitely. Since in practice there are only finite-length pipes and horns, a microphone near the end of the anechoically terminated finite-length horn with an infinitesimally small solid angle would practically sense the same sound pressure as it would in a pipe.

Let us now explore the behavior of our linear horn given in Eq. (10.17) at solid angles of practical interest. Equation (10.17) yields

$$W_{\text{rad}} = q^2(\rho_0 c_0)\left(\frac{k^2}{4\pi}\right) n \quad \text{N}\cdot\text{m/sec} \tag{10.19}$$

where $n = 1$ when the volume source is located in an infinite, undisturbed fluid;
$n = 2$ when the volume source is flash mounted in an infinite, hard, flat baffle and radiates into a half space;
$n = 4$ when the sound source is located in a two-dimensional corner and radiates into a quarter space; and
$n = 8$ when located in a three-dimensional corner and radiating into an eighth space.

If there is a net volume displacement (as far as the far-field sound pressure and the radiated sound power are concerned), the specific distribution of the velocity over the vibrating surface is unimportant. This is because the non–volume-displacing vibration patterns (dipole, quadrupole, etc.) radiate low-frequency sound much less efficiently than volume-displacing patterns.

Figure 10.4 shows volume sources with different distributions of the vibration velocity but having the same net volume velocity. The solid and dashed lines represent the location of the vibrating surface at two time instances. The solid line shows the maximum and the dashed line the minimum volume displacement positions, respectively.

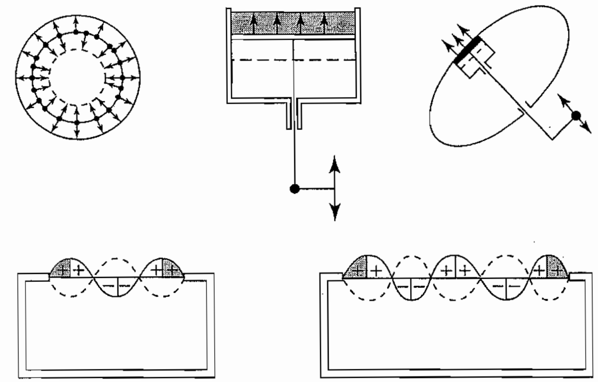

FIGURE 10.4 Small volume sources with different distributions of the vibration velocity but the same net volume velocity.

Limits of Maximum Achievable Volume Velocity of Pulsating Sphere. The maximum peak volume velocity $\hat{q}_{\max}$ achievable with a small pulsating sphere of volume $V_{\text{sphere}} = 4\pi a^3/3$ is limited by (1) the impossibility of having a larger volume displacement than the volume of the sphere, (2) the desire of not having supersonic surface velocity, and (3) the desire of keeping nonlinear distortion within acceptable limits. These requirements are accounted for in Eq. (10.20) below.

$$\frac{\hat{q}_{\max}}{V_{\text{sphere}}} \le \frac{n}{a/(3c_0) + 1/(12\pi\omega)} \quad \text{s}^{-1} \tag{10.20}$$

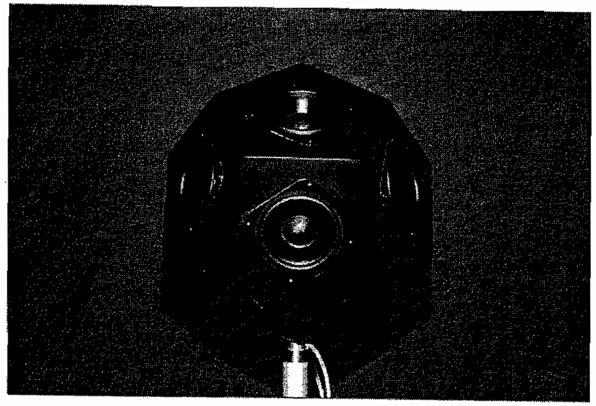
where the first summand in the denominator accounts for the first limit, the second for the second limit, and the factor $n \ll 1$ in the numerator for the third limit.

Combining Eqs. (10.19 and (10.20) and solving for $\hat{W}_{\text{rad}}$ yield the maximum peak acoustical power a pulsating sphere of radius a can produce:

$$\begin{aligned} \hat{W}_{\text{rad}}(\max) &\le 2\pi\left(\frac{\rho_0 c_0^3 a^4 k^2 n^2}{\{1 + [3/(12\pi)][1/(ka)]\}^2}\right) \\ &= 2\pi\left(\frac{\rho_0 \omega^2 c_0 a^4 n^2}{1 + [3/(12\pi)][c_0/(\omega a)]}\right) \quad \text{N}\cdot\text{m/s} \end{aligned} \tag{10.21}$$

If we use the pulsating sphere as a loudspeaker to reproduce voice and music, it would be appropriate to choose n in the range of 0.001–0.01 to keep distortion at peak events within tolerable limits.

A dodecahedron-shaped enclosure with a loudspeaker flash mounted on each of the 12 faces of the enclosure is often used to simulate an omnidirectional volume sound source. The top photograph in Fig. 10.5 shows such a special reciprocity transducer[5–7] (loudspeaker) that the author has developed for the NASA



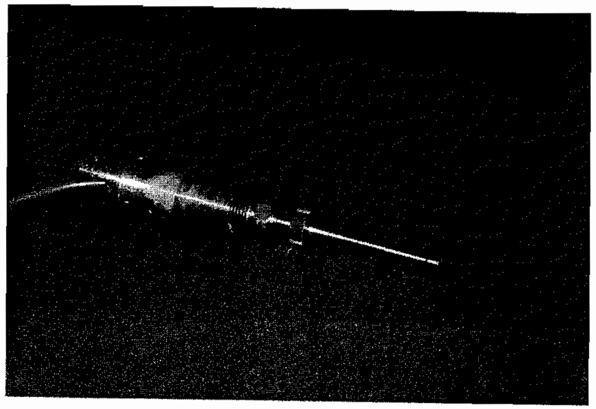


FIGURE 10.5 Photographs of a 4-in. edge-length dodecahedron loudspeaker to simulate a pulsating sphere as an omnidirectional sound source with volume velocity calibration and compensation for acoustical loading. Top: View of the loudspeaker. Bottom: Removed internal $\frac{1}{4}$-in. microphone used for volume velocity calibration and for correcting the acoustical loading when the source is placed in a confined environment.

Langley Research Center. The lower photograph in Fig. 10.5 shows the internal microphone removed from the center of the speaker. The internal microphone is used for volume velocity calibration at low frequencies, for measuring and compensating for the effect of acoustical loading (when the loudspeaker is placed in a small, confined environment such as inside an automobile or in the cockpit of an airplane or placed near a boundary) on the volume velocity, and for measuring nonlinear distortion at low frequencies. The volume velocity calibration of the transducer at mid- and high frequencies was accomplished experimentally by calibrating the transducer as a microphone and utilizing the principle of

reciprocity to obtain the volume velocity as a function of the applied voltage to the loudspeakers.

Example 10.1. determine the minimum radius $a_{\min}$ of a pulsating sphere that should radiate 1 W peak acoustical power at 100 Hz for a distortion parameter $n = 0.005$ and $n = 0.01$.

Solution solving Eq. (10.21) for the radius a yields

$$a_{\min} = \begin{cases} 0.088 \text{ m} \cong 3.5 \text{ in.} & \text{for } n = 0.005 \\ 0.075 \text{ m} \cong 3 \text{ in.} & \text{for } n = 0.01 \end{cases}$$

The investigations above indicates that to radiate a practically meaningful amount of sound power at low frequencies requires a sizable sound source. Consequently, a *point sound source* is a practical impossibility. Furthermore, if the point sound source does not exist, then there are no physically meaningful acoustic dipoles and quadrupoles.

Consequently, it wound be physically more meaningful to substitute the following in the engineering acoustical vocabulary:

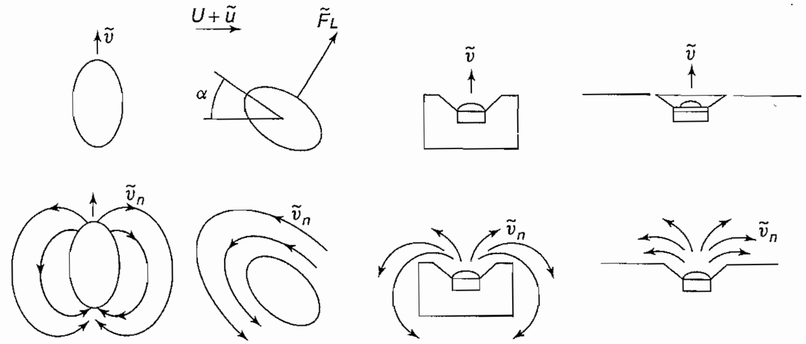
small-volume sound source instead of *monopole* or *point source*,
force (acting on the fluid) instead of *dipole*, and
moment (acting on the fluid) instead of *quadrupole*.

Sound Radiation by Non-Volume-Displacing Sound Sources

Parts (a) and (b) in Figure 10.6 show the response of an unbounded fluid to rigid, non-volume-displacing sound sources and parts (c) and (d) that of volume-displacing sound sources. All of the sources are small compared with the acoustical wavelength. The upper row depicts the body and shows the variables that are responsible for the sound generation. The lower row shows, in a schematic manner, how the fluid particles are pushed aside, creating a near field. The symbol $\tilde{v}_b$ represents the dynamic velocity of the body and $\tilde{v}_n$ the particle velocity in the near field. As we will show latter, the kinetic energy flux of this near field, $\omega(0.5\rho_0\tilde{v}_n)$, integrated over the entire fluid volume outside the body represents the added mass, which is a measure for the vibrating body's ability to exert a dynamic force on the fluid ("grab onto it").

In Fig. 10.6 (a) and (b) are examples of non-volume-displacing sound sources and (c) and (d) of volume-displacing sound sources.

In Fig. 10.6a the upper sketch depicts a small rigid body that exhibits random motion in one dimension with a velocity $\tilde{v}_b$ and the lower sketch depicts the direction and path of the particle velocity in the near field at a given moment in time. Note that the fluid "pushed aside" by the forward face of the body is



(a) (b) (c) (d)

FIGURE 10.6 Schematic representation of various non-volume-displacing and volume-displacing sound sources and the associated particle velocity in the near field. The symbol $\tilde{v}$ is the vibration velocity of the body and $\tilde{v}_n$ is the particle velocity in the near field. (*a*) Non-volume-displacing sound source; small, rigid body of arbitrary shape moving with a velocity $\tilde{v}$ in an unbounded fluid. (*b*) Stationary, small, rigid body exposed to a flow field of stationary velocity U with a fluctuating component $\tilde{u}$. The angle of attack is α and the resulting dynamic force is $\tilde{F}_L = C_L\left(\frac{1}{2}\rho_0\tilde{u}^2\right)$ and C_L is the lift coefficient of the body. (*c*) Volume-displacing small sound source typified by a loudspeaker mounted on the face of an airtight, rigid enclosure. (*d*) Volume-displacing small sound source flash mounted in an infinitely large, plane, rigid baffle.

"sucked in" by the void created by the receding backward face of the body. This "push–pull" situation results in a very small force. Borrowing from the vocabulary of electronic engineers, this situation is referred to as an "acoustical short circuit."

In Fig. 10.6*b* the upper sketch depicts a small stationary body exposed to a flow field of average velocity U and a fluctuating component $\tilde{u}$. The fluctuating component of the flow produces a fluctuating lift force $\tilde{F}_L$ and a fluctuating drag force $\tilde{F}_D$ (the drag force is not shown to preserve clarity).

In Fig. 10.6*c* the upper sketch shows a loudspeaker mounted on a face of a rigid-walled enclosure. In this case the rigid enclosure prevents the "pulling" by the receding back face of the speaker. Moving aside the fluid by "push" alone, without the help of the "pull," requires more force. More force acting on the fluid translates into higher sound radiation. This is the reason that a small oscillating surface radiates sound more efficiently if its back side is enclosed than the same surface would radiate if the back side is not enclosed.

Sound sources with an enclosed back side displace the same volume in the back side as on the front side. However, the volume displaced by the back side is prevented from "communicating" with the surrounding fluid by the rigid enclosure. If a dynamic force of constant amplitude drives the vibration velocity (which is the case for our loudspeaker shown in the upper sketch in Fig. 10.6*c*),

the obtainable vibration velocity is limited either by the volume stiffness of the air in the enclosure volume or by the mass of the moving part of loudspeaker.

If the enclosure is small compared with the acoustical wavelength, the sound pressure that is produced at the surface of the active part has time to spread around the outside wall of the enclosure during each vibration cycle. As a direct consequence of this, all small volume-displacing sound sources, independent of their geometry, have an omnidirectional sound radiation pattern in the far field.

In Fig. 10.6*d* the upper sketch shows a vibrating surface (in the form of a loudspeaker membrane) flush mounted in a flat infinite rigid baffle. This is a situation that basically resembles the configuration in Fig. 10.6*c*, except that the sound radiation must take place in a hemisphere (half space). Consequently, for the same volume displacement the mean-square sound pressure p^2_{rms} at a given radial distance r will be twice as large as an omnidirectionally radiating source would produce.

Response of Unbounded Fluid to Excitation by Oscillating Small Rigid Body. The dynamic "near-point" force acting on the fluid is always in the form of a dynamic pressure over a small area. By *small*, we mean here and in the rest of this chapter that the body is small compared with the acoustic wavelength ($\lambda = c_0/f$).

The quintessential question is, "How does the organized motion that a small rigid body imparts on the fluid spread out, that is, diffuse in various directions with increasing distance through the molecular collision process.

Diffusion of Sound Energy in Response to Excitation of Fluid by Oscillating Small Rigid Sphere. This section deals with the prediction of the sound radiation pattern and the radiated sound power of small, rigid, oscillating bodies for one-dimensional, harmonic, and random motion.

Harmonic Excitation. The sound field that the harmonic, one-dimensional, oscillatory velocity $v(\omega) = \hat{v}_b\, e^{j\omega t}$ of a small rigid sphere generates is well known and for $r \geq a$ is given by[4]

$$\hat{p}(r,\varphi,\omega) = \hat{v}_b(\omega)\cos(\varphi)\left(\frac{j\omega\rho_0 a^3}{2 - k^2a^2 + j2ka}\right)\left(\frac{1+jkr}{r^2}\right)e^{-jk(r-a)}\,e^{j\omega t}\ \text{N/m}^2 \tag{10.22}$$

where
$\hat{p}(r,\varphi,\omega)$ = peak sound pressure (N/m^2) at distance r (m) in direction ϕ
$\hat{v}_b$ = peak velocity of body in $\phi = 0$ direction, m/s
ω = radian frequency, $2\pi f$ Hz
f = frequency of oscillation, Hz
ρ_0 = density fluid, kg/m^3
a = radius of sphere, m
k = wavenumber, ω/c_0, m^{-1}
c_0 = propagation speed of sound, m/s

It is instructive to evaluate Eq. (10.22) at the two extreme cases, namely on the surface of the sphere ($r = a$) and in the geometric far field where $kr \gg 1$.

On the surface of the oscillating sphere Eq. (10.22) yields the reaction pressure of the fluid

$$\hat{p}(a, \varphi, \omega) = \hat{v}_b(\omega)\cos(\varphi)\, e^{j\omega t}\frac{k^4a^4 + jka(2 + k^2a^2)}{4 + k^4a^4} \quad \text{N/m}^2 \tag{10.23}$$

The radiation impedance of the sphere, defined as the ratio of the surface pressure and the radial velocity $\hat{v}_b\cos(\varphi)$, is

$$Z_{\text{rad}} = \begin{cases} \rho_0 c_0 \left\{\dfrac{k^4a^4 + jka(2 + k^2a^2)}{4 + k^4a^4}\right\} \quad \text{Ns/m}^3 & (10.24\text{a}) \\[2ex] \rho_0 c_0 \left(\dfrac{k^4a^4}{4} + \dfrac{jka}{2}\right) \quad \text{for } ka \ll 1 & (10.24\text{b}) \\[2ex] \rho_0 c_0 \quad \text{for } ka \gg 1 & (10.24\text{c}) \end{cases}$$

The dynamic force exerted on the fluid in the direction of the oscillation, F_{ax}, is obtained by integrating the axial component of the elementary radial force, $dF_x = \cos(\varphi)\, dF_{\text{rad}} = p(a, \varphi)\cos(\varphi)\, dS$ over the surface of the sphere, yielding

$$\hat{F}_{\text{ax}} = \begin{cases} \dfrac{2}{3}\hat{v}_0\rho_0 c_0(2\pi a^2)\dfrac{k^4a^4 + jka(2 + k^2a^2)}{4 + k^4a^4} \quad N & (10.25\text{a}) \\[2ex] j\omega\rho_0\hat{v}_0\dfrac{2\pi a^2}{3} = j\omega\hat{v}_0\rho_0 V_{\text{ad}} \quad \text{for } ka \ll 1 & (10.25\text{b}) \\[2ex] \dfrac{4\pi a^2}{3}\rho_0 c_0\hat{v}_0 \quad \text{for } ka \gg 1 & (10.25\text{c}) \end{cases}$$

where V_{ad} is the added volume and $\rho_0 V_{\text{ad}}$ is the added mass (as we will define latter on). Observing Eq. (10.24b) note that at low frequencies $\hat{F}_{\text{ax}}$ is the force needed to produce the same acceleration as that of the sphere ($j\omega\hat{v}_0$) on a concentrated mass that is equal the added mass.

The radiated sound power, W_{rad}, is obtained as a product of the oscillatory velocity and the component of the axial force that is in-phase with it, yielding

$$W_{\text{rad}} = \begin{cases} \dfrac{1}{2}|\hat{v}_0|\text{Re}\{F_{\text{ax}}\} = \dfrac{1}{2}|\hat{v}_0|^2\rho_0 c_0(4\pi a^2)\dfrac{k^4a^4}{4 + k^4a^4} \quad \text{Nm/s} & (10.26\text{a}) \\[2ex] \dfrac{1}{2}|\hat{v}_0|^2\rho_0 c_0(\pi a^2/3)k^4a^4 \quad \text{for } ka \ll 1 & (10.26\text{b}) \\[2ex] \dfrac{1}{2}|\hat{v}_0|^2\rho_0 c_0(4\pi a^2/3) \quad \text{for } ka \gg 1 & (10.26\text{c}) \end{cases}$$

Equation (10.25) indicates that at low frequencies ($ka \ll 1$) the radiated sound power is small and increases with the fourth power of the frequency and at high frequencies ($ka \gg 1$) reaches a frequency-independent value.

In the far field ($kr \gg 1$) Eq. (10.22) takes the form

$$\hat{p}(r, \varphi, \omega) = \begin{cases} -\dfrac{\hat{v}_0}{r}\cos(\varphi)\rho_0 c_0 k^3 a^3\dfrac{(2 - k^2a^2) + j2ka}{4 + k^4a^4} \quad \text{N/m}^2 & (10.27\text{a}) \\[2ex] -\dfrac{\hat{v}_0(\omega)\cos(\varphi)}{4\pi c_0 r}\omega^2\rho_0 2\pi a^3 \quad \text{for } ka \ll 1 & (10.27\text{b}) \\[2ex] -\hat{v}_b\rho_0 c_0\left(\dfrac{a}{r}\right)\cos(\varphi) \quad \text{for } ka \gg 1 & (10.27\text{c}) \end{cases}$$

Sound Radiation of Oscillating Small Rigid Nonspherical Bodies. Realizing that $2\pi a^3/2 = 4\pi a^3/3 + 2\pi a^3/3$ and that $V_b = 4\pi a^3/3$ is the volume of the sphere and $V_{\text{ad}} = 2\pi a^3/3$ is the added mass of an oscillating rigid sphere, we can write Eq. (10.24) in the form

$$\hat{p}(r, \varphi, \omega) \approx -\frac{\omega^2\rho_0}{4\pi rc}\hat{v}_b(\omega)\cos(\varphi)[V_b + V_{\text{ad}}(\square, \Psi)]\, e^{j(\omega t - kr)} \quad \text{N/m}^2 \tag{10.28}$$

where the symbols $\square$ and Ψ in the argument of V_{ad} signify that the added mass depends on the geometry of the body and the specific direction of its oscillatory motion.

While Eq. (10.27b) is valid only for a small oscillating rigid sphere, Eq. (10.28) is exact for an oscillating sphere and is a good engineering approximation for small rigid bodies of any shape. It is instructive to rewrite Eq. (10.28) in the form

$$\hat{p}(r, \varphi, \omega) \simeq -\frac{\omega^2\rho_0}{4\pi rc_0}\hat{v}_b(\omega)\cos(\varphi)(S_p l_v)\, e^{j(\omega t - kr)} \quad \text{N/m}^2 \tag{10.29}$$

where S_p is the projected area of the body on a plane perpendicular to the oscillatory motion and

$$l_v \equiv \frac{V_b + V_{\text{ad}}(\square, \Psi)}{S_p} \quad \text{m} \tag{10.30}$$

is a length defined by the author in Eq. (10.30), where the angle Ψ corresponds to the direction of the oscillation of the body. The importance of the length l_v is that it defines the frequency range to $ka \ll 1$, where the body can be considered small and where Eq. (10.29) is valid.

The $\cos(\varphi)$ dependence of the directivity pattern in the vicinity of the oscillating body is strictly valid only for spheres. However, in the far field of any oscillating small rigid body (i.e., $kr \gg 1$ and $kl_v \ll 1$) the same $\cos(\varphi)$ dependence applies provided that the fluid displaced by the forward-moving face of the body is free to move to the void left by the opposite face. A detailed mathematical proof of this is given by Koopmann and Fahnline.[8]

Prediction of l_v. The length l_v of various three-dimensional and two-dimensional bodies are listed in Table 10.1. The l_v values in Table 10.1 where computed utilizing the formulas for V_{ad} given by Newman[9]

For the spheroid with major axis $2a$ and minor axes $2b$ and aspect ratio b/a, the *Ver-lengths* l_{vx}, l_{vy}, and l_{vz} are obtained by finding $m''_{11} = V_{ad}(x)/V_b$ and $m''_{22} = V_{ad}(y)/V_b = V_{ad}(z)/V_b$ in Fig. 10.7 at the desired b/a ratio and performing the operation indicated in Table 10.1. The increase in moment of inertia (in addition to that measured in a vacuum) when the ellipsoid body rotates around any of the minor axes is obtained by finding the numerical value of m'_{55} that belongs to the appropriate b/a ratio and performing the operation indicated in Table 10.1.

Predicting Radiated Sound Power. The sound power radiated by small oscillating rigid bodies is obtained by integrating the far-field intensity $I = p^2(r, \varphi, \omega)/\rho_0 c_0$ over the surface of a large sphere of radius r centered at the oscillating small rigid body, namely

$$W_{rad} \simeq \int_0^{\pi} \frac{|\hat{p}|^2(r, \varphi, \omega)}{\rho_0 c_0} 2\pi r^2 \sin(\varphi)\, d\varphi \quad \text{N} \cdot \text{m/s} \tag{10.31}$$

Combining Eqs. (10.29) and (10.31) yields

$$W_{rad} \simeq \frac{k^4 \rho_0 c_0 S_p^2 (l_v)^2}{12\pi} v_{b,\text{rms}}^2 \quad \text{N} \cdot \text{m/s} \tag{10.32}$$

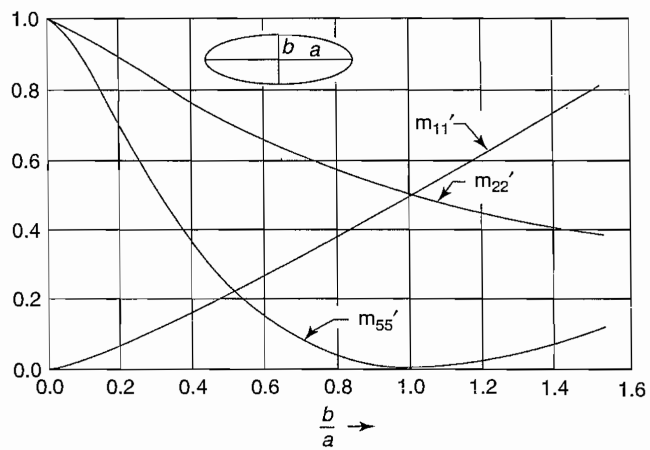


FIGURE 10.7 Added-mass coefficient V_{ad}/V_b for a spheroid, of length $2a$ and maximum diameter $2b$. The added-mass coefficient m'_{11} corresponds to longitudinal acceleration, m'_{22} corresponds to lateral acceleration in the equatorial plane, and m'_{55} denotes the added moment of inertia coefficient for rotation about an axes in the equatorial plane representing the ratio of the added moment of inertia and the moment of inertia of the displaced volume of the fluid. [a] NPI = not of practical interest

[b] $M_x = [\pi^{-1}\csc^4(\alpha)][2\alpha^2 - \alpha \sin(4\alpha) + (1/2)\sin^2(2\alpha)] - \pi/2]$, $\sin(\alpha) = 2ab/(a^2+b^2)$, and $\pi/2 < \alpha < \pi$

For a oscillating, small, rigid spherical body of radius a the area projected on the plane perpendicular to the direction of the oscillatory motion $S_p = \pi a^2$ and $l_v = 2a$ and Eq. (10.32) yield

$$W_{\text{rad}}(\text{Sphere}) = \frac{\rho_0 c_0 (4\pi a^2)(ka)^4}{24} |v_b|^2 \quad \text{N} \cdot \text{m/s} \tag{10.33}$$

This is the well-known[3,4] formula for the sound power radiated by a small ($ka \ll 1$) sphere of radius a oscillating with an rms velocity amplitude of $v_{b,\text{rms}}$.

Random Excitation. Let us investigate the case where a small rigid sphere exhibits random motion in one dimension (e.g., in the x direction). As described in Chapter 3, the random motion is characterized by the power spectrum of its velocity in the x direction, $S_{vv}(x)$.

The *power spectrum*, as defined in Chapter 3, represents the quantity obtained by filtering the random time signal in a 1-Hz bandwidth multiplying by itself and time averaging the product. In this chapter we use the symbol S with a double subscript to represent a power spectrum or cross spectrum. The double-letter subscript of S identifies which of the two filtered signal are multiplied with the other before time averaging. For example the symbol $S_{vv}(\omega)$ represents the autospectrum of the random velocity signal filtered in a 1-Hz bandwidth centered at the angular frequency $\omega = 2\pi f$, where f is the frequency in hertz. The symbol $S_{xy}(\omega)$ represents a cross spectrum of two random signals $x(t)$ and $y(t)$ obtained by filtering both signals in a 1-Hz bandwidth, multiplying them, and time averaging the product. The power spectrum of a signal resulting from the superposition of two signals $z(t) = x(t) + y(t)$ is computed as $S_{zz}(\omega) = S_{xx}(\omega) + S_{yy}(\omega) + 2S_{xy}(\omega)$. If the two random processes $x(t)$ and $y(t)$ are not correlated, $S_{xy}(\omega) = 0$. If the two random processes of the same power spectral density are fully correlated (i.e., they have the same cause), the cross spectrum is identical to the autospectrum, $S_{xy}(\omega) = S_{xx}(\omega) = S_{yy}(\omega)$ and $S_{zz}(\omega) = 4S_{xx}(\omega) = 4S_{yy}(\omega)$.

If the velocity of the vibrating body is exclusively in the x direction and is a random function of time, with a power spectrum of $S_{v_x v_x}(\omega)$ the power spectrum of the sound at distance r in the direction ϕ from the positive x axis, $S_{pp}(r, \varphi, \omega)$, is

$$S_{pp}(\omega, r, \varphi) = S_{v_x v_x}(\omega) |h_1(\omega, \rho_0, k, a, r, \varphi)|^2 \quad \text{N}^2/\text{m}^4 \tag{10.34}$$

where

$$h_1(\omega, \rho_0, k, l_v, r, \varphi) = \frac{\omega^2 \rho_0}{4\pi r c_0} \cos(\varphi)(S_p l_v) e^{jkr} \tag{10.35}$$

Hypothetical Experiment 2: Force Acting on Fluid. To find the dynamic force acting on the fluid F_f, let us perform the thought experiment shown in Fig. 10.8. Let a dynamic force $\mathbf{F}_b$ act on a small, rigid, hollow body of arbitrary shape at its center of gravity and determine the oscillatory velocity $\mathbf{v}_b$ of the

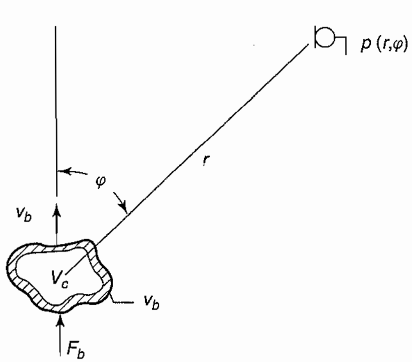

FIGURE 10.8 Hypothetical experiment to determining the force F_f that acts on the fluid and the sound field it produces by letting the wall thickness of an oscillating, hollow rigid body approach zero.

body responding to the force as

$$\mathbf{F}_b = \mathbf{v}_b(j\omega m_b + Z_{\text{rad}}) \quad \text{N} \tag{10.36}$$

where m_b is the mass of the body and $Z_{\text{rad}} = F_f/v_b$ is the radiation impedance:

$$\mathbf{F}_b = j\omega \mathbf{v}_b[\rho_M(V_b - V_c) + \rho_0 V_c + \rho_0 V_{\text{ad}}(\square, \Psi)] \quad \text{N} \tag{10.37}$$

where V_b is the volume of the oscillating, hollow, rigid body and V_c is the volume of the inside cavity, filled with the same fluid that surrounds the body. Both volumes are in cubic meters. The symbol ρ_M represents the density of the solid part of the body in kilograms per cubic meter. The symbol V_{ad}, in cubic meters, is the added volume, or in the hydrodynamic vocabulary the added mass coefficient. The symbols $\square$ and Ψ in the argument of V_{ad} is to remind us that it is a function of the body's geometry and the particular angle of its oscillatory motion to one of the designated axes of the body.

Let us now investigate the very important extreme case of Eq. (10.37) where the wall thickness of the hollow body approaches zero (and still remains rigid) by setting $V_c \to V_b$. In this case the entire applied dynamic excitation force $F_b = F_f$ is acting directly on the fluid, yielding

$$\mathbf{F}_f = v_b j\omega\rho_0 V_b + \mathbf{v}_b j\omega\rho_0 V_{\text{ad}}(\square, \Psi) \quad \text{N} \tag{10.38}$$

The first term in Eq. (10.38) represents the flux of the momentum of the fluid volume displaced by the body, $\rho_0 V_b[\partial(v_b)/dt]$, and the second term, $\rho_0 V_{\text{ad}}\,(\square, \Psi)[\partial(v_b)/dt]$, the flux of the momentum of the near field obtained by integrating the component of the particle velocity that is out phase with the velocity of the body over the entire volume outside of the body. Fortunately, we do not need to perform this integration to obtain $V_{\text{ad}}(\square, \Psi)$ because

(a) hydrodynamists have computed it for many body geometries of interest (see Table 10.1 and Fig. 10.7),
(b) for most bodies of practical interest it can be well approximated by spheroids of the appropriate aspect ratio (see Fig.10.7), and
(c) it can be determined experimentally.

Equation (10.38) is of fundamental importance. It signifies the following:

1. The force acting on the fluid acts in the direction of the oscillatory motion.
2. Two-dimensional bodies, which have no volume ($V_b = 0$) can exert force on the fluid provided their velocity has a component perpendicular to their plane and, consequently, $V_{\text{ad}} \neq 0$.
3. No force can be exerted on the fluid without a finite added mass (i.e., $V_{\text{ad}} \neq 0$).

The far-field sound pressure as a function of distance r, direction φ, and frequency ω produced by a pointlike force F_f is obtained by solving Eq. (10.38) for v_b and inserting this value into Eq. (10.25), yielding

$$p(r, \varphi, \omega) = -j\frac{kF_f\cos(\varphi)}{4\pi r}e^{j(\omega t - kr)} = -j\frac{F_f\cos(\varphi)}{2r\lambda}e^{j(\omega t - kr)} \quad \text{N/m}^2 \tag{10.39}$$

The radiated sound power W_{rad} is obtained by integrating the intensity $I = p^2(r, \vartheta, \omega)/\rho_0 c_0$ over the surface of a sphere of radius $r \gg (1/k)$ centered on the excitation point. Carrying out the integration yields

$$W_{\text{rad}} = \frac{k^2 F_{f,\text{rms}}^2}{12\pi\rho_0 c_0} = \frac{\omega^2 F_{f,\text{rms}}^2}{12\pi\rho_0 c_0^3} \quad \text{N}\cdot\text{m/s} \tag{10.40}$$

If the excitation is random, the excitation and response parameters have to be replaced by their respective power spectra.

Equation (10.39) describes the diffusion law of acoustics. It gives the full answer to the question "How does this organized motion—that is, in the direction of the force at the application point—diffuse with increasing distance in other directions through the molecular collision process?"

Equation (10.39)signifies that:

1. The sound pressure in any particular direction is proportional the projection of the force vector in that direction, $F_f\cos(\phi)$, indicating that the strength of the diffusion varies as $\cos(\phi)$. The radiated sound pressure has its maximum in the direction of the force and it is zero perpendicular to it. This is consistent with the fact that the oscillatory motion of the body exerts on the fluid the maximum force in the motion direction and no force at all in the direction perpendicular to it. The directivity pattern $\cos(\phi)$ in three dimensions is represented by two spheres of unit diameter aligned in the

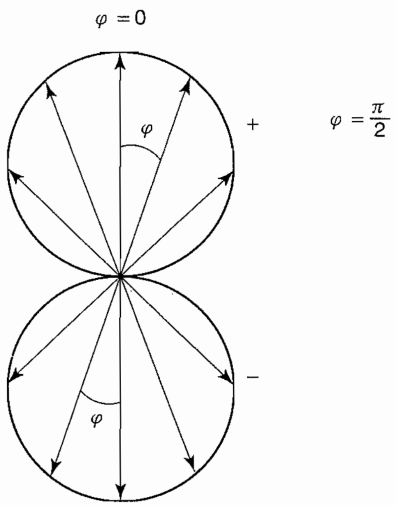

FIGURE 10.9 Far-field sound radiation pattern of a small rigid body oscillating in the $\phi = 0$ direction or an oscillatory force acting on the fluid in the $\phi = 0$ direction.

direction of the oscillatory motion or the direction of the force and centered on the line of the oscillating body or on the point where the force acts on the fluid, as shown (in two dimensions) in Fig. 10.9.

2. The sound pressure in any direction is inversely proportional to the source–receiver distance r.
3. Independent of what causes the dynamic force F_f which acts on the fluid, the sound pressure fully determines the sound radiation pattern and sound power output of small rigid bodies. The force can be, for example, the reaction force to the oscillatory movement of the body or that caused by fluctuating lift or drag forces generated on small stationary bodies by the fluctuation of the inflow velocity or by vortex shedding at the trailing edge of airfoils. Fluctuating inflow is caused by incoming turbulence of a scale that is large compared with the size of the body. If the scale of the convected pressure fluctuations (turbulence) is large compared with the size of the rigid body, the force would be identical to that obtained by moving the body in a stationary fluid in the direction and with the velocity of the fluctuating component of the unsteady inflow and predicting lift and drag forces.
However, a rigid stationary body exposed to fluctuating aerodynamic forces radiates sound into a moving media. Consequently, the radiated sound pressure and sound power is different from that an oscillating rigid body, that exerts the same dynamic force on the fluid, would produce in a stationary media. The effect of moving media on sound radiation is treated in Chapter 15.

4. The sound pressure is independent of the density of the surrounding fluid. This is because the acceleration of the fluid caused by the force is inversely proportional to the density and the sound pressure is proportional to the product of the density and acceleration.

If the force applied to the F_f is of random nature, it is characterized by its power spectral density $S_{FF}(\omega)$ and the sound pressure it produces by its power spectral density $S_{pp}(r, \varphi, \omega)$, as defined in Chapter 3. In this case Eq. (10.39) takes the form

$$S_{pp}(\omega, r, \varphi) = S_{FF}(\omega,) \left| \frac{\omega \cos(\varphi)}{4\pi r c_0} \right|^2 \quad (\text{N/m}^2)^2 \qquad (10.41)$$

and the power spectrum of the radiated sound power takes the form

$$S_w(\omega) = S_{FF}^2(\omega) \left| \frac{\omega^2}{12\pi \rho_0^2 c_0^3} \right|^2 \quad (\text{N} \cdot \text{m/s})^2 \qquad (10.42)$$

Response of Bounded Fluid to Point Force Excitation. It is instructive to investigate briefly what effects nearby boundaries have on the sound radiation pattern and on the sound power radiated by a point force. We will consider

1. the most severe restricting boundaries, surrounding the oscillating rigid body by an infinitely long (or finite-length but at both ends anechoically terminated) small-diameter rigid pipe;
2. rigid plane boundaries; and
3. yielding plane boundaries.

Rigid Pipe Surrounding Point Force. Figure 10.10 shows the situation where a point force of arbitrary orientation is acting in a fluid inside of a pipe of diameter d and cross-sectional area $S = d^2\pi/4 = r^2\pi$ that is anechoically terminated at both ends. Let the axis of the pipe coincide with the x axis of the Cartesian coordinate system and let the point force, which acts at $x = 0$, have components F_x, F_y, and F_z. [If we place a small rigid oscillating body with known velocity v_b into the tube, we must first determine the oscillatory force F_f according to Eq. (10.38).] Let restrict our analysis to the frequency range where the acoustical wavelength is large compared with the internal diameter of the pipe (i.e., $\lambda \gg d$) when only plain sound waves can propagate in the pipe and assume that

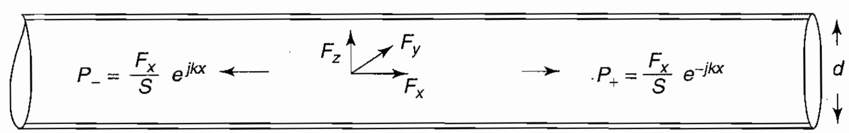

FIGURE 10.10 Force exerted on the fluid inside of a small-diameter, infinitely long, or on both ends anechoically terminated rigid pipe.

the near field of the body giving rise to the force is not influenced by the presence of the pipe (i.e., $kl_v \ll d$). This is not an unreasonable assumption because we can always choose a reasonably small size body and compensate for it by appropriately increasing its oscillatory velocity (as long as $v_b \ll c_0$) to produce the same force on the fluid. With these minor restrictions, the sound pressure at a distance $x \gg d$ the sound pressure $p(x)$ and the power spectrum S_{pp} for any $x \gg d$ will be

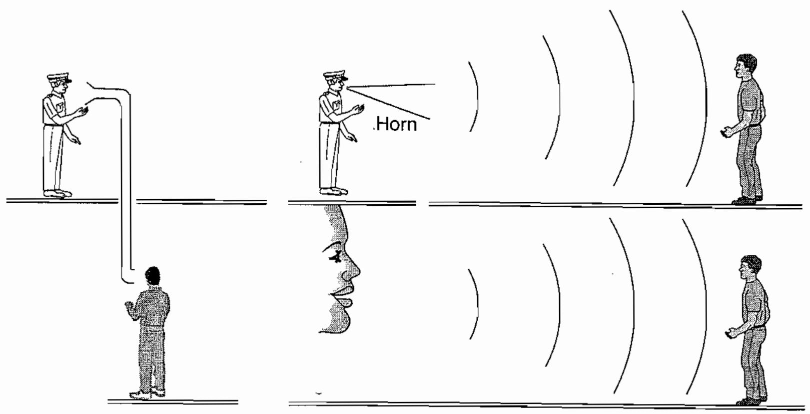
$$p(x) = -p(-x) = \left(\frac{F_x}{S}\right) e^{-kx} e^{j\omega t} \quad \text{N/m}^2 \tag{10.43}$$

$$S_{pp}(f) = \left(\frac{S_{FF}(f)}{S}\right) \quad \text{N/m}^2 \tag{10.44}$$

Note that Eq. (10.40) signifies that the amplitude of the sound propagating inside the rigid pipe does not diminish with increasing distance, as was the case when the point force was acting on an unbounded fluid [see Eq. (10.39)]. Before electroacoustical communication was invented, sea captains communicated with distant crew in the belly of a ship through pipes, as shown in Fig. 10.11a, and on the deck by using an acoustical horn, as depicted in Fig. 10.11b.

Equal sound power is radiated toward the right and left and the total sound power is

$$W'_{\text{rad}} = \frac{2[(F_x)^2/S]}{\rho_0 c_0} \quad \text{N/m}^2 \tag{10.45}$$



(a) (b)

FIGURE 10.11 Passive devices used for voice communication to large distances before the invention of electroacoustical devices. (a) Captain gives orders to crew member located in a lower deck. (b) Top: Captain gives orders to distant crew member on deck using an acoustical horn. Bottom: Using a horn is equivalent to enlarging the mouth of the speaker to the size of the downstream cross-sectional area of the horn.

$$S'_{ww}(f) = \frac{S^2_{F_x F_x}(f)}{|S(\rho_0 c_0)|^2} \quad \text{N/m}^2 \tag{10.46}$$

where $S'_{ww}(f)$ is the power spectrum density of the radiated sound power. The prime notation signifies that the parameter is obtained when the point force is acting inside a small-diameter ($kr \ll 1$) rigid pipe.

The ratio $W'_{\text{rad}}/W_{\text{rad}}$ is a measure of the effect that enclosing the force with a rigid pipe has on the radiated sound power. It is obtained by dividing Eq. (10.45) by Eq. (10.39), yielding

$$\frac{W'_{\text{rad}}}{W_{\text{rad}}} = \left(\frac{6\pi}{S}\right)\left(\frac{1}{k^2}\right)\left\{\frac{1}{1 + (F_y/F_x)^2 + (F_z/F_x)^2}\right\} \tag{10.47}$$

Equation (10.47) indicates that no sound power is radiated if $F_x = 0$, independent of how large F_y and F_z might be. The effect of placing the force inside the pipe reaches its maximum if the force is aligned with the axis of the tube (i.e., $F_y = F_z = 0$) and the value inside the curly brackets is unity. In this case Eq. (10.47) simplifies to

$$\frac{W'_{\text{rad}}}{W_{\text{rad}}} = \left(\frac{3}{2\pi}\right)\frac{c_0^2}{sf^2} \tag{10.48}$$

Example 10.2. Calculate the increase in radiated sound power and the sound power level when an axially oriented force located in a rigid pipe of $a = 2.5$ cm $= 0.025$ m internal radius at a frequency $f = 100$ Hz at a temperature of 20°C = 68°F.

Solution Utilizing Eq. (10.2), we find $c_0 = 342.6$ m/s and with the above values Eq. (10.48) yields

$$\frac{W'_{\text{rad}}}{W_{\text{rad}}} = \frac{(3/2\pi)(342.6)^2}{\pi(0.025)^2(100)^2} = 2854$$

indicating that the same point force oriented axially in this rigid tube radiates 2854 times as much sound power than it does in a unbounded fluid. This corresponds to a $10\log_{10}(2854) = 34.6$ dB increase of the sound power level.

10.2 EFFECT OF NEARBY PLANE BOUNDARIES ON SOUND RADIATION

In this section we only consider entirely rigid and fully yielding plane boundaries. Other boundaries of practical interest, such as lining the rigid boundary with a porous sound-absorbing material of finite thickness, is beyond the scope of this chapter. For guidance in this situation see Chapter 6. The infinitely rigid plane boundary is approached by an infinitely large, nonporous wall and the fully yielding plane boundary by the undisturbed horizontal air–water interface. With regard to their effect on the sound power radiated by a point force (or by an oscillating small rigid body), the plane boundaries do not need to be infinitely large. For practical purposes it is sufficient that they extend, in each direction from the position of the force, many acoustical wavelengths.

A water tank with practically all boundaries pressure releasing (pressure reflection coefficient $R \simeq -1$) is realized by lining the retaining sidewalls and the bottom of the pool with a thin impervious foil with an elastic layer behind. These pools are the equivalent of reverberation chambers with the important exception that in this case the sound pressure reflection coefficient $R \approx -1$ instead of $R \approx +1$ in the case of the (air-filled) reverberation chamber. In both cases the walls have theoretically zero sound absorption coefficient, $\alpha \cong [1 - |R^2|]$ (see Chapter 8). As we will show latter, the vicinity of a rigid boundary increases the sound power output and that of a yielding boundary decreases the sound power output provided that the sound source is less than a half wavelength from the plain boundary.

Effect of Nearby Plane Rigid Boundaries. Rigid plane boundaries are places where the particle velocity is zero and the sound pressure doubles. If the sound source is a small, oscillating, rigid body or a dynamic force acting on the fluid, the directivity pattern of the image source must have the same strength but a mirrored directivity pattern of the actual sound source to produce zero particle velocity in the direction perpendicular to the plane of the boundary and, at the same time, double the sound pressure at all locations in the plane of the rigid boundary, as illustrated in Fig. 10.12.

The sound field in the receiver side of the rigid plane boundary can be constructed as the superposition of the sound fields that would result from the real sound source and its mirror image if both were placed in an infinite fluid. Then, as the sound source approaches the plane rigid interface, the sound field on the source side approaches that of a single source with doubled sources strength.

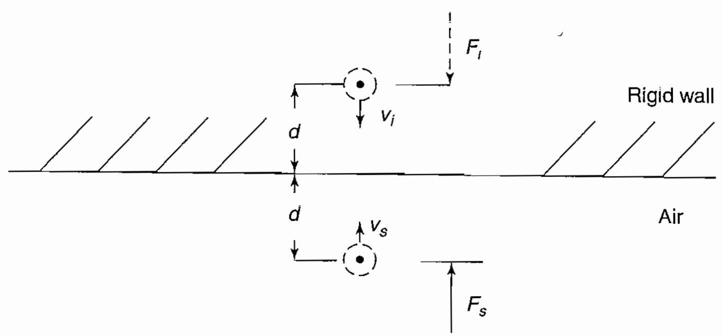


FIGURE 10.12 Representation of a plane rigid boundary, such as at air–hard wall interface, by mirroring the original sound source and superimposing the sound field of the real and in–phase image source in the source-side half space.

If it approaches a rigid two-dimensional corner (i.e., the intersection of two perpendicular plane rigid surfaces), there will be three collapsing mirror images and the sound field in the source-side quarter space approaches that of a single source with 4 times larger source strength. Finally, if the sound source approaches a three-dimensional corner (the intersection of three perpendicular rigid plane surfaces), there will be seven collapsing mirror images and the sound field in the source-side one-eighth space approaches that of a single source with 8 times the source strength.

Effect of Nearby Plane Pressure-Release Boundaries. The pressure-release boundary is well approximated by the plane water–air interface shown schematically in Fig. 10.13 for the force acting perpendicular to the interface and Fig. 10.14 when it acts parallel to the interface. For an oblique-incidence force, the force vector can be decomposed into a component that is perpendicular to the interface and into components that are parallel to the interface. Consequently, we will investigate the perpendicular and parallel cases only. If the sound source is a small, oscillating, rigid body or a dynamic force acting on the fluid, the directivity pattern of the image source must have the same strength but opposite phase and a mirrored directivity pattern of the actual sound source to produce zero sound pressure on the entire interface and, at the same time, double the sound particle velocity at all locations in the plane of the pressure release boundary.

Excitation Is Perpendicular to Pressure-Release Boundary. For the case shown in Fig. 10.13, where the distance to the interface is small compared to the wavelength ($kd \ll 1$) and the body exerting the force is small ($kl_v \ll 1$) and the direction of motion and the force exerted on the fluid are perpendicular to the plane pressure-release interface, the superposition of the sound pressures produced by the real source and that produced by its negative mirror image yields

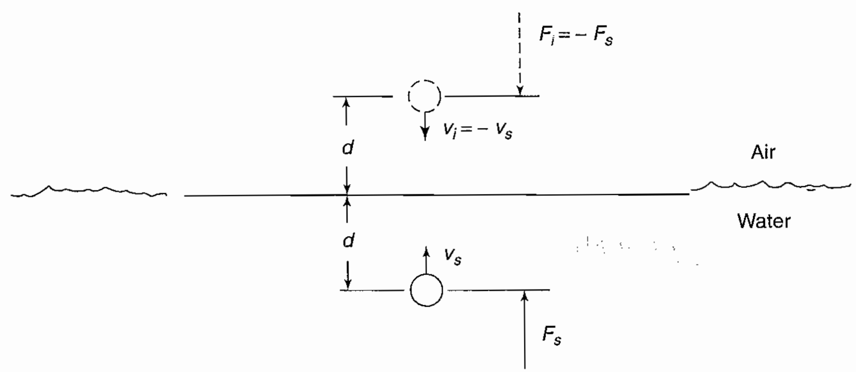

FIGURE 10.13 Representation of a plane pressure-release boundary, such as the water–air interface, by mirroring the original sound source and the 180° out-of-phase mirror image superimposing the sound field of the real and image sources in the source-side half space. Motion is perpendicular to the interface.

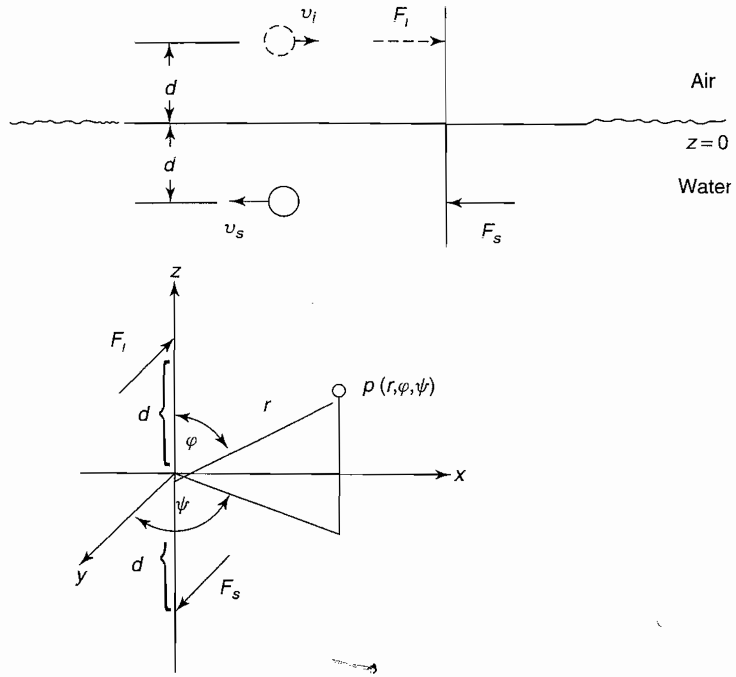

FIGURE 10.14 Representation of a plane pressure-release boundary, such as the water–air interface, by mirroring the original sound source 180° out of phase and superimposing the sound field of the original sound source and the image in the source-side half space. Motion is parallel to the interface.

the sound pressure, intensity, and radiated sound power in the liquid obtained by substituting $F = \rho_0 \omega Q h$ in the respective formulas given by Bies and Hansen[10] for the sound radiation of longitudinal quadrupoles constituted from two dipoles of strength Qh, where Q is the volume velocity of the monopoles that make up the dipole and 2 h is the distance between them:

$$p(r,\varphi,\omega) = \left(\frac{1}{\pi r}\right)\left(\frac{\omega^2}{c_0^2}\right) Fd\cos^2(\varphi) = \left(\frac{1}{\pi r}\right) k^2 Fd\cos^2(\varphi) \quad \mathrm{N/m^2} \qquad (10.49)$$

$$I(r,\varphi,\omega) = \left(\frac{F^2 d^2 k^4 \cos^4(\varphi)}{(\pi r)^2 \rho_0 c_0}\right) = \frac{F^2 d^2 \omega^4 \cos^4(\varphi)}{(\pi r)^2 \rho_0 c_0^5} \quad \mathrm{N/m\cdot s} \qquad (10.50)$$

$$W_{\mathrm{rad}} = \left(\frac{4}{5\pi}\right)\frac{F^2 d^2 k^4}{\rho_0 c_0} = \left(\frac{4}{5\pi}\right) F^2 d^2 \omega^4 \cos^4(\varphi) \quad \mathrm{N\cdot m/s} \qquad (10.51)$$

where $p(r,\varphi,\omega)$ is the sound pressure at distance r at an angle φ from the direction of the motion or from the force at the angular frequency $\omega = 2\pi f$, $I(r,\varphi,\omega)$ is the sound intensity in the radial direction from the excitation point,

W_{rad} is the radiated sound power, F is the rms value of the force, and d is the distance between the excitation point and the plain pressure-release boundary (i.e., the depth of the excitation point in the water.

Note that Eqs. (10.49)–(10.51) are valid for both cases:

(a) A single excitation source is at a distance d from the plane pressure-release boundary.
(b) Two identical small bodies at a distance $2d$ oscillate with the same amplitude but opposite phase in an infinite fluid (for practical purposes far enough from the interface).

Observing Eq. (10.49), note that (1) the radiation pattern is much more directional than that obtained when the body radiates into an infinite fluid [$\cos^2(\varphi)$ vs. $\cos(\varphi)$]; (2) here again the sound pressure is independent of the density of the fluid; and (3) comparing Eq. (10.49) to Eq. (10.39) reveals that the vicinity of the pressure-release boundary substantially reduces the efficiency of the sound radiation at low frequencies. Those familiar with quadrupoles will realize that Eqs. (10.49)–(10.51) describe a longitudinal quadrupole constituted either by two opposing forces of equal magnitude acting on the fluid a short distance $2d$ apart or by two equal-size small rigid bodies oscillating in opposite directions in a small distance $2d$ apart.

Excitation Is Parallel to Pressure-Release Boundary. Figure 10.14 shows the situation where the excitation is parallel to the plane pressure-release boundary. For this case the sound field descriptors, obtained in a similar manner as for the longitudinal quadrupole above, are

$$p(r,\varphi,\omega) = \left(\frac{1}{\pi c_0^2 r}\right)\omega^2 Fd\cos(\varphi)\sin^2(\psi) \quad \mathrm{N/m^2} \qquad (10.52)$$

$$I(r,\varphi,\psi,\omega) = \left(\frac{1}{\rho_0 c_0^5}\right)\left(\frac{1}{\pi r}\right)^2 \omega^4 (Fd)^2 \cos^2(\varphi)\sin^4(\psi) \quad \mathrm{N/m\cdot s} \qquad (10.53)$$

$$W_{\mathrm{rad}} = \left(\frac{4}{15\pi}\right)\left[\frac{(Fd)^2 k^4}{\rho_0 c_0}\right] = \left(\frac{4}{15\pi}\right)\left[\frac{(Fd)^2 \omega^4}{\rho_0 c_0^5}\right] \quad \mathrm{N\cdot m/s} \qquad (10.54)$$

Those familiar with quadrupoles will realize that Eqs. (10.52)–(10.54) describe a lateral quadrupole.

Sound Radiation of Oscillating Moment in Infinite Liquid. An oscillating moment consists of a pair of oscillating forces which (a) act in the same plane, (b) have the same magnitude but opposite direction and phase, and (c) are at a short distance apart.

Observing Fig. 10.14, we realize that the force pair has all the above attributes. Consequently, if we substitute M in place of Fd in Eqs. (10.52)–(10.54), the

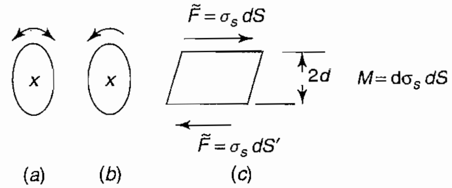

FIGURE 10.15 Different ways of exerting a moment on a fluid: (*a*) rotary oscillation around axes of nonrevolution; (*b*) rotation around axes of nonrevolution; (*c*) by shear stresses.

equations describe the sound radiation of an oscillating moment, yielding

$$p(r,\varphi,\omega) = \left(\frac{1}{\pi c_0^2 r}\right)\omega^2 M\cos(\varphi)\sin^2(\psi)\quad \text{N/m}^2 \tag{10.55}$$

$$I(r,\varphi,\psi,\omega) = \left(\frac{1}{\rho_0 c_0^5}\right)\left(\frac{1}{\pi r}\right)^2 \omega^4 M^2\cos^2(\varphi)\sin^4(\psi)\quad \text{N/m}\cdot\text{s} \tag{10.56}$$

$$W_{\text{rad}} = \left(\frac{4}{15\pi}\right)\left[\frac{M^2 k^4}{\rho_0 c_0}\right] = \left(\frac{4}{15\pi}\right)\left[\frac{M^2\omega^4}{\rho_0 c_0^5}\right]\quad \text{N}\cdot\text{m/s} \tag{10.57}$$

The moment can be any combination of F and d provided that $kd \ll 1$.

As shown in Fig. 10.15, the moment M can be the result of the oscillatory rotation of solid bodies around axes of nonrotational symmetry, shear stresses acting on the fluid (as it is the main source of noise of high-speed jets), or any other acceleration motion that results in a increase of the rotary inertia of the body above that which would exist if the oscillatory rotation would be taking place in a vacuum. For a large number of body shapes this additional moment of rotary inertia M that acts on the fluid is given in Table 10.1 under heading M_x and for ellipsoids of different aspect ratios in Fig. 10.7.

Figure 10.15 shows various ways for the moment excitation of a fluid. Figure 10.15*a* depicts moment excitation by an oscillatory rotation of a body around a nonsymmetric axis, and Fig. 10.15*b* shows excitation by steady rotation along the same axes. Figure 10.15*c* shows moment excitation by shear forces, where $\tilde{F} = \tilde{\sigma}\, dS$ acts on a small fluid volume $dV = 2(dS)d$. The symbol $\tilde{\sigma}$ is the fluctuating shear stress in newtons per square meter. This is the type of moment excitation found in the shear layer of high-speed jets and is treated in Chapter 15.

10.3 MEASURES TO REDUCE SOUND RADIATION

In this section we will discuss some of the measures noise control engineers and machine designers might employ to minimize the sound radiation of vibrating bodies. Most of these measures have been already discussed in a qualitative manner in Section 10.1. In this section we will show certain specific measures in

the form of conceptual sketches and give references where the reader can find more detailed design information.

Fish as Example for Minimized Added Mass. Through evolutionary development, fish have developed body shapes that minimize the reaction force on them when they accelerate their motion in the forward direction. If not in motion, most fish have their pectoral fins deployed perpendicular to their body. If they sense danger and want to dart away as fast as possible, the pectoral fins move rapidly backward (just like the oars of a paddleboat). For moving their pectoral fin in this direction they have a large added mass and can produce a large impulsive force on the water, which propels them forward. As the pectoral fins come near their body, the fins rotate 90° to align their body so that they contribute only a negligible amount to the friction coefficient. After this first impulsive burst, the pectoral fins are not deployed again until the fish want to use them to rapidly stop forward motion. With pectoral fins aligned the forward motion is propelled by the movement of the tail. At rest they deploy the pectoral fins again to be ready for the next dart.

To survive, predator fish must develop a body that minimizes the added mass for swimming in the forward direction so that they can generate a minimum of waterborne sound when they increase their speed (accelerate) when closing in on their prey. Otherwise the prey would sense the sound generated by their acceleration early enough to dart into a safe hiding space. In choosing body shapes that, for a given oscillatory velocity, radiate the least amount of sound in the direction of the body's motion, noise control engineers are well advised to choose the shape of the vibrating body to resemble the body of a fish.

As shown in Fig. 10.16, the most promising body shape would resemble that obtained by cutting two identical-size fish perpendicularly at the location of their largest cross-sectional area and fitting the two head-parts together so that the two mouths point in the opposite direction. For motion in a direction different

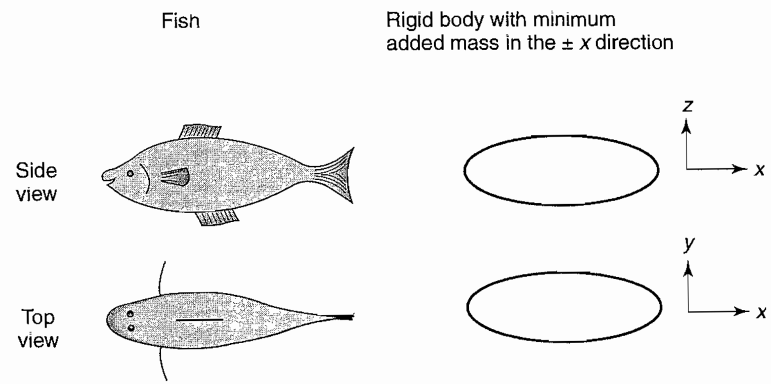

FIGURE 10.16 Learning from fish how to design bodies of minimum sound radiation owing to minimum added mass when oscillating in a specific direction.

from forward, especially in the direction perpendicular to it, the added mass of the fish is much larger, indicating the importance of the directional and shape dependence of the added mass of vibrating bodies of a geometry that is different from a sphere. The sphere has the distinction of having the same, large added mass for accelerating in any direction of motion. This large added mass is the reason that fish do no have a spherelike body (except some slow- swimming variety that inflate themselves to deceive their would-be predator). If fish would rotate instead of swim (mostly along straight paths), all of them would have a near-sphere-like body. On the other hand, if we wish to reduce the noise generated by the spinning of a rigid body, the sphere is the best choice. Surrounding a rotating nonspherical body with a spherical shell that rotates with the body will substantially reduce the noise radiation.

Reduction of Sound Radiation at Specific Frequencies. There is a class of noise sources, such as power transformers and turbine-generators, that radiate exclusively or predominantly tonal noise. Figures 10.17 and 10.18 show how the tonal noise produced by such equipment can be controlled by lining their radiating surface with Helmholtz resonator arrays tuned to the frequency (or frequencies) of their tonal noise output.

As shown in the lower sketch in Fig. 10.18, the noise radiation at the tuning frequency of the resonators is achieved by the low impedance of the resonator mouth in the vicinity of its resonance frequency. The fluid displaced by the solid part of the face of the resonator finds it easier to enter the resonator volume than to undergo compression. The smaller the compression, the lower is the radiated sound. Information on how to design Helmholtz resonators can be found in Chapter 8.

In the case of power transformers these tonal frequencies are 120, 240, 360, and 480 Hz in the United States and 100, 200, 300, and 400 Hz in Europe. Noise

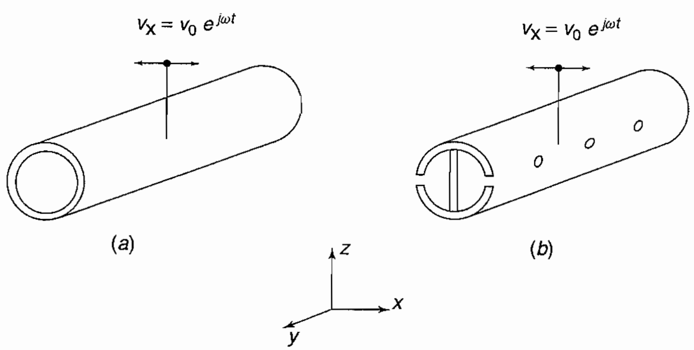

FIGURE 10.17 Frequency-selective reduction of sound generation owing to incorporation of Helmholtz resonators into the body: stiffened structural pipe beam vibrating perpendicular to its axes or rotating at constant rate as a spoke of a wheel.

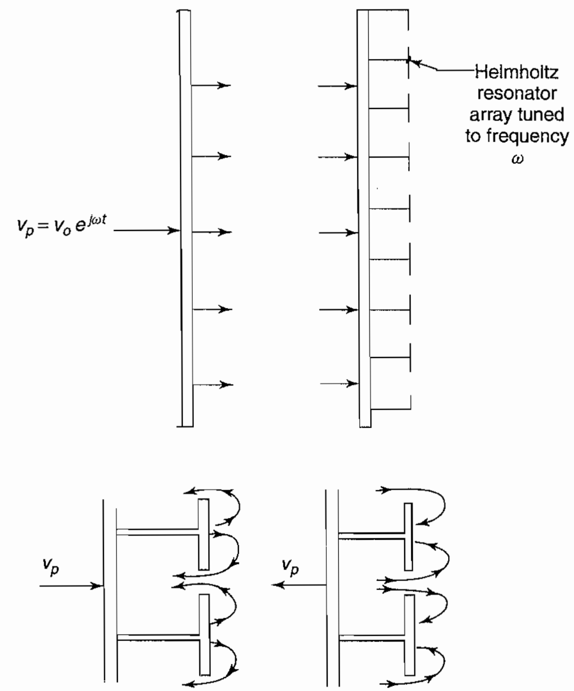

FIGURE 10.18 Frequency-selective reduction of sound radiation of a large flat surface, such as the outside wall of transformer tank, by lining it with a Helmholtz resonator array.

control measures for such noise sources and their advantages, disadvantages, and cost are compiled in reference 11.

Vacuum Bubbles. Figure 10.19 shows the concept of reducing the sound radiation of a transformer tank by lining the oil-side surface of the transformer tank with vacuum bubbles and how the presence of the vacuum bubbles, owing to their very large compliance, relieves the dynamic pressure on the tank wall and, consequently, reduces the sound radiation. As shown schematically in Fig. 10.20*a*, vacuum bubbles are twin curved thin shells with a small volume in between. When the cavity is evacuated, the shell nearly flattens out. In this evacuated final state they yield a compliance (inverse of the dynamic volume stiffness) that can be up to 50 times larger than the compliance of the air volume they replace and up to 1000 times that of the compliance of oil volume they replace. A unique feature of the vacuum bubbles is that there is vacuum in the cavity and there is no limit for the dynamic compliance, as there would be if the cavity were filled with a fluid. Below their resonance frequency, which is determined by the surface mass of the shell and its dynamic volume compliance, their volume compliance is independent of frequency. They work well even if the frequency approaches

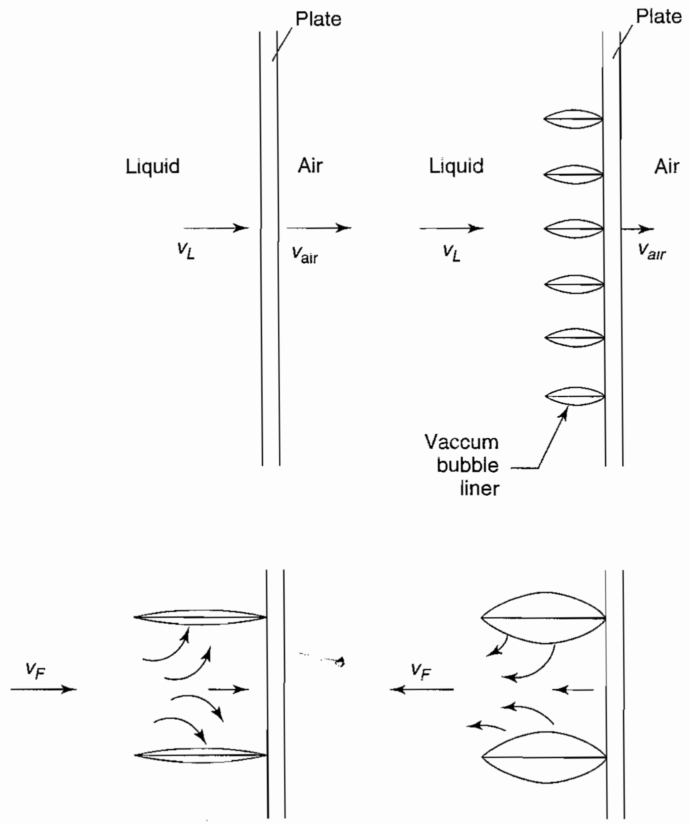

FIGURE 10.19 Reduction of the sound radiation from a transformer tank by lining the oil-side face of the tank wall with an array of vacuum bubbles of extremely high volume compliance. The vacuum bubbles can be oriented either perpendicular to the wall (as shown here) or parallel to it. Lower sketches indicate how the vacuum bubbles, which are much more compliant than either the oil or the tank wall, "soaks up" the momentum of the periodically approaching and receding oil. The velocity of the oil is due to the vibration of the transformer core driven by magnetostrictive forces.

zero. Information on how to design a vacuum bubbles for specific applications is given in references 12–14.

Figure 10.20 shows the geometry of a vacuum bubble (also called Scillator by its inventor Dr. Bschorr[12]) before and after evacuation of the cavity. As the name vacuum bubble implies, it is useful only in the evacuated state.

Vacuum bubbles are very sensitive to changes in static pressure (barometric pressure in air and depth-dependent pressure in liquids). Consequently, their most promising application would be in space stations, where the static air pressure can be controlled accurately.

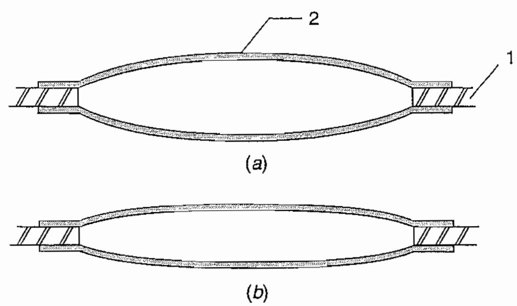

FIGURE 10.20 Conceptual sketch of a vacuum bubble. (*a*) Cross-sectional shape before evacuation of the cavity: 1, double-curved thin shell in the form of a top segment of a large-radius hollow sphere; 2, flat-plate strip base with punched holes. (*b*) Shape after evacuation of the cavity.

CHAPTER 11

Interaction of Sound Waves with Solid Structures

ISTVÁN L. VÉR

Consultant in Acoustics, Noise, and Vibration Control
Stow, Massachusetts

The response of structures to dynamic forces or dynamic pressures is the subject of structural dynamics and acoustics. Structural dynamics is concerned predominantly with dynamic stresses severe enough to endanger structural integrity. Structural acoustics deals with low-level dynamic processes in structures resulting from excitation by forces, moments, and pressure fields. The primary interest in airborne and structure-borne noise problems is the prediction of

1. power input into the structure,
2. the response of the excited structure,
3. propagation of structure-borne sound to connecting structures, and
4. sound radiated by the vibrating structure.

The subject matter of this chapter is specific to noise control problems and thus is restricted to the audible frequency range and to air as the surrounding medium, though many of the concepts are directly applicable to liquid media or to higher or lower frequencies.

A typical noise control problem is illustrated in Fig. 11.1. A resiliently supported floor slab in the room to the left (source room) is excited by the periodic impacts of a tapping machine, while the microphone in the receiving room to the right registers the resulting noise. A part of the vibrational energy is dissipated in the floating slab, a part is radiated directly as sound into the source room, and the remainder is transmitted through the resilient layer into the building structure.

The radiated sound energy builds up a reverberant sound field in the source room that in turn excites the walls. The vibrations in the wall separating the two rooms, identified as path 1 in Fig. 11.1, radiate sound directly into the receiver room. The vibrations in the other partitions of the source room travel in the form of structure-borne sound to the six partitions of the receiving room and radiate

CHAPTER 11

Interaction of Sound Waves with Solid Structures

ISTVÁN L. VÉR
Consultant in Acoustics, Noise, and Vibration Control
Stow, Massachusetts

The response of structures to dynamic forces or dynamic pressures is the subject of structural dynamics and acoustics. Structural dynamics is concerned predominantly with dynamic stresses severe enough to endanger structural integrity. Structural acoustics deals with low-level dynamic processes in structures resulting from excitation by forces, moments, and pressure fields. The primary interest in airborne and structure-borne noise problems is the prediction of

1. power input into the structure,
2. the response of the excited structure,
3. propagation of structure-borne sound to connecting structures, and
4. sound radiated by the vibrating structure.

The subject matter of this chapter is specific to noise control problems and thus is restricted to the audible frequency range and to air as the surrounding medium, though many of the concepts are directly applicable to liquid media or to higher or lower frequencies.

A typical noise control problem is illustrated in Fig. 11.1. A resiliently supported floor slab in the room to the left (source room) is excited by the periodic impacts of a tapping machine, while the microphone in the receiving room to the right registers the resulting noise. A part of the vibrational energy is dissipated in the floating slab, a part is radiated directly as sound into the source room, and the remainder is transmitted through the resilient layer into the building structure.

The radiated sound energy builds up a reverberant sound field in the source room that in turn excites the walls. The vibrations in the wall separating the two rooms, identified as path 1 in Fig. 11.1, radiate sound directly into the receiver room. The vibrations in the other partitions of the source room travel in the form of structure-borne sound to the six partitions of the receiving room and radiate

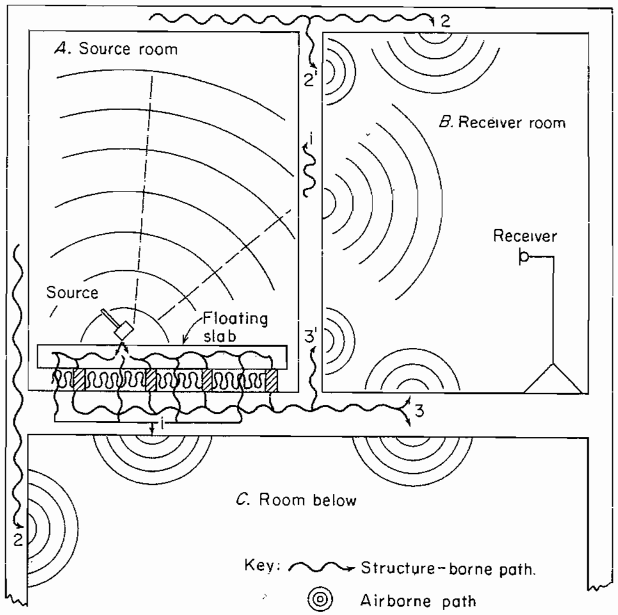

FIGURE 11.1 Sound transmission paths between an impact source in room A and a receiver in room B. Also shown are the paths to room C below.

sound into the receiver room. The structure-borne paths are identified by waves, 2, 2′ and 3, 3′.

To reduce the noise level in the receiving room by a desired amount, the acoustical engineer must estimate the sound power transmitted from the source room to the receiver room through each path and then design appropriate measures to (1) reduce power input to the floating slab, (2) increase power dissipation in the slab, (3) increase vibration isolation, (4) reduce the structure-borne noise along its propagation path between source and receiver room, (5) reduce the sound radiated by the partitions of the source room, and (6) reduce the reverberation buildup of the sound in the receiver room by increasing sound absorption.

The aim of this chapter is to provide the information needed to solve such typical noise control engineering problems.

11.1 TYPES OF WAVE MOTION IN SOLIDS

Wave motion in solids can store energy in shear as well as in compression. The types of waves possible in solids include compressional waves, flexural waves, shear waves, torsional waves, and Rayleigh waves. Compressional waves are of practical importance in gases and liquids, which can store energy only in

compression. The different types of waves in solids result from different ways of stressing. For a wave to propagate in solids, liquids, and gases, the medium must be capable of storing energy alternatively in kinetic and potential form. Kinetic energy is stored in any part of a medium that has mass and is in motion, while potential energy is stored in parts that have undergone elastic deformation.

Solid materials are characterized by the following parameters:

Density	ρ_M	kg/m^3
Young's modulus	E	N/m^2
Poisson's ratio	ν	
Loss factor	η	

The shear modulus G is related to Young's modulus as

$$G = \frac{E}{2(1+\nu)} \quad \text{N/m}^2 \tag{11.1}$$

The sketches on the left of Table 11.1 illustrate the deformation pattern typical for compressional, shear, torsional, and bending waves in bars and plates. Acoustically important parameters of solid materials are compiled in Table 11.2. Note that all tables in this chapter are placed at the end of the text. Thickness and weight per unit surface area of steel plates are listed in Table 11.10. Percentage open area of perforated metal is given in Table 11.11.

In dealing with structure-borne sound, we must distinguish between velocity and propagation speed. The term *velocity* refers to vibration velocity of the structure (i.e., the time derivative of the local displacement), which is linearly proportional to the excitation and will be designated by the letter v. As illustrated on the left of Table 11.1, the displacement and velocity are in the direction of wave propagation for longitudinal waves and perpendicular to it for shear and bending waves.

The term *speed* refers to the propagation speed of structure-borne sound, which is a characteristic property of the structure for each type of wave motion and is independent of the strength of excitation provided that the deformations are small enough to avoid nonlinearities. Propagation speeds will be designated by the letter c. We must distinguish between *phase speed* and *group speed* (or energy speed).

The phase speed c is defined in terms of (1) the wavelength λ, which is the distance in the propagation direction for which the phase of a sinusoidal wave changes 360°, and (2) the frequency f of the sinusoid. Consequently, $c = \lambda f$. Formulas to calculate phase speed of the various wave types are given on the right side of Table 11.1. Note that the phase speed for longitudinal, shear, and torsional waves is independent of frequency. Consequently, they are referred to as nondispersive waves. This means that the time history of an impulse, such as caused by a hammer blow striking axially on one end of a semi-infinite bar, as illustrated in Fig. 11.2a, will have the same shape regardless of where the

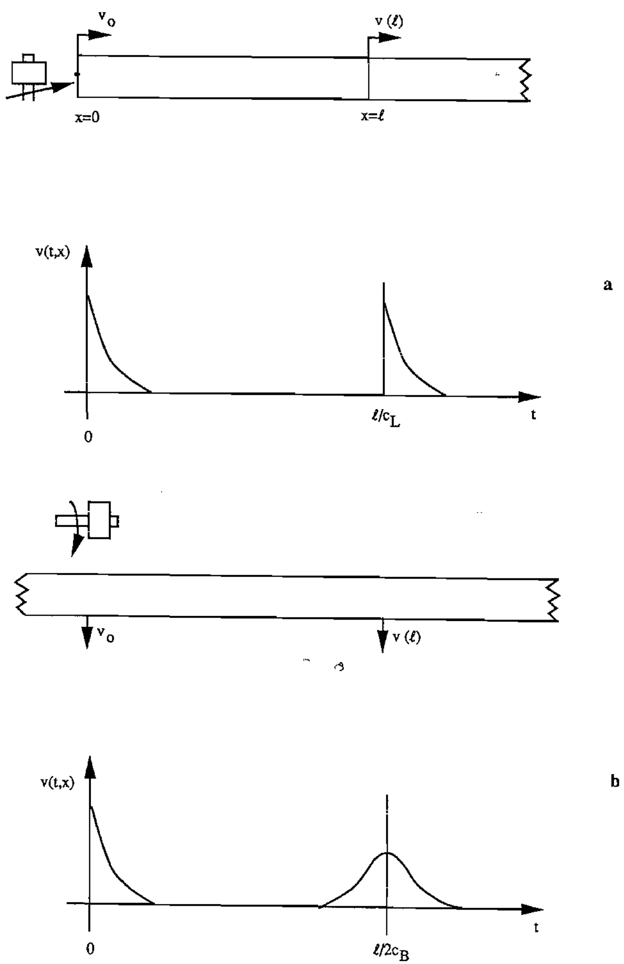

FIGURE 11.2 Time history of beam motion for impulsive excitation: (*a*) axial impact-generating nondispersive compressional waves; (*b*) normal impact-generating dispersive bending waves.

axial motion is sensed. Because the pulses sensed at different locations are time-delayed versions of each other, the propagation speed of the longitudinal wave can be determined experimentally as the ratio of the axial distance and the difference of arrival time. Since all frequency components travel at the same speed, the phase speed (which is defined only for a steady-state sinusoidal excitation) is identical with the speed of energy transport.

The phase speed of the bending wave can be easily measured by exciting the infinite beam with a steady-state sinusoidal force acting normal to the beam

axis and measuring the gradient of the phase $d\phi/dx$ along the beam. The phase velocity c_B is defined as

$$c_B = \frac{2\pi f}{|d\phi/dx|} \quad \text{m/s} \tag{11.2}$$

However, the situation is much more complicated in the case of a complex waveform such as illustrated in Fig. 11.2*b*, where an infinite beam is impacted normally and a bending-wave pulse that contains a wide band of frequencies is created. Because of their higher phase speed, high-frequency components speed ahead of the low-frequency component. Consequently, the width of the pulse increases as it travels along the beam. The speed of energy transport for the bending-wave pulse is not obvious. In case of light fluid loading (when the energy carried in the surrounding fluid is negligible), it is meaningful to define the energy transport speed as the ratio of transmitted power W and the energy density E'' (per unit length of beam). For a pulse whose spectrum peaks at frequency f the energy speed c_{BG} is twice the phase speed[1]:

$$c_{BG}(f) = 2c_B(f) \quad \text{m/s} \tag{11.3}$$

Accordingly, the power transmitted by a plane bending wave in the direction of propagation per unit area of a structure normal to that direction is

$$W_S = c_{BG}E'' = 2c_B\rho_M v^2 \quad \text{W/m}^2 \tag{11.4}$$

where v is the rms value of the bending-wave velocity and ρ_M is the density of the material. According to Eq. (11.4), the bending-wave power in an infinite beam of cross section S is given by

$$W = 2c_B S\rho_M v^2 \quad \text{W} \tag{11.5}$$

and power transmitted by a plate of thickness h across a line length l aligned parallel to the wave front is

$$W = 2c_B hl\rho_M v^2 \quad \text{W} \tag{11.6}$$

11.2 MECHANICAL IMPEDANCE AND POWER INPUT

Except for the initial transient, the velocity at the excitation point is zero if a structure is subjected to a static force. Accordingly, a static force does not transmit power into a fixed structure. For dynamic excitation by a point force or moment [the moment $M = Fl_m$ is defined as a pair of forces (F) of equal magnitude but opposite direction acting simultaneously at a short distance ($\frac{1}{2}l_M$) on both sides of the excitation point], there is always a finite dynamic velocity or dynamic rotation at the excitation point. If the velocity at the excitation point has a component that is in phase with the force, or the angular velocity has a component that is in phase with the moment, then power is fed continuously into the structure.

Mechanical Impedance

The mechanical impedance is a measure of how a structure "resists" outside forces or moments. A thorough understanding of mechanical impedances is a necessary requirement for understanding and for solving most noise control problems. The concept of mechanical impedance is best introduced by considering a harmonic force $F = \hat{F}e^{j\omega t}$ acting on an ideal lumped-parameter system such as a rigid unrestrained mass, a massless spring, or a dashpot. The velocity response is also a harmonic function of the form $v = \hat{v}e^{j\omega t}$. The force impedance Z_F is defined as

$$Z_F = \frac{\hat{F}}{\hat{v}} \quad \text{N} \cdot \text{s/m} \tag{11.7}$$

and the moment impedance Z_M as

$$Z_M = \frac{\hat{M}}{\hat{\dot{\theta}}} \quad \text{N} \cdot \text{s/m} \tag{11.8}$$

where M is the exciting moment (torque) and $\dot{\theta}$ is the angular velocity at the excitation point.

The point force impedance for these basic lumped elements are listed below:

Element	Z_F	
Mass	$j\omega m$	Spring	$-js/\omega$	
Dashpot	r	
where m is the mass of a rigid body, s is the stiffness of the spring, and r is the resistance of the dashpot. Note that the direction of the force must go through the center of gravity of the mass so that the velocity response is free of rotation and is in the direction of the force. For the rigid mass and the massless spring the force impedance is imaginary, indicating that the force and velocity are in quadrature and the power input is zero.

Formulas for computing the point force and moment impedances of infinite structures are given in references 2–12 and in Tables 11.3 and 11.4, respectively. Both force and moment impedances are idealized concepts, defined for point

forces and point moments. Forces or moments can be considered applied at a point, provided that the surfaces over which they act are smaller than one-sixth of the structural wavelength. Naturally, the excited surface area must be large enough so that the force does not cause plastic deformation of the structure. There is proportionality between force and moment impedances in the form of

$$Z_M = l_M^2 Z_F \quad \text{N} \cdot \text{m/s} \tag{11.9}$$

where l_M is the effective length given in Table 11.5.

Power Input

For the dashpot the force impedance is real. The velocity is in phase with the force and the power that is fed continuously into the dashpot and dissipated in it is given by $\frac{1}{2}|\hat{F}|^2/r$. More generally, for a system with a complex force impedance Z_F, the input power is

$$W_{\text{in}} = \frac{\omega}{2\pi}\int_0^{2\pi/\omega} F(t)v(t)\, dt = \tfrac{1}{2}|\hat{F}|\ |\hat{v}|\cos\phi = \tfrac{1}{2}|\hat{F}|^2\, \text{Re}\left\{\frac{1}{Z_F}\right\} \quad \text{W} \tag{11.10}$$

where $\hat{F}$ and $\hat{v}$ are the peak amplitude of the exciting force and the velocity, ϕ is the relative phase between $F(t)$ and $v(t)$, and Re{} refers to the real part of the bracketed quantity. Equation (11.10) is valid for any situation, not only for the dashpot.

Rigid masses, massless springs, and dashpots are useful abstractions that represent the dynamic properties of structural elements. At sufficiently low frequencies, the housing of a resiliently mounted pump behaves like a rigid mass, while the resilient rubber mount that supports it behaves like a spring. This lumped-parameter characterization of mechanical elements becomes invalid when, with increasing frequency, the structural wavelength becomes smaller than the largest dimensions of the structural element.

To deal with finite structures that are large compared with the structural wavelength, we need another useful abstraction. Regarding their input impedance—which governs power input—it is useful to consider such structures as infinite. The strategy for predicting the vibration response and sound radiation for these structures is to estimate the power input as if they were infinite and then predict the average vibration that such input power will cause in the actual finite structure. Because most structures are made of plates and beams, our strategy requires us to characterize the impedance of infinite plates and beams. The abstraction of infinite size is invoked so that no structural waves reflected from the boundaries come back to the excitation point. In this respect, structures can be considered infinite if no reflected waves that are coherent with the input come back to the excitation point because the boundaries are completely absorbing or because there is sufficient damping so that the response attributable to the reflected waves is small compared to that attributable to the local excitation.

In respect to point force excitation, infinite structures are characterized by their point force impedance $\tilde{Z}_{F\infty}$ or point input admittance (also called mobility) $\tilde{Y}_{F\infty}$, defined as

$$\tilde{Z}_{F\infty} = \frac{\tilde{F}_0}{\tilde{v}_0} \quad \mathrm{N \cdot s/m} \tag{11.11}$$

$$\tilde{Y}_{F\infty} = \frac{1}{\tilde{Z}_{F\infty}} = \frac{\tilde{v}_0}{\tilde{F}_0} \quad \mathrm{m/N \cdot s} \tag{11.12}$$

where $\tilde{F}_0$ is the applied point force and $\tilde{v}_0$ is the velocity response at the excitation point. The tilde above the symbols (which we will drop in further considerations) signifies that F_0 and v_0 are complex scalar quantities characterized by a magnitude and phase. Since $\tilde{v}_0$ usually has a component that is in phase with $\tilde{F}_0$ and one that is out of phase with $\tilde{F}_0$, the parameters $\tilde{Z}_F$ and $\tilde{Y}_F$ usually have both real and imaginary parts.

The power inputs to infinite structures excited by a point force or by a point velocity source (i.e., a vibration source of high internal impedance) are, respectively,

$$W_{\text{in}} = |\tfrac{1}{2}\hat{F}_0^2| \,\mathrm{Re}\left\{\frac{1}{Z_{F\infty}}\right\} \quad \mathrm{W} \tag{11.13a}$$

$$W'_{\text{in}} = G_{FF} \,\mathrm{Re}\left\{\frac{1}{Z_{F\infty}}\right\} \quad \mathrm{W/Hz} \tag{11.13b}$$

$$W_{\text{in}} = (\tfrac{1}{2}\hat{v}_0^2) \,\mathrm{Re}\{Z_{F\infty}\} \quad \mathrm{W} \tag{11.14a}$$

$$W'_{\text{in}} = G_{VV} \,\mathrm{Re}\{Z_{F\infty}\} \quad \mathrm{W/Hz} \tag{11.14b}$$

where $\hat{F}_0$ and $\hat{v}_0$ are peak amplitudes of the exciting sinusoidal force and velocity and G_{FF} and G_{VV} are the force and velocity spectral densities when the excitation is of broadband random nature. For excitation by a moment of peak amplitude $\hat{M}$ or by an enforced angular velocity of peak amplitude $\hat{\theta}$, the corresponding expressions are

$$W_{\text{in}} = |\tfrac{1}{2}\hat{M}_0^2| \,\mathrm{Re}\left\{\frac{1}{Z_M}\right\} \quad \mathrm{W} \tag{11.15a}$$

$$\frac{W'_{\text{in}}}{\mathrm{Hz}} = G_{MM} \,\mathrm{Re}\left\{\frac{1}{Z_M}\right\} \quad \mathrm{W/Hz} \tag{11.15b}$$

$$W_{\text{in}} = |\tfrac{1}{2}\hat{\theta}| \,\mathrm{Re}\{Z_M\} \quad \mathrm{W} \tag{11.16a}$$

$$W'_{\text{in}} = G_{\theta\theta} \,\mathrm{Re}\{Z_M\} \quad \mathrm{W/Hz} \tag{11.16b}$$

Table 11.3 lists the point force impedance $Z_{F\infty}$ and Table 11.4 the moment impedance $Z_{M\infty}$ for semi-infinite and infinite structures. Table 11.5 lists the effective length l_M that connects the point force and moment impedances according

to Eq. (11.9). Information regarding power input to infinite structures for force, velocity, moment, and angular velocity excitation is compiled in Table 11.6. The most complete collection of impedance formulas, which includes beams, box beams, orthotropic and sandwich plates with elastic or honeycomb core, grills, homogeneous and rib-stiffened cylinders, spherical shells, plate edges, and plate intersections and transfer impedances of various kinds of vibration isolators, is presented in reference 12.

For approximate calculations or for cases where no formulas are given in Tables 11.3–11.6, the power input to infinite structures can be estimated according to Heckl[10,11] as

$$W_{\text{in}} = \frac{\tfrac{1}{2}\hat{F}_0^2}{Z_{\text{eq}}} \quad \mathrm{W} \tag{11.17}$$

$$W_{\text{in}} = (\tfrac{1}{2}\hat{v}_0^2) Z_{\text{eq}} \quad \mathrm{W} \tag{11.18}$$

where Eq. (11.17) is used for localized force excitation (i.e., low-impedance vibration source) and Eq. (11.18) for localized velocity excitation (i.e., high-impedance vibration source) and Z_{eq} is estimated as

$$Z_{\text{eq}} = \omega\rho_M S\epsilon[\alpha\lambda] \quad \mathrm{N \cdot s/m} \quad \text{(beam)} \tag{11.19a}$$

$$Z_{\text{eq}} = \omega\rho_M h\epsilon[\pi(\alpha\lambda)^2] \quad \mathrm{N \cdot s/m} \quad \text{(plate)} \tag{11.19b}$$

$$Z_{\text{eq}} = \omega\rho_M \epsilon[\tfrac{4}{3}\pi(\alpha\lambda)^3] \quad \mathrm{N \cdot s/m} \quad \text{(half space)} \tag{11.19c}$$

where ρ_M is the density of the material, S is the cross-sectional area of the beam, h is the plate thickness, λ is the wavelength of the motion excited most strongly (bending, shear, torsion, or compression), and ϵ is 1 when the structure is excited in the "middle" and 0.5 when it is excited at the end or at the edge (semi-infinite structure) and α is a number in the range of 0.16–0.6. If not known, it is customary to use $\alpha = 0.3$.

The equivalent impedance Z_{eq} in Eq. (11.19) has an instructive and easy-to-remember interpretation, namely that the magnitude of the point input impedance is roughly equal to the impedance of a lumped mass that lies within a sphere of radius $r \simeq \frac{1}{3}\lambda$ centered at the excitation point. This portion of the structure is shown in the third column of Table 11.3. This principle can be extended to composite structures[10] such as beam-stiffened plates where the combination of Eqs. (11.19a) and (11.19b) yields

$$Z_{\text{eq}} \cong \omega\rho_B S_B(\tfrac{1}{3}\lambda_{BB}) + \omega\rho_p h(\tfrac{1}{3}\lambda_{BP}) \quad \mathrm{N \cdot s/m} \tag{11.20}$$

Another useful rule of thumb is that, regarding power input, excitation by a moment $\hat{M}$ and by an enforced angular velocity $\hat{\theta}$ can be represented by an equivalent point force $\hat{F}_{\text{eq}}$ or equivalent velocity $\hat{v}_{\text{eq}}$,[11]

$$\hat{F}_{\text{eq}} \cong \frac{\hat{M}}{0.2\lambda_B} \quad \text{N} \tag{11.21}$$

$$\hat{v}_{\text{eq}} \cong \hat{\dot{\theta}}(0.2\lambda_B) \quad \text{m/s} \tag{11.22}$$

If the excitation force extends over an area that is large compared with the bending wavelength, the power transmitted into the structure becomes substantially less than it would be for a concentrated force. For extended velocity source the power transmitted becomes significantly larger than it would be for a concentrated velocity excitation.

According to reference 5, the real part of the point force impedance, Re $\{Z_{F\infty}\}$, can be predicted according to Bode's theorem as

$$\text{Re}\{Z_{F\infty}\} \cong |Z_{\text{eq}}| \cos(\tfrac{1}{2}\epsilon\pi) \quad \text{N}\cdot\text{s/m} \tag{11.23}$$

where ϵ is defined here as an exponent of the Z_{eq}-versus-frequency curve (i.e., $Z_{\text{eq}} \sim \omega^{\epsilon}$), where $\epsilon = 0$ for homogeneous isotropic thick plates, $\epsilon = 0.5$ for beams in bending, and $\epsilon = \frac{2}{3}$ for cylinders below the ring frequency.

Parameters Influencing Power Input. When the excitation point is near a structural junction, part of the incident vibration wave is reflected. This reflected wave influences the velocity at the excitation point and thereby also the driving point impedance and consequently the power input. Fig. 11.3*a* shows the effect of the vicinity of a T-junction comprised of identical, anechoically terminated beams on the point force impedance $Z_2(x_0)$ as a function of the distance x_0 between the junction and the excitation point.[13] As expected, the impedance increases rapidly with decreasing distance when $x_0 < \frac{1}{3}\lambda_B$. The junction has a considerable effect even for large x_0, causing approximately a 2 : 1 fluctuation in the magnitude of the impedance. Figure 11.3*b* shows the measured distribution of the beam vibration velocity $|v(x)|$ along each of the three beam branches, indicating that the observed strong standing-wave pattern is limited to that part of beam 2 that lies between the junction and the excitation point.

The impedance formulas presented in Tables 11.3–11.6 are strictly valid only when the surrounding fluid medium has no appreciable effect on the response of the structure. This is generally true for air as the surrounding medium but not for water, which is 800 times more dense than air. The effect of fluid loading at low frequencies is equivalent[14] to adding a virtual mass per unit area ρ_s',

$$\rho_s' = \frac{\rho_0 c_B(f)}{\omega} \cong \rho_0[\tfrac{1}{6}\lambda_B(f)] \quad \text{kg/m}^2 \tag{11.24}$$

to the mass per unit area of the plate. In Eq. (11.24), ρ_0 is the density of the fluid and $c_B(f)$ and $\lambda_B(f)$ are the bending-wave speed and the wavelength of the free bending waves in the unloaded plate (see Table 11.1). Because ρ_s' is inversely proportional to $\omega^{1/2}$, fluid loading results in greater reduction of the response

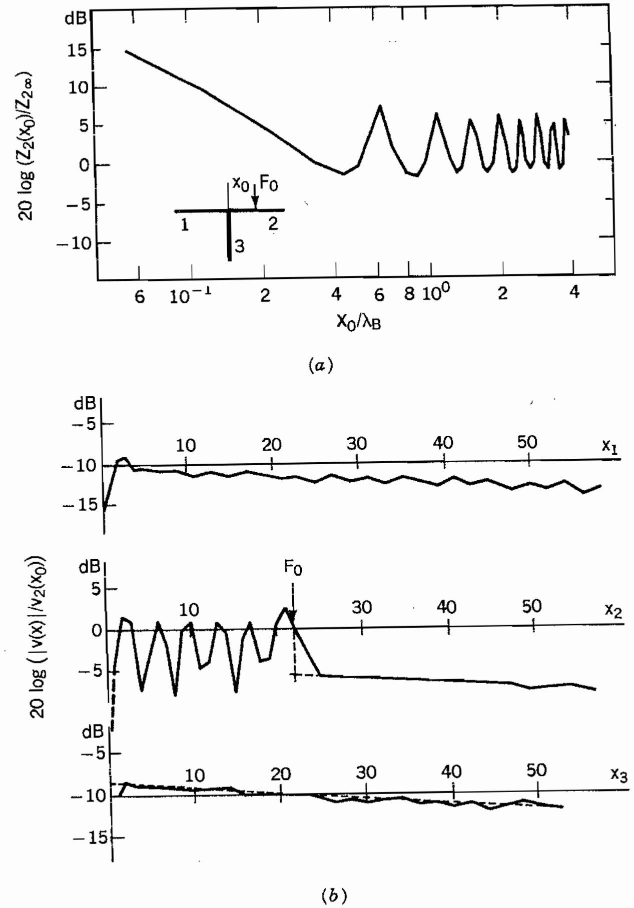

FIGURE 11.3 Effect of the vicinity of T-junction on the measured point force impedance and velocity response[13]: (*a*) normalized force impedance $Z_1(x_0)/Z_{1\infty}$ as a function of the normalized distance x_0/λ_B and x_i is the distance from the junction along beam i; (*b*) distribution of normalized velocity, $v(x)/v_0$, along the three beam branches as numbered in (*b*).

at the excitation point at low than at high frequencies. Fluid-loading effects are treated in references 14–17.

11.3 POWER BALANCE AND RESPONSE OF FINITE STRUCTURES

For finite structures, the response at the excitation point, and accordingly also the input admittance, $Y = 1/Z$, depends on the contribution of the waves reflected from the boundaries or discontinuities. Consequently, Y varies with the location of the excitation point and with frequency. However, both the space-averaged and frequency-averaged input admittances of the finite structure $\langle Y(x, f)\rangle_x$ and $\langle Y(x, f)\rangle_f$ equal the point input admittance of the equivalent infinite structure,[18] namely,

$$\langle Y(x, f)\rangle_x = \langle Y(x, f)\rangle_f = Y_\infty \quad \text{m/N} \cdot \text{s} \tag{11.25}$$

Figures 11.4*a* and 11.4*b* show the typical variation of the real and imaginary parts of the point input admittance of a finite plate with location x and frequency f, respectively. This particular behavior has considerable practical importance:

1. The power introduced into a finite structure by a point force of random-noise character can be well approximated by the power that the same force would introduce into an equivalent infinite structure.
2. The power introduced into a finite structure by a large number of randomly spaced point forces can be approximated by the power the same forces would introduce into an equivalent infinite structure.

Resonant Modes and Modal Density

The peaks in Fig. 11.4*a* correspond to resonance frequencies of the finite structure, where waves reflected from the boundaries travel in closed paths such that they arrive at their starting point in phase. The spatial deformation pattern that corresponds to such a particular closed path is referred to as the *mode shape* and the frequency where it occurs as the *eigenfrequency* or *natural frequency* of the finite structure. The importance of such resonances lies in the high transverse velocity caused by the in-phase superposition of the multiple reflections that may result in increased sound radiation or fatigue.

Exact calculation of the natural frequencies is possible only for a few highly idealized structures. Fortunately, the modal density $n(f)$, which is defined as the average number of natural frequencies in a 1-Hz bandwidth, depends not too strongly on the boundary conditions. Accordingly, one can make a reliable statistical prediction of the modal density using the formulas obtained for the equivalent idealized system.

For example, the modal density of a thin, flat, homogeneous, isotropic plate of not too high aspect ratio two octaves above the first plate resonance is already well approximated by the modal density of a rectangular plate of equal surface area, which is given by[1]

$$n(f) \approx \frac{\sqrt{12}S}{2c_L h} \quad \text{s} \tag{11.26}$$

where S is the area (one side) and h is the thickness. Note that $n(f)$ is independent of frequency and that it is large for large and thin plates.

The modal density of rooms of volume V one octave above the first room resonance is usually well approximated by the first term of the modal density of

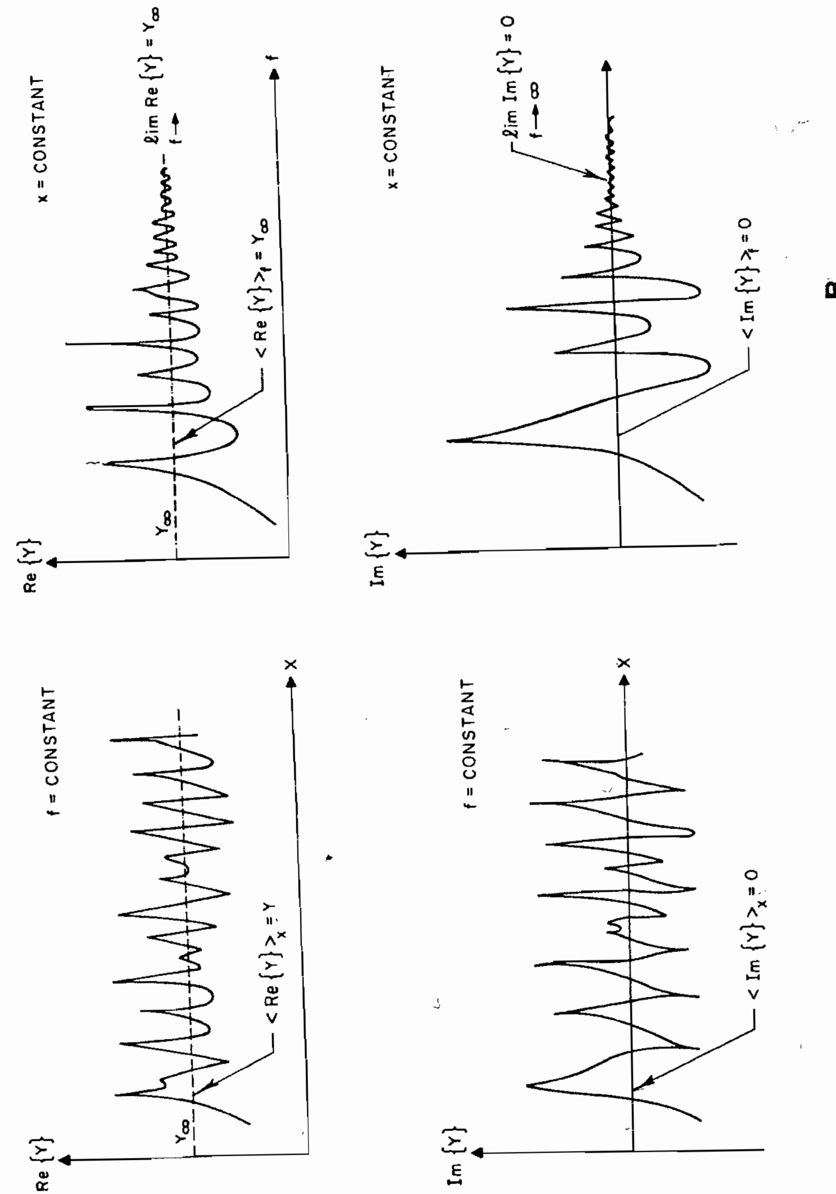

FIGURE 11.4 Typical fluctuations of the real part, Re{Y}, and imaginary part, Im{Y}, of the point input admittance of a finite plate as a function of (*a*) location x, $\langle \cdots \rangle_x$ is spatial average at a fixed frequency; (*b*) frequency f, $\langle \cdots \rangle_f$ is frequency average at a fixed location

a rectangular room with hard walls,

$$n(f) = \frac{4\pi V}{c_0^3} f^2 + \frac{\pi S}{c_0^2} + \frac{L}{8c_0} \quad \text{s} \tag{11.27}$$

where S is the total wall surface area and L is the longest dimension of the rectangular room. The first resonance frequency, modal densities, and mode shapes of a number of finite structures and the point input impedance (the inverse of the admittance) of the equivalent infinite structure are compiled in Table 11.7. More detailed information on mode shapes, natural frequencies, and modal densities are given in reference 19. The following important relationship exists between the modal density and the real part of the point force admittance of the equivalent infinite system[1]:

$$\operatorname{Re}\{Y_\infty\} = \frac{n(f)}{iM} \quad \text{m/N} \cdot \text{s} \qquad i = \begin{cases} 4 \text{ for thin plate} \\ 2 \text{ for thin cylinder} \\ 1 \text{ for thin sphere} \end{cases} \tag{11.28}$$

where M is the total mass of the finite system.

Power Balance

The power balance given in Eq. (11.29),

$$W_{\text{in}} = W_d + W_{\text{tr}} + W_{\text{rad}} \quad \text{W} \tag{11.29}$$

states that, in steady state, the power introduced, W_{in}, equals the power dissipated in the structure, W_d, the power transmitted to connected structures, W_{tr}, and the power radiated as sound into the surrounding fluid, W_{rad}. If the excitation is by a point force of peak amplitude $\hat{F}_0$ and the structure is a homogeneous isotropic thin plate of thickness h, area S (one side), density ρ_M, with longitudinal wave speed c_L, immersed in a fluid of density ρ_0, and speed of sound c_0, Eq. (11.29) takes the form

$$\tfrac{1}{2}\hat{F}^2 \operatorname{Re}\{Y_F\} = \langle v^2 \rangle S[\rho_s \omega \eta_d + \rho_s \omega \eta_{\text{tr}} + 2\rho_0 c_0 \sigma] \quad \text{W} \tag{11.30}$$

where $\rho_s = \rho_M h$ is the mass per unit area of the plate, $\omega = 2\pi f$ is the radian frequency, η_d and η_{tr} are the dissipative and transmissive loss factors, and σ is the sound radiation efficiency of the plate (see Section 11.6). Combining dissipative and transmissive losses into a single composite loss factor $\eta_c = \eta_d + \eta_{\text{tr}}$ and assuming $\operatorname{Re}\{Y_F\} = Y_{F\infty} = 1/Z_{F\infty} = 1/(2.3\rho_s C_L t)$, as given in Table 11.3, and solving for the space–time averaged mean-square plate velocity $\langle v^2 \rangle$ yield

$$\langle v^2 \rangle = \frac{\hat{F}_0^2}{4.6\rho_s^2 c_L t \omega \eta_c S(1 + 2\rho_0 c_0 \sigma/\rho_s \omega \eta_c)} \quad \text{m}^2/\text{s}^2 \tag{11.31}$$

Example 11.1. Predict the space–time averaged velocity response $(\langle v^2 \rangle)^{1/2}$ of a 2-mm-thick, 1×2-m steel plate to a point force $\hat{F}_0 = 10$ N peak amplitude at a frequency of 10 kHz when $\sigma = 1$ and $\eta_c = 0.01$. Compare $\langle v^2 \rangle$ with the mean-square velocity at the excitation point v_0^2. The input parameters to be used in connection with Eq. (11.31) and Table 11.2 are

$$\begin{aligned} &\hat{F}_0 = 10 \text{ N} \qquad \rho_s = \rho_M t = 7700 \text{ kg/m}^3 \times 2 \times 10^{-3} \text{ m} = 15.4 \text{ kg/m}^2 \\ &c_L = 5050 \text{ m/s} \qquad \omega = 2\pi f = 2\pi \times 10^4 \text{ rad/s} \qquad \eta_c = 0.01 \\ &S = 2 \text{ m}^2 \qquad \rho_0 = 1.2 \text{ kg/m}^3 \qquad c_0 = 340 \text{ m/s} \qquad \sigma = 1 \end{aligned}$$

yielding

$$\begin{aligned} \langle v^2 \rangle &= \frac{10^2}{4.6 \times (15.4)^2 \times 5.05 \times 10^3 \times 2 \times 10^{-3} \times 2\pi \times 10^4 \times 10^{-2}} \\ &\quad \times \frac{1}{2(1 + 2 \times 1.2 \times 340/15.4 \times 2\pi \times 10^4 \times 2 \times 10^{-2})} \\ &= 6.7 \times 10^{-6} \text{ m/s}^2 \\ \sqrt{\langle v^2 \rangle} &= 2.6 \times 10^{-3} \text{ m/s} \\ v_0^2 &= \frac{1}{2}\hat{F}_0^2 Y_\infty = \frac{\hat{F}^2}{4.6\rho_s c_L t} = \frac{10^2}{4.6 \times 15.4 \times 5.03 \times 10^3 \times 2 \times 10^{-3}} \\ &= 0.14 \text{ m/s} \\ \frac{v_0^2}{\langle v^2 \rangle} &= \frac{(0.14)^2}{6.7} \times 10^6 = 2925 \qquad \sqrt{\frac{\langle v^2 \rangle}{v_0^2}} = 54 \end{aligned}$$

11.4 REFLECTION AND TRANSMISSION OF SOUND AT PLANE INTERFACES

When a plane sound wave traveling in a homogeneous medium encounters a plane interface with another medium, it may be (1) totally reflected, (2) partially reflected, or (3) totally transmitted depending upon the angle of incidence, the propagation speed of sound, and the density of the materials on both sides of the interface. Interfaces of practical importance are between air and water, between air and solid materials, between air and porous materials (such as ground or sound-absorbing materials), and between layers of fibrous sound-absorbing material such as treated in Chapter 8.

The simplest case is when the wave front of the incident plane wave is parallel to the plane of the interface (i.e., the wave propagates normal to the interface), as shown schematically in Fig. 11.5. In this simple case the transmitted wave p_{tran} retains the propagation direction of the incident wave p_{inc} and the following

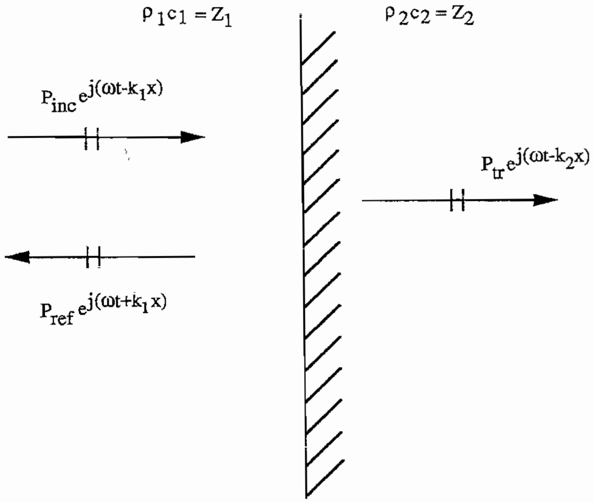

FIGURE 11.5 Reflection and transmission of a plane sound wave normally incident on the plane interface of an infinitely thick medium: p_{inc}, p_{ref}, p_{tr}, peak amplitudes of incident, reflected, and transmitted pressure; ρ, c, density and speed of sound of respective media.

relationships apply:

$$\frac{p_{tran}}{p_{inc}} = \frac{4R_e\{Z_2\}/R_e\{Z_1\}}{|Z_2/Z_1 + 1|^2} = \frac{2Z_2}{Z_2 + Z_1} \tag{11.32}$$

$$\frac{p_{ref}}{p_{inc}} = 1 - \frac{W_{tran}}{W_{ref}} = \frac{Z_2 - Z_1}{Z_2 + Z_1} \tag{11.33}$$

and for the power transmission and reflections

$$\frac{W_{tran}}{W_{inc}} = 1 - \left|\frac{Z_2 - Z_1}{Z_2 + Z_1}\right|^2 \tag{11.34}$$

$$\frac{W_{ref}}{W_{inc}} = \left|\frac{Z_2 - Z_1}{Z_2 + Z_1}\right|^2 \tag{11.35}$$

where $Z_i = \rho_i c_i$ is the characteristic impedance of media i for plane waves and ρ_i and c_i are the density and sound speed of the medium. For an air–steel interface and for a water–steel interface where $Z_2/Z_1 = 3.9 \times 10^7/4.1 \times 10^2$ and $Z_2/Z_1 = 3.9 \times 10^7/1.5 \times 10^6$, respectively, Eqs. (11.32)–(11.35) yield

Interface	p_{tran}/p_{inc}	p_{ref}/p_{inc}	W_{tran}/W_{inc}	W_{ref}/W_{inc}
Air–steel	1.99998	0.99998	0.00004	0.99996
Water–steel	1.927	0.927	0.141	0.859

indicating that plane waves normally incident from air onto bulk solid materials transmit only an extremely small portion of the incident energy while those incident from liquids are able to transmit an important fraction of the incident sound energy.

If the plane wave arrives at the plane interface at an oblique angle ϕ_1 ($\phi_1 = 0$ is normal incidence), the angle of the reflected wave $\phi_r = \phi_i$ but the angle of the transmitted wave ϕ_2 depends on the ratio of the propagation speeds in the two materials according to Snell's law:

$$\frac{c_1}{c_2} = \frac{\sin\phi_1}{\sin\phi_2} \tag{11.36}$$

If the plane interface is between two semi-infinite fluids or between a fluid and a porous sound-absorbing material, only compressional waves are generated. However, at interfaces between a fluid and a solid the energy transmitted into the semi-infinite solid contains both compressional and shear waves. As illustrated in Fig. 11.6, the transmitted wave breaks toward the normal of the interface if $c_2 < c_1$ and away from the normal if $c_2 > c_1$.

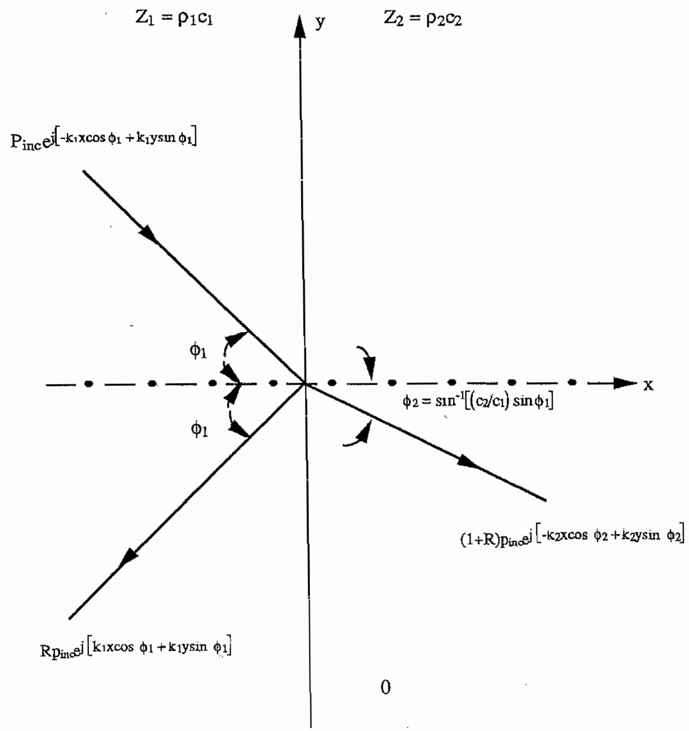

FIGURE 11.6 Reflection and transmission of an oblique-incidence plane sound wave at the plane interface of two semi-infinitely thick medium, $k_1 = \omega/c_1$, $k_2 = \omega/c_2$.

If $c_2 < c_1$, there is always a transmitted wave even for grazing incidence ($\phi_1 = 90°$), and for lossless media the power transmission reaches 100% at an oblique-incidence angle ϕ_1 when

$$\left(\frac{Z_1}{Z_2}\right)^2 = \frac{1 - (c_2/c_1)^2 \sin^2 \phi_1}{\cos^2 \phi_1} \tag{11.37}$$

If $c_2 > c_1$ sound transmission occurs only in a limited incidence angle range $0 < \phi_1 < \phi_{1L} = \sin^{-1}(c_1/c_2)$. For angles $\phi_1 > \phi_{1L}$ there is a total reflection and the sound wave penetrates into the second medium only in the form of a near field that exponentially decays with distance from the interface. The pressure reflection coefficient for oblique-incidence sound is given by

$$R(\phi_1) = \frac{p_{\text{ref}}(\phi_1)}{p_{\text{inc}}(\phi_1)} = \begin{cases} \dfrac{Z_2/\sqrt{1 - [(c_2/c_1)\sin\phi_1]^2} - Z_1/\cos\phi_1}{Z_2/\sqrt{1 - [(c_2/c_1)\sin\phi_1]^2} + Z_1/\cos\phi_1} \\ \quad \text{for } c_2 < c_1 \text{ or } c_2 > c_1 \text{ and } \phi_1 < \phi_{1L} \\ 1 \text{ for } c_2 > c_1 \text{ and } \phi_1 > \phi_{1L} \end{cases} \tag{11.38}$$

The limiting angle for plane-wave sound transmission from air to steel is $\phi_{LC} = \sin^{-1}(c_0/c_s) = 3.8°$ for compressional waves and $\phi_{LS} = \sin^{-1}(c_0/c_s) = 4.5°$ for shear waves. For sound transmission from water to steel, the corresponding limiting angles are $\phi_{LC} = 13°$ and $\phi_{LS} = 15°$, respectively. For angles larger than these, there is total reflection and only exponentially decaying near fields exist in the solid.

11.5 POWER TRANSMISSION BETWEEN STRUCTURAL ELEMENTS

In the preceding sections, the power lost to a connected structure was considered only as an additional mechanism that increases the loss factor of the excited structure. In many practical problems, however, the power transmitted to a neighboring structure is the prime reason for a noise reduction program.

The power balance equation states that the power introduced into the directly excited structure is either dissipated in it or is transmitted to neighboring structures. Accordingly, if in a noise reduction problem the power is to be *confined* to the excited structure, the power *dissipated* in the structure must greatly exceed the power *transmitted* to the neighboring structures. This requires a *high loss factor* for the excited structure and a construction that *minimizes the power transmission* to neighboring structures. Methods to achieve high damping are the subject of Chapter 14.

Reduction of Power Transmission through a Change in Cross-Sectional Area

The simplest construction that causes a partial reflection of an incident compression or bending wave is a sudden change in cross-sectional area, as shown schematically in Fig. 11.7.

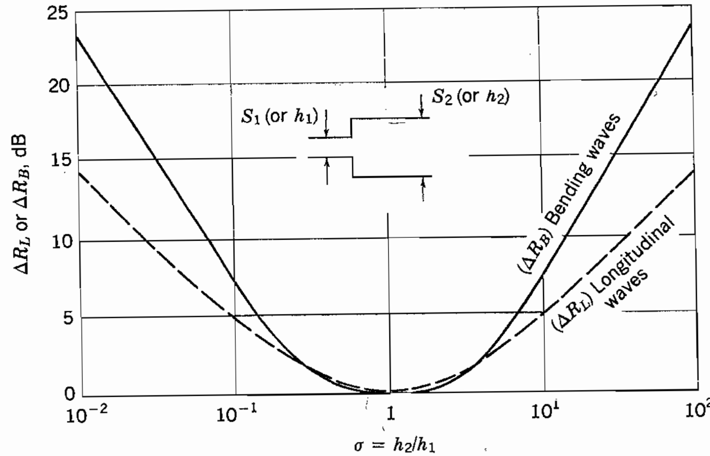

FIGURE 11.7 Attenuation at discontinuity in cross section as a function of thickness ratio. (After reference 1.)

Reflection Loss of Compression Waves. The *reflection loss* ΔR_L, defined as the logarithmic ratio of the incident to the transmitted power (for both sections of the same material), is calculated as[1]

$$\Delta R_L = 20 \log[\tfrac{1}{2}(\sigma^{1/2} + \sigma^{-1/2})] \quad \text{dB} \tag{11.39}$$

where $\sigma = S_2/S_1$ is ratio of the cross-sectional areas (see Fig. 11.7).

The reflection loss as a function of cross-sectional area ratio is plotted as the dashed line in Fig. 11.7. Since Eq. (11.39) is symmetrical for S_1 and S_2, the reflection loss is independent of the direction of the incident wave. This equation is also valid for plates where $\sigma = h_2/h_1$ is the ratio of the thicknesses. Note that a 1 : 10 change in cross-sectional area yields only 4.8 dB reflection loss. To achieve 10 dB reflection loss, a 1 : 40 change in cross-sectional area would be necessary!

Reflection Loss of Bending Waves. The reflection loss for bending waves of perpendicular incidence at low frequencies is independent of frequency and is given by[1]

$$\Delta R_B = 20 \log \frac{\frac{1}{2}(\sigma^2 + \sigma^{-2}) + (\sigma^{1/2} + \sigma^{-1/2}) + 1}{(\sigma^{5/4} + \sigma^{-5/4}) + (\sigma^{3/4} + \sigma^{-3/4})} \quad \text{dB} \tag{11.40}$$

The equation is also plotted in Fig. 11.7 (solid line).

We conclude from Fig. 11.7 that a change in cross-sectional area is not a practical way to achieve high reflection loss in load-bearing structures.

Reflection Loss of Free Bending Waves at an *L*-Junction

Structural elements that necessitate a change in the direction of a bending wave play an important role in structures. We consider here normally incident bending waves at a junction between two plates (or beams) at right angles: For low frequencies both the transmitted and reflected energy is predominantly in the form of bending waves. In this frequency range the reflection loss (logarithmic ratio of incident to transmitted power) for plates and beams of the same materials is given by[1]

$$\Delta R_{BB} = 20 \log \left[\frac{\sigma^{5/4} + \sigma^{-5/4}}{\sqrt{2}} \right] \quad \text{dB} \tag{11.41}$$

This equation is plotted in Fig. 11.8. Because ΔR_{BB} is symmetric in σ, the reflection factor does not depend upon whether the original bending wave is incident from the thicker or from the thinner beam or plate. Note that the lowest reflection loss of 3 dB occurs for equal thicknesses ($\sigma = 1$). If the two plates or beams constituting the junction are of different material, replace the ratio $\sigma = h_2/h_1$ by

$$\sigma = \left(\frac{B_2 c_{B1}}{B_1 c_{B2}} \right)^{2/5} \tag{11.42}$$

where B and c_B are the bending stiffness and propagation speed of free bending waves, respectively (see Table 11.1). At higher frequencies the incident bending wave also excites longitudinal waves in the second structure.[1]

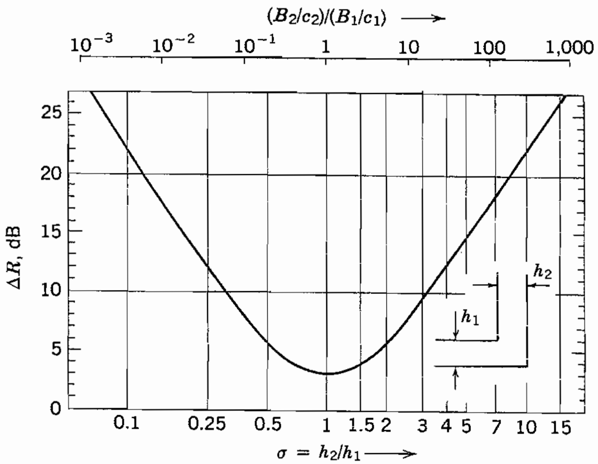

FIGURE 11.8 Attenuation of bending waves at corners (in absence of longitudinal wave interactions) as a function of thickness ratio. (After reference 1.)

Reflection Loss of Bending Waves through Cross Junctions and T-Junctions

Other structures that may provide a substantial reflection of an incident bending wave are the *cross junction* of walls shown schematically in Fig. 11.9 and the *T-junction* in Fig. 11.10. If a bending wave of perpendicular incidence reaches

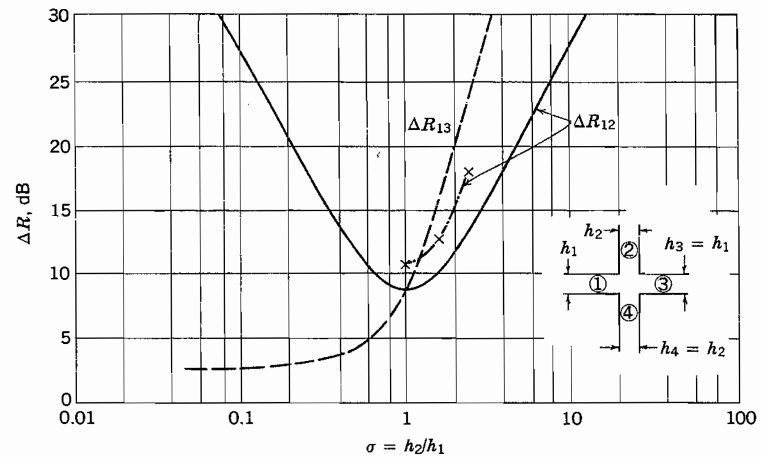

FIGURE 11.9 Attenuation of bending waves at plate intersections (in absence of longitudinal wave interactions) as a function of thickness ratio. (After reference 1.) (—·—) ΔR_{12} for random incidence computed by Kihlman.[20]

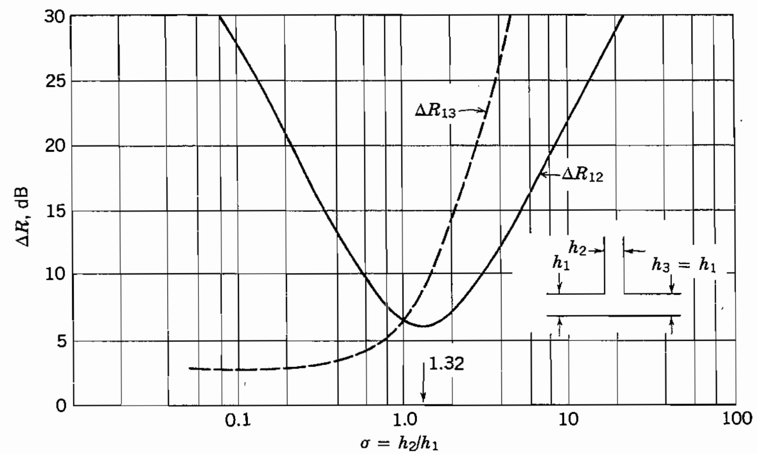

FIGURE 11.10 Attenuation of bending waves at plate intersections (in absence of longitudinal wave interactions) as a function of thickness ratio. (After reference 1.)

the cross junction from plate 1, it is partially reflected and partially transmitted to the other plates. The transmitted power splits into a number of different wave types, namely, bending waves in plate 3 and longitudinal and bending waves in plates 2 and 4. Because of the symmetry in the geometry, plates 2 and 4 will have the same excitation.[1]

The reflection loss (defined as the logarithmic ratio of the power in the incident to that in the transmitted bending wave) is given as a function of the ratio of the plate thickness for plates or beams of the same material and is shown in Figs. 11.9 and 11.10. When the plates are made of different material, the ratio $\sigma = h_2/h_1$ is given by Eq. (11.42). The amplitudes of the bending waves transmitted without a change in direction are restrained by the perpendicular plate, and the reflection loss in this direction, ΔR_{13}, increases monotonically with increasing thickness of the restraining plate, h_2. Since this plate effectively stops the vertical motion of the horizontal plate at the junction, even for very thin vertical walls, ΔR_{13} remains level at 3 dB, indicating that only the power carried by the bending moment can pass the junction. For those bending waves that change direction at the junction, the reflection loss becomes a minimum ($\Delta R_{12} =$ 9 dB) at a thickness ratio $\sigma = h_2/h_1 = 1$ for the cross junction; corresponding numbers for the T-junction are 6.5 dB at a thickness ratio $\sigma = h_2/h_1 = 1.32$. The reflection loss then increases symmetrically for increasing or decreasing thickness ratio (h_2/h_1).

The transmission of free bending waves at cross junctions for random incidence has been computed and the reflection loss for a number of combinations of dense and lightweight concrete plates determined.[20] The results for ΔR_{12} are plotted in Fig. 11.9 (as x's), which indicate that ΔR_{12} for random incidence is somewhat higher than that for normal incidence. It was also found that for random incidence ΔR_{12} is independent of frequency but ΔR_{13} decreases with increasing frequency.

Power Transmission from a Beam to a Plate

The structural parts of a modern building frequently include columns and structural floor slabs. Consequently, the power transmission from a beam to a plate, which models this situation, is of practical interest. Let us first consider the reflection loss for longitudinal and bending waves incident *from* the beam onto an infinite homogeneous plate.

Reflection Loss for Longitudinal Waves. When a longitudinal wave in the beam reaches the plate, its energy is partly reflected back up the beam and is partly transmitted to the plate in the form of a bending wave. The reflection loss (equal to the logarithmic ratio of the incident to the transmitted power) is given by[21]

$$\Delta R_L = -10 \log \left(1 - \left| \frac{Y_b - Y_p}{Y_b + Y_p} \right|^2 \right) \quad \text{dB} \tag{11.43}$$

where $Y_b = 1/Z_b$ = admittance of semi-infinite beam for longitudinal waves, m/N · s

Y_p = point admittance of infinite plate, $1/Z_p$, m/N · s

Both Y_p and Y_b are real and frequency independent and can be found for infinite beams and plates from Table 11.3 by taking the reciprocal of the impedances, that is, $Y_b = 1/\rho_b c_{Lb} S_b$ and $Y_p = 1/2.3\rho_p c_{Lp} h^2$.

Complete Power Transmission between Beam and Plate for Longitudinal Waves. Inspecting Eq. (11.43), we note that the reflection factor is zero (all the incident energy is transmitted to the plate) when $Y_b = Y_p$. Equating the values for Y_p and Y_p given above yields the requirements for complete power transmission from the beam to the plate:

$$S_b = 2.3 \frac{\rho_p c_{Lp} h^2}{\rho_b c_{Lb}} \quad \text{m}^2 \tag{11.44}$$

If the column and the slab are of the same material so that $\rho_p c_{Lp} = \rho_b c_{Lb}$, Eq. (11.44) simplifies to

$$S_b = 2.3 h^2 \quad \text{m}^2 \tag{11.45}$$

This equation says that for perfect power transfer from a beam of square cross section to a large plate, the cross dimension of the beam must be 1.52 times the thickness of the plate and for a beam of circular cross section the radius must be 0.86 times the plate thickness. Actually, this is well within the range of slab thicknesses–column cross section ratios commonly found in architectural structures. The reflection factor for different geometries of steel beam and plate connections has been measured.[21] The results for a substantial mismatch (a) and for a near matching (b) are plotted in Fig. 11.11.

Reflection Loss for Bending Waves. When a beam carries a free bending wave, a part of the energy carried by the wave is transmitted to the plate by the effective bending moment and excites a radially spreading free bending wave in the plate. A part of the incident energy is reflected from the junction. Here the reflection loss is determined by the respective moment impedances[1,21] of the plate and the beam:

$$\Delta R_b = -10 \log \frac{Y_b^M - Y^M}{Y_b^M + Y_p^M} \quad \text{dB} \tag{11.46}$$

where the moment admittances Y_b^M and Y_p^M are given by[1,20]

$$Y_b^M = \frac{2}{1+j} \frac{k_b^2}{\rho_b S_b c_{B_b}} \quad \text{m/N} \cdot \text{s} \tag{11.47}$$

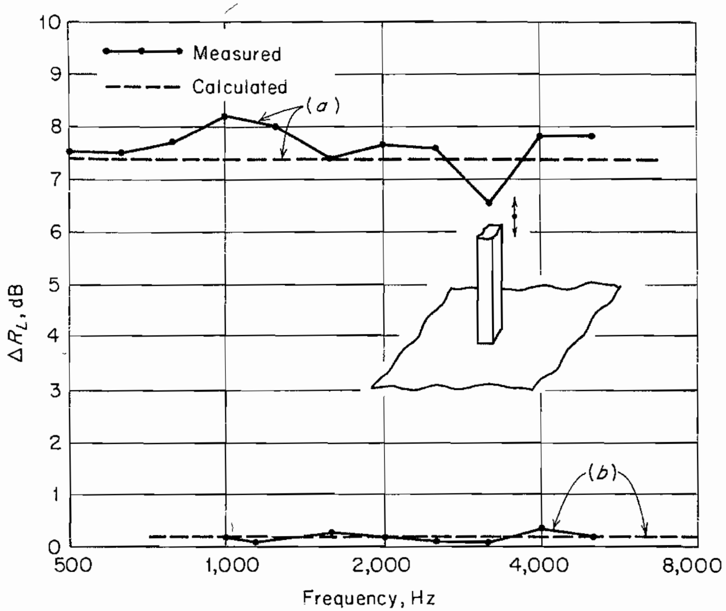

FIGURE 11.11 Reflection loss for longitudinal waves, ΔR_L, for a steel beam plate system: (*a*) plate thickness 2 mm, beam cross section 10 × 20 mm; (*b*) plate thickness 4 mm, beam cross section 5 × 10 mm. (After reference 21.)

and

$$Y_b^M = \frac{\omega}{16B_p}\left(1 + j\frac{4}{\pi}\ln\frac{1.1}{k_p a}\right) \quad \text{m/N} \cdot \text{s} \tag{11.48}$$

where k = wavenumber, m^{-1}
B_p = bending stiffness per unit width of plate, N · m
a = effective distance of pair of point forces making up moment on plate, m; for rectangular and circular beam cross section $a_r = \frac{1}{3}d$ and $a_c = 0.59r$
d = side dimension of rectangular beam cross section (in direction of bending), m
r = radius of circular beam cross section, m

The reflection loss obtained[21] for the bending-wave excitation of a steel rod of 1 × 2 cm cross-sectional area attached to a 0.2-cm-thick semi-infinite steel plate for two perpendicular directions of bending of the rod is plotted in Fig. 11.12.

Complete Power Transmission for Bending Waves. Since the moment impedances of the plate and beam are both frequency dependent, complete power transmission ($\Delta R_B = 0$) can occur only at a single frequency. The criteria for

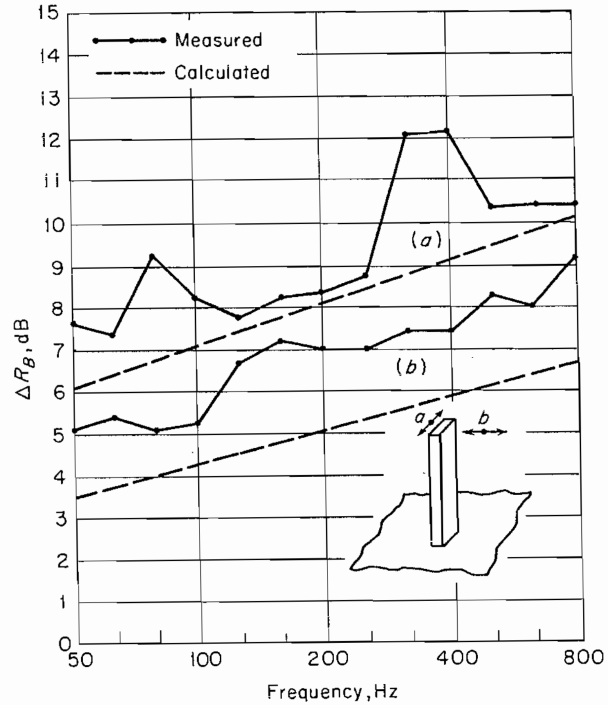

FIGURE 11.12 Reflection loss for bending waves, ΔR_B, for a steel beam plate system for two different directions of bending of the beam (*a* and *b*). Plate thickness 2 mm, beam cross section 10 × 20 mm. (After reference 21.)

perfect power transmission is achieved when both the real and imaginary parts of the moment impedances of the beam and plate are equal, which requires that

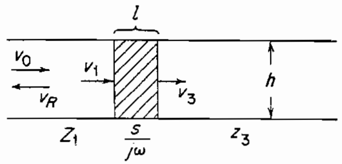
$$\lambda_b = 0.39\frac{B_b}{B_p} \quad \text{m} \tag{11.49}$$

$$\lambda_p = 2.6a \quad \text{m} \tag{11.50}$$

where B_p = bending stiffness of beam, N · m^2
λ_b = bending wavelength in beam, m
λ_p = bending wavelength in plate, m

Reduction of Power Transmission between Plates Separated by Thin Resilient Layer

In architectural structures it is customary to provide a so-called vibration break by inserting a thin layer of resilient material between structural elements. The



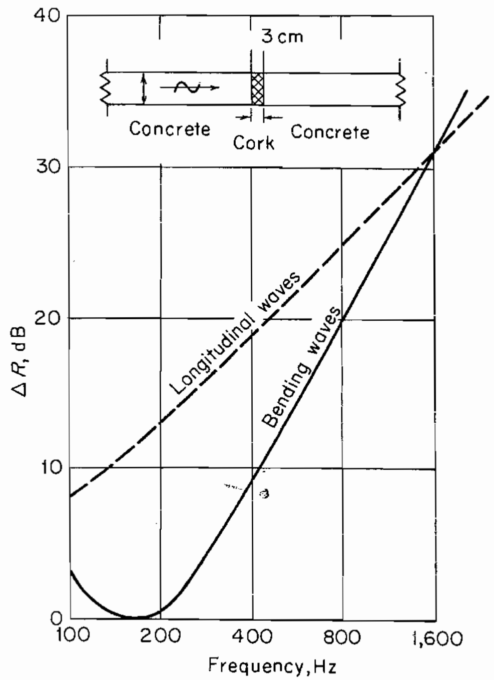


FIGURE 11.13 Attenuation due to an elastic interlayer of 3-cm-thick cork between 10-cm-thick slabs of concrete as a function of frequency. (After reference 1.)

geometry of such a vibration break is shown in Fig. 11.13. Often this construction serves also as an expansion joint.

Reflection Loss for Compression Waves. The reflection loss is given by[1]

$$\Delta R_L = 10 \log \left[1 + \left(\frac{\omega Z_1}{2 s_i} \right) \right] \quad \text{dB} \qquad (11.51)$$

where Z_1 = impedance of solid structure for compressional waves, N · s/m
s_i = stiffness of resilient layer in compression, N/m

Above a certain frequency ($\omega = 2s_i/Z_1$) the ΔR_L-versus-frequency curve increases with a 20-dB/decade slope with increasing frequency. Below this frequency the resilient layer transmits the incident wave almost entirely. As an example,[1] the ΔR_L-versus-frequency curve for a 3-cm-thick layer of cork inserted between two 10-cm-thick concrete slabs (or columns) is shown in Fig. 11.13.

To achieve a high reflection loss, the resilient layer must be as soft as is permitted by the load-bearing requirements ($s_i/\omega \ll Z_1$). However, the stiffness of the layer cannot be reduced indefinitely by increasing the thickness. For frequencies where the thickness of the layer is comparable with the wavelength of compressional waves in the resilient material, the layer can no longer be considered as a simple spring characterized by its stiffness alone. The reflection loss in this frequency region is given by[1]

$$\Delta R_L = 10 \log \left[\cos^2 k_i l + \frac{1}{4} \left(\frac{Z}{Z_i} + \frac{Z_i}{Z} \right)^2 \sin^2 k_i l \right] \quad \text{dB} \qquad (11.52)$$

where k_i = wavenumber for compressional waves in resilient material, m^{-1}
Z = impedance of equivalent infinite structure for compression waves, $= Z_1 = Z_3$, N · s/m
Z_i = impedance of equivalent infinite (length) resilient material for compression waves, N · s/m
l = length of resilient layer, m

The impedances Z, Z_i and the wavenumber k_i are assumed real; thus Eq. (11.52) does not account for wave damping in the resilient material. As expected, $\Delta R_L = 0$ for $Z_i = Z$. The maximum of ΔR_L is reached when $k_i l = (2n + 1)(\frac{1}{2}\pi)$; here the reflection loss becomes

$$\Delta R_{L,\max} = 20 \log \frac{Z_i^2 + Z^2}{2 Z Z_i} \quad \text{for } l = \tfrac{1}{2}(2n+1)\lambda_i \qquad (11.53)$$

For $k_i l = n\pi (l = \frac{1}{2} n \lambda_i)$, the denominator of Eq. (11.51) becomes unity independent of the magnitude Z, yielding

$$\Delta R_{L,\min} = 0 \quad \text{for } l = \tfrac{1}{2} n \lambda_i$$

Finally for $k_i l \ll 1$ and $Z_i \ll Z$, Eq. (11.52) simplifies to Eq. (11.51).

Reflection Loss for Bending Waves. The geometry in Fig. 11.13 suggests that for bending waves of perpendicular incidence the moments and forces acting on both sides of the junction must be equal. However, the transverse velocity and angular velocity on both sides of the junction are different because of shear and compressional deformation of the resilient layer. The elastic layer behaves quite differently for bending waves than it does for compressional waves.[1] The most striking difference is the *complete transmission* of the incident bending wave at a certain frequency and a *complete reflection* of it at another, higher frequency. Unfortunately, it turns out that the frequency of complete transmission for architectural structures of interest usually occurs in the audio frequency range. As an example, Fig. 11.13 shows the reflection factor for bending waves as a function of frequency for a layer of 3-cm-thick cork between 10-cm-thick concrete slabs. The transmission is complete at a frequency of 170 Hz and then decreases with increasing frequency. The reflection loss for bending waves can be approximated by[1]

$$\Delta R_B \cong 10 \log \left[1 + \frac{1}{4} \left(1 - \frac{E}{E_i} \frac{2\pi^3 l h^2}{\lambda_B^3} \right)^2 \right] \quad \text{dB} \tag{11.54}$$

where E = Young's modulus of structural material
E_i = Young's modulus of elastic material
l = length of elastic layer, m
h = thickness of structure, m
λ_B = wavelength of bending waves in structure, m

The bending wavelength in the structure for which the elastic layer provides a complete transmission of bending waves is given by

$$\lambda_{B,\text{trans}} = \pi \left(\frac{E}{E_i} h^2 l \right)^{1/3} \quad \text{m} \tag{11.55}$$

If one wishes to reduce the frequency of complete transmission, the ratio E/E_i and the length of the resilient layer must be large. However, the length of the resilient material should always be small compared with the wavelength of bending waves in the elastic layer to avoid resonances.

A complete reflection of the incident bending wave occurs when the bending wavelength in the plate equals π times the plate thickness, $\lambda_{Bs} = c_b/f_s = \pi h$. Consequently, the frequency where *complete reflection* occurs is *independent* of the dynamic properties and the length of the elastic layer and is given by the thickness and the dynamic properties of the plate or beam.

11.6 SOUND RADIATION

The sound radiation of small rigid bodies is treated in Chapter 10. This section deals exclusively with the sound radiation of thin flexible plates excited to vibration by point forces or by sound fields. Sound radiation of small rigid bodies is treated in Chapter 10.

Vibration of rigid and elastic structures forces the surrounding fluid or gas particles at the interface to oscillate with the same velocity as the vibrating structure and thus causes sound. The sound waves propagate in the form of compressional waves that travel with the speed of sound in the surrounding medium.

Infinite Rigid Piston

Conceptually the simplest sound-radiating structure is an infinite plane rigid piston. The motion of the piston forces the fluid particles to move along parallel lines that are perpendicular to the plane of the piston. There is no divergence that could lead to inertial reaction forces, such as those that can occur along the edges of a finite piston where the fluid can move to the side. Consequently, the reaction force per unit area (i.e., the sound pressure) is fully attributable to compression effects. This is the same situation as if the piston would be placed in a tube of rigid walls, as discussed already in Chapter 10. If the piston vibrates with velocity $\hat{v} \cos \omega t$, it generates a plane sound wave traveling perpendicular to the plane of the piston. The sound pressure as a function of distance is

$$p(x, t) = \hat{v} \rho_0 c_0 \cos(\omega t - k_0 x) \quad \text{N/m}^2 \tag{11.56}$$

and the radiated sound power per unit area is

$$W'_{\text{rad}} = 0.5 \hat{v}^2 \rho_0 c_0 = \langle v^2 \rangle_t \rho_0 c_0 \quad \text{W/m}^2 \tag{11.57}$$

where ρ_0 and c_0 are the density and speed of sound of the medium, $\omega = 2\pi f$ is the radian frequency, $k_0 = \omega/c_0 = 2\pi/\lambda_0$ is the wavenumber, $\lambda_0 = c_0/f$ is the wavelength of the radiated sound, and $\langle v^2 \rangle_t$ is the time-averaged mean-square velocity (i.e., $v = v_{\text{rms}}$).

Infinite Thin Plate in Bending

If a plane bending wave of velocity amplitude $\hat{v} = \sqrt{2} v$ and bending wave speed c_B travels on a thin plate in the positive x direction, the sound pressure as a function of x and perpendicular distance z is given by[1]

$$\hat{p}(x, y) = \frac{j \hat{v} \rho_0 c_0 e^{j\omega t}}{\sqrt{(k_B/k_0)^2 - 1}} e^{-jk_B z} \exp(-z \sqrt{k_B^2 - k_0^2}) \quad \text{N/m}^2 \tag{11.58}$$

where $k_B = 2\pi f/c_B = 2\pi/\lambda_B$ and $k_0 = 2\pi f/c_0 = 2\pi/\lambda_0$ are the bending wavenumber in the plate and the wavenumber in the air, respectively. Inspecting Eq. (11.58), one finds that for $c_B \langle c_0$ $(k_B/k_0 \rangle 1)$ the sound pressure is 90° out of phase with the velocity at the interface so that no sound power is radiated by the plate. The sound pressure constitutes a near field that decays exponentially with increasing z. For $c_B > c_0$; $k_B/k_0 < 1$, Eq. (11.58) has the form

$$\hat{p}(x, y) = \frac{\hat{v} \rho_0 c_0 e^{-j\omega t}}{\sqrt{1 - (k_B/k_0)^2}} e^{-jk_B x} \exp\left(-jk_0 z \sqrt{1 - \left(\frac{k_B}{k_0}\right)^2} \right) \quad \text{N/m}^2 \tag{11.59}$$

where the pressure and velocity are in phase at the interface ($z = 0$) and the sound power radiated by a unit area of the plate is

$$W'_{\text{rad}} = \begin{cases} \dfrac{0.5\hat{v}^2 \rho_0 c_0}{\sqrt{1-(\lambda_0/\lambda_B)^2}} \quad \text{W/m}^2 & \text{for } \lambda_B > \lambda_0 \\ 0 & \text{for } \lambda_B < \lambda_0 \end{cases} \tag{11.60}$$

which, with increasing frequency ($\lambda_0/\lambda_B \ll 1$), approaches that of an infinite rigid piston as given in Eq. (11.57).

Radiation Efficiency

It is customary to define the radiation efficiency of a vibrating body as

$$\sigma_{\text{rad}} = \frac{W_{\text{rad}}}{\langle v_n^2 \rangle \rho_0 c_0 S} \tag{11.61}$$

where $\langle v_n^2 \rangle$ is the normal component of the space–time average mean-square vibration velocity of the radiating surface of area S and W_{rad} is the radiated sound power. With this definition, Eqs. (11.57) and (11.60) yield for the piston

$$\sigma_{\text{rad}} = \begin{cases} 1 & \text{for infinite rigid piston} \\ 0 & \text{for } \lambda_B < \lambda_0 \text{ for infinite plate in bending} \\ [1-(\lambda_0/\lambda_B)]^{-1/2} & \text{for } \lambda_B > \lambda_0 \text{ for infinite plate in bending} \\ (k_0 a)^2/[1+(k_0 a)^2] & \text{for pulsating sphere} \end{cases} \tag{11.62}$$

It is important to know that the radiation efficiency depends not only on the size and shape of the radiating body as compared with the wavelength but also on the manner the body is vibrating. If a sphere vibrates back and forth instead of pulsating, then the net volume displacement is zero and the radiation efficiency is[22]

$$\sigma_{\text{rad}} = \frac{(k_0 a)^4}{4 + (k_0 a)^4} \tag{11.63}$$

Comparing Eqs. (11.62) and (11.63) reveals that at low frequencies a rigid body vibrating in translation radiates much less (approximately $\frac{1}{4}(k_0 a)^2$ times) sound power than a pulsating body of the same surface area. Radiation efficiencies of some typical structural elements are given in Table 11.8 (see references 22 and 23 for a more extensive collection). Radiation efficiencies for oscillating three-dimensional bodies of near-unity aspect ratio (such as a sphere or cube) are plotted in Fig. 11.14 and those of pipes of circular rods oscillating as rigid bodies in Fig. 11.15. Note that with increasing frequency, when the distance between the neighboring, out-of-phase moving parts of the vibrating body becomes larger than the wavelength of the radiated sound (i.e., $2\pi a > \lambda_0$ for oscillating bodies and $\lambda_B > \lambda_0$ for plates in bending), it becomes more difficult to push the air

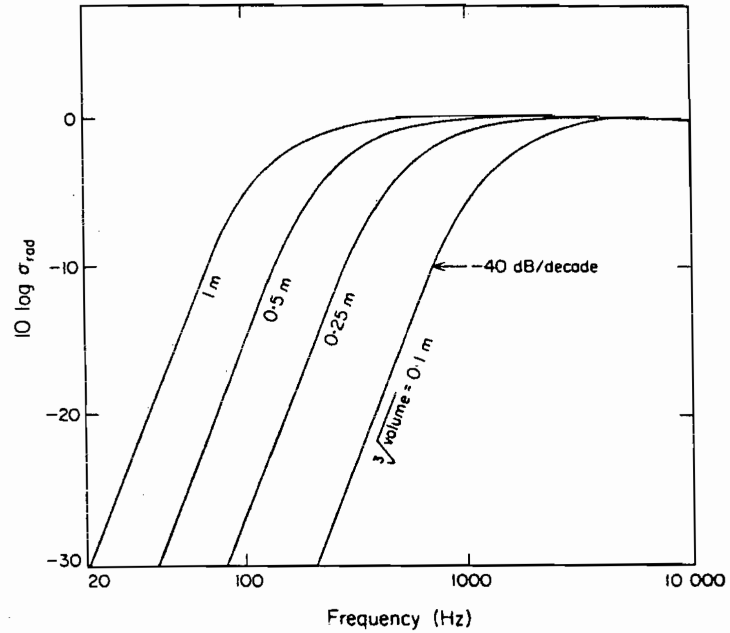

FIGURE 11.14 Radiation efficiency of oscillating three-dimensional bodies. (After reference 22.)

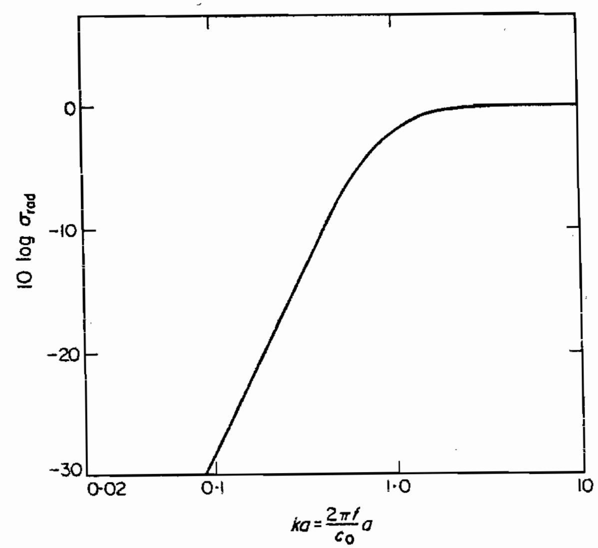

FIGURE 11.15 Radiation efficiency of oscillating rigid pipes and rods of radius a. (After reference 22.)

rapidly enough aside then to compress it, and the radiation efficiency approaches unity.

Point-Excited Infinite Thin Plate

When a very large homogeneous isotropic thin plate is excited by a point force of amplitude $\hat{F}_0$ or by an enforced local velocity of amplitude $\hat{v}_0$, free bending waves with a propagation speed of $c_B(f) \sim \sqrt{f}$ propagate radially from the excitation point. At low frequencies, where $c_B < c_0$, the free bending waves radiate no sound. Far from the excitation point, where the wave front approaches a straight line, the sound radiation that does occur is due to the in-phase vibration of the plate in the vicinity of the excitation point. The sound intensity radiation pattern has a $\cos^2\phi$ dependence, where ϕ is the angle to the normal of the plate. The mechanical power input W_{in}, the radiated sound power W_{rad}, and the acoustical–mechanical conversion efficiency $\eta_{\text{am}} = W_{\text{rad}}/W_{\text{in}}$ are listed below:

	Point Force Excitation	Point Velocity Excitation	
$W_{\text{in}} =$	$\frac{1}{2}\hat{F}_0^2 \dfrac{1}{2.3\rho_s c_L h}$	$(\frac{1}{2}\hat{v}_0^2)2.3\rho_s c_L h$	(11.64)
$W_{\text{rad}}(f < f_c) =$	$\hat{F}^2 \dfrac{\rho_0}{4\pi\rho_s^2 c_0}$	$\hat{v}^2 \dfrac{c_L^2 h^2 \rho_0}{2.38 c_0}$	(11.65)
$\eta_{\text{am}}(f < f_c) =$	$0.37\dfrac{\rho_0}{\rho_M}\dfrac{c_L}{c_0}$	$0.37\dfrac{\rho_0}{\rho_M}\dfrac{c_L}{c_0}$	(11.66)

where $\rho_s = \rho_M h$ is the mass per unit of the plate, ρ_M is the density and c_L the speed of longitudinal waves in the plate material, h is the plate thickness, and ρ_0 and c_0 are the density and speed of sound in the surrounding fluid.

Equations (11.64)–(11.66) contain the following, quite surprising, information:

1. W_{in}, W_{rad}, and η_{am} are independent of frequency and plate loss factor.
2. For point force excitation, the radiated sound power depends only on the mass per unit area of the plate ($W_{\text{rad}} \sim 1/\rho_s^2$) and not on stiffness.
3. For point velocity excitation, the radiated sound power depends only on stiffness ($W_{\text{rad}} \sim c_L^2 h^2$) and not on the plate material density.
4. The acoustical–mechanical conversion efficiency is the same for point force or point velocity excitation, and it is independent of plate thickness h and is a material constant [$\eta_{\text{am}} \sim (c_L/\rho_M)(\rho_0/c_0)$].

For noise control engineers, observations 2 and 3, embodied in Eq. (11.65), are very important. To minimize sound radiation from highly damped, point-excited, thin, platelike structures, the plate should have large mass per unit area for force excitation (e.g., by a low-impedance vibration source) and low stiffness (low E/ρ_M) for velocity excitation (by a high-impedance vibration source).

Equation (11.66) supplies the rationale for violin makers, who want to convert as large a portion of the mechanical power of the vibrating string as possible into radiated sound, to use wood ($\eta_{\text{am}} = 0.024$) and not steel ($\eta_{\text{am}} = 0.0023$) or lead ($\eta_{\text{am}} = 0.0004$) for the body of the violin.

Note also that the radiated sound power given in Eq. (11.65) usually represents the minimum achievable for a finite-size plate since it accounts only for the sound radiated from the vicinity of the excitation point.

Point-Excited Finite Plates

For finite-size plates, the sound power radiated has two components. The first component is radiated from the vicinity of the excitation point given in Eq. (11.65). The second component is radiated by the free bending waves as they interact with plate edges and discontinuities. The contribution of these two components to total radiated noise is represented by the first and second terms in Eqs. (11.67a) and (11.67b), where the first equation is valid for point force and the second for point velocity excitation:

$$W_{\text{rad}}^F \cong \hat{F}^2\left[\frac{\rho_0}{4\pi\rho_s^2 c_0} + \frac{\rho_0 c_0 \sigma_{\text{rad}}}{4.6\rho_s^2 c_L h\omega\eta_c}\right] \quad \text{W} \tag{11.67a}$$

$$W_{\text{rad}}^v \cong \hat{v}^2\left[\frac{\rho_0 c_L^2 h^2}{2.38 c_0} + 1.15\left(\frac{c_L h}{\omega\eta_c}\right)\rho_0 c_0 \sigma_{\text{rad}}\right] \quad \text{W} \tag{11.67b}$$

where η_c is the composite loss factor and σ_{rad} is the radiation efficiency of the plate for free bending waves. The second term in Eqs. (11.67) has been derived by the power balance (see Section 11.3) of the finite plate, assuming that the mechanical power input to the finite plate can be well approximated by the power input to the equivalent infinite plate.

Equations (11.67a) and (11.67b) can be used to assess the useful upper limit of the composite loss factor ($\eta_c^{\max}$) which, if exceeded, results only in added expense but no meaningful reduction of the radiated noise. This is done by equating the first and second terms in the square brackets and solving for η_c.

11.7 SOUND EXCITATION AND SOUND TRANSMISSION

The sound transmission process has the following three components: (1) description of the sound field at the source side, (2) prediction of the vibration response, and (3) sound radiation from the receiver side of the partition into the receiver room. Item 1 is treated in Chapter 7. Items 2 and 3 will be treated in this section. Regarding the appropriate way of analysis, partitions can be classified as either small or large compared with the acoustical wavelength.

Sound Transmission of Small Partitions

In the following analyses we define a partition small if its dimensions are small compared with the acoustical wavelength. Consequently, if the frequency is sufficiently low, even partitions of large size are considered "acoustically small."

The subject of sound transmission of acoustically small plates has been mostly ignored or treated only qualitatively in books on noise control engineering. The reason for this is that the traditional definition of sound transmission loss, which is based on the ratio of the incident and transmitted sound power, does not make sense in this low-frequency region where the sound power radiated into the receiver room is independent of the angle of incidence of the sound striking the source side of the partition. In this low-frequency region the partition will radiate the same sound power for grazing incidence (sound wave on the source side propagates parallel to the partition) than it does at normal incidence (where it propagates perpendicular to the plane of the partition).

It is instructive to start the investigation of sound transmission with a small, single, homogeneous, isotropic plate that is flash mounted in the test section between two reverberation rooms, as shown schematically in Fig. 11.16.

Let our investigation start at very low frequencies and proceed by gradually increasing the frequency of the incident sound. We will investigate the following cases:

1. The size of the panel, L, is small compared with the acoustical wavelength λ and the frequency of the incident sound wave, f, is small compared with the frequency of the first mechanical resonance of the plate, f_{M1}:

$$L \ll \lambda \qquad \text{and} \qquad f \ll f_{M1}$$

2. The size of the panel, L, is small compared with the acoustical wavelength λ and the frequency of the incident sound wave, f, matches the frequency of the first mechanical resonance of the plate, f_{M1}.

$$L \ll \lambda \qquad \text{and} \qquad f = f_{M1}$$

3. The size of the panel, L, is small compared with the acoustical wavelength λ and the frequency of the incident sound wave, f, is much larger than the frequency of the first mechanical resonance of the plate, f_{M1}.

$$L \ll \lambda \qquad \text{and} \qquad f \gg f_{M1}$$

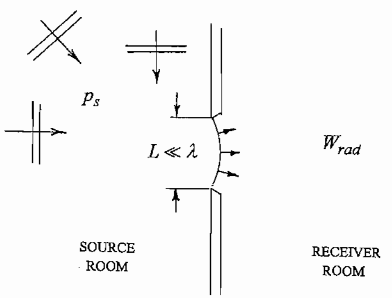

FIGURE 11.16 Sound Transmission of a small homogeneous isotropic partition.

Case 1 ($L \ll \lambda$ *and* $f \ll f_{M1}$). If the size of the partition is much smaller than the acoustical wavelength, the sound pressure, even at grazing incidence (i.e. the sound wave propagates parallel to the plate), is nearly constant across the source side of the plate. At any other angle of incidence, the sound pressure is even more evenly distributed across the plate than at grazing. At normal incidence, where the sound wave propagates perpendicular to the plane of the plate, the sound pressure is absolutely evenly distributed over the surface of the plate independent of the wavelength (for normal incidence the trace wavelength is infinitely large at all frequencies). In the case 1 frequency range the sound transmission of the plate is controlled by its volume compliance C_v defined as

$$C_v \equiv \frac{\Delta V}{p} \quad \text{m}^5/\text{N} \tag{11.68}$$

where C_v = volume compliance of plate, m^5/N
$p \approx$ sound pressure on source side of plate, N/m^2

As long as the dimensions of the plate are small compared with the acoustical wavelength, $p_s = 2p_{\text{inc}}$, where p_{inc} is the amplitude of the incident sound wave.

Considering now that the volume velocity $q = d\,\Delta V/dt = j\omega C_v p_s$ and using Eq. (10.49) from Chapter 10 the formula for the radiated sound power yields

$$W_{\text{rad}} = q^2(\rho_0 c_0)\left(\frac{k^2}{2\pi}\right) = \frac{\omega^4 C_v^2(\rho_0/c_0)}{2\pi} p_s^2 \quad \text{N} \cdot \text{m/s} \tag{11.69}$$

where ρ_0 = density of gas, kg/m^3
c_0 = speed of sound in gas, m/s.

Considering that our small plate radiates omnidirectionally into a half space, the sound pressure as a function of distance is

$$p(r) = \frac{p_s}{2\pi r}(\omega^2 C_v \rho_0) \quad \text{N/m}^2 \tag{11.70}$$

where r is the radial distance in meters from the center of the panel.

Formulas to predict the volume compliance C_v and resonance frequency f_{M1} for rectangular plates with simply supported and clamped edges are given in Chapter 12. Panels found in practical applications have a C_v that is larger than predicted for clamped edges and smaller than that predicted for simply supported edges. Also the resonance frequency of practical panels falls between those resonance frequencies predicted for clamped and simply supported edges.

Case 2 ($L \ll \lambda$ *and* $f \approx f_{M1}$). At the first resonance frequency of the panel, f_{M1}, the mass part of the panel impedance (which increases with increasing frequency) becomes equal in magnitude but opposite in phase to the stiffness part of the panel impedance, which is decreasing with increasing frequency. At and in the vicinity of the resonance frequency even a small sound pressure on the source side can cause a large volume velocity and the panel motion is limited only by energy dissipation in the panel and by its radiation resistance. In the vicinity of f_{M1} the sound power radiated by the receiver side of the panel reaches a maximum. The dissipative losses in the panel cannot be predicted analytically. Consequently, the sound transmission cannot be predicted with satisfactory accuracy. In designing enclosures for equipment with a high-intensity tonal component at low frequencies the panels or subpanels should be chosen that their first resonance frequency should be substantially higher than the frequency of the low-frequency tonal component of the enclosed equipment. The first resonance frequency of platelike elements can be increased by curving them in two perpendicular directions to gain form stiffness.

Case 3 ($L \ll \lambda$ *and* $f \gg f_{M1}$). Above the first mechanical resonance frequency the velocity of the plate is controlled by the mass per unit area $\rho_s = \rho_M h$
ρ_M = density of plate material, kg/m^3
h = plate thickness, m

The volume velocity of the plate in this frequency region can be approximated by

$$q \approx p_s \frac{S}{j\omega\rho_s} \quad \text{m}^3/\text{s} \tag{11.71}$$

the radiated sound power by

$$W_{\text{rad}} \approx p_s^2 \frac{\omega^2 S^2(\rho_0 c_0)}{2\pi} \quad \text{N} \cdot \text{m/s} \tag{11.72}$$

and the sound pressure at a distance r by

$$p(r) \approx p_s \frac{\omega^2 \rho_0^2 S}{2\pi r} \quad \text{N/m}^2 \tag{11.73}$$

where S is surface area (one side) of the plate in square meters.

More accurate prediction of the transmitted sound power can be obtained by determining the response of each of the volume-displacing modes of the plate responding to the spatially uniform sound pressure on the source side of the plate and determining the net volume velocity as the sum total of the volume velocities of all modes, as done in Chapter 6.

If the spatial distribution of the plate vibration $v(x, y)$ is known, the sound pressure in the receiver-side half space $p(x, y, z, \omega)$ can be computed as[1]

$$p(x, y, z, \omega) = \frac{j\omega\rho_0}{2\pi} \int v(x, y, \omega) \frac{e^{-jkr}}{r} \, dS \quad \text{N/m}^2 \tag{11.74}$$

where r is the distance between the small surface element of the plate and the observation point. Equation (11.74) is valid only for a flat plate flash mounted in an infinite, flat, hard wall.

In the low-frequency region, where the plate dimensions are small compared with the acoustical wavelength ($\sqrt{S} \ll \lambda$), the transmitted sound power depends only on the sound pressure on the source side of the plate p_s and does not depend on the angle of incidence or the sound power incident on the source side of the plate, W_{inc}. Consequently, the traditional definition of the sound transmission loss given in Eqs. (11.79) and (11.80) makes no sense in this frequency region.

Sound Transmission of Large Partitions

This section deals with the sound transmission loss of acoustically large partitions, where it is meaningful to characterize the excitation by the sound power incident on the source side of the partition and define the transmission coefficient τ and the sound transmission loss R as given in Eqs. (11.75) and (11.76), respectively.

The most common problem that noise control engineers have to deal with is the transmission of sound through solid partitions such as windows, walls, and floor slabs. The problem may be either prediction or design. The prediction problem is typically this: Given a noise source, a propagation path up to the partition, and the size and construction of the partition and the room acoustics parameters of the receiver room, predict the noise level in the receiver room. The design problem is typically stated as: Given a source, a propagation path, the room acoustics parameters of the receiver room, and a noise criterion (in the form of octave-band sound pressure levels), determine the construction of those partitions that would assure that the noise criteria are met with a sufficient margin of safety.

The transmission coefficient τ and sound transmission loss R, which characterize sound transmission through partitions, are defined as

$$\tau(\phi, \omega) = \frac{W_{\text{trans}}(\phi, \omega)}{W_{\text{inc}}(\phi, \omega)} \tag{11.75}$$

$$R(\phi, \omega) = 10 \log \frac{1}{\tau(\phi, \omega)} = 10 \log \frac{W_{\text{inc}}(\phi, \omega)}{W_{\text{trans}}(\phi, \omega)} \quad \text{dB} \tag{11.76}$$

where $W_{\text{inc}}(\phi, \omega)$ is the sound power incident at angle ϕ at frequency $\omega = 2\pi f$ on the source side and $W_{\text{trans}}(\phi, \omega)$ is the power transmitted (radiated by the receiver side).

Though knowledge of the sound transmission loss of a window or curtain wall for a particular angle of incidence may be desirable sometimes, it is a more common problem to characterize the transmission of sound between two adjacent rooms where the sound is incident on the separating partition from all angles with approximately equal probability. In such "random incident" sound fields, the sound intensity (energy incident on a unit area) I_{random} is related to the space-averaged mean-square sound pressure in the source room $\langle p^2 \rangle$ as

$$I_{\text{random}} = \frac{\langle p^2 \rangle}{4\rho_0 c_0} \quad \text{W/m}^2 \tag{11.77}$$

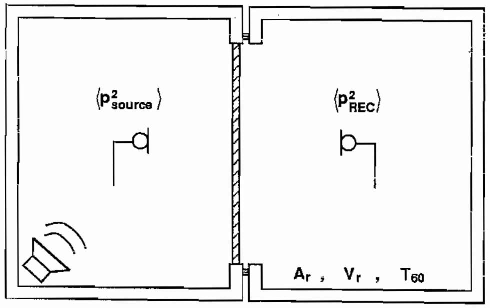

FIGURE 11.17 Experimental setup for laboratory measurements of the sound transmission loss of partitions (see text for definition of symbols).

Laboratory procedures ASTM E90-02[24] and ISO 140-1 : 1997,[25] adopted for measuring the sound transmission loss of partitions, are based on such a diffuse sound field obtained by utilizing large reverberation rooms (see Chapter 7) as source and receiver rooms. The measurement procedure depicted in Fig. 11.17 has three steps. The first step is to measure the sound power incident on the source-side face of the test partition of area S_w:

$$W_{\text{inc}} = I_{\text{inc}} S_w = \frac{\langle p^2_{\text{source}} \rangle S_w}{4\rho_0 c_0} \quad \text{W} \tag{11.78}$$

by measuring the space–time average mean-square sound pressure level $\langle p^2_{\text{source}} \rangle$ in the source room by spatially sampling the sound field. The second step is to measure the transmitted sound power W_{trans} from the power balance of the receiver room,

$$W_{\text{trans}} = \frac{\langle p^2_{\text{rec}} \rangle A_r}{4\rho_0 c_0} \quad \text{W} \tag{11.79}$$

yielding the laboratory sound transmission loss

$$R_{\text{lab}} = 10 \log \frac{W_{\text{inc}}}{W_{\text{trans}}} = \langle L_p \rangle_s - \langle L_p \rangle_R + 10 \log \frac{S_w}{A_r} \quad \text{dB} \tag{11.80}$$

where A_r is the total absorption in the receiving room. The third step is to determine A_r from the known volume and the measured reverberation time T_{60} of the receiver room, as described in Chapter 7.

Once R_{lab} has been measured, it can be used for predicting the mean-square sound pressure in a particular receiver room acoustically characterized by its total absorption A_r through a partition of surface area S_w for an incident sound field of intensity I_{inc} as

$$\langle p_r^2 \rangle = \frac{\overline{\tau} I_{\text{inc}} S_w (4\rho_0 c_0)}{A_r} = \frac{\overline{\tau} S_w < p^2_{\text{source}}}{A_r} \quad \text{N}^2/\text{m}^4 \tag{11.81a}$$

$$\langle \text{SPL}_R \rangle = \langle \text{SPL}_s \rangle - R_{\text{lab}} + 10 \log \frac{S_w}{A_r} \quad \text{dB} \tag{11.81b}$$

provided that the partition is not much smaller than tested and that edge conditions are not much different. Curves of measured random-incidence sound transmission loss versus frequency for standard windows, doors, and walls are available from manufacturers and should be used in design and prediction work. Measured sound transmission losses of some selected partitions are given by Bies and Hansen in their Table 8.1 (see the Bibliography).

The purpose of the discussion that follows is to identify the physical processes and the key parameters that control sound transmission through partitions and to provide analytical methods that further the development of an informed judgment needed for working with data obtained in laboratory measurements. Most importantly, however, this will focus on predicting sound transmission loss for situations that are different from those employed in the standardized laboratory measurements (i.e., for near-grazing incidence) and for the task of designing nonstandard partitions for unique applications.

Excitation of structures by an incident sound wave is significantly different from excitation by localized forces, moments, enforced velocities, or angular velocities. As discussed in the previous sections, the response of thin, platelike structures to localized excitation results in radially spreading free bending waves. The propagation speed of these waves, $c_B(f)$, is as unique a characteristic of the plate as is the period of a pendulum. The thinner the plate and the lower the frequency, the lower is the propagation speed.

If the structure is excited by an incident sound wave, forcing occurs simultaneously over the entire exposed surface of the plate. The incident sound enforces its spatial pattern on the plate, causing it to instantaneously conform to its trace. The trace "runs" along the plate with a speed that approaches the speed of sound in the source-side media when the sound runs nearly parallel to the plate (grazing incidence) and approaches infinity as the sound incidence approaches normal. This "sound-forced" response of the thin plate to sound excitation is referred to as the "forced wave." In contrast to the free bending waves, the speed of the forced bending wave is independent of frequency, plate thickness, and mass per unit area (though the amplitude of the response depends on them). Because of their supersonic speed, forced waves radiate sound very efficiently at all frequencies (e.g., their radiation efficiency $\sigma_F \geq 1$), except for panels that are small compared with the acoustical wavelength.

Transmission of Normal-Incidence Plane Sound Waves through an Infinite Plate

It is advisable to introduce the complex process of sound transmission by considering first the least complicated case when a plane sound wave is normally incident on a uniform homogeneous, isotropic, flat plate of thickness h, as shown in Fig. 11.18. Because the pressure exerted on the plate is in phase over the

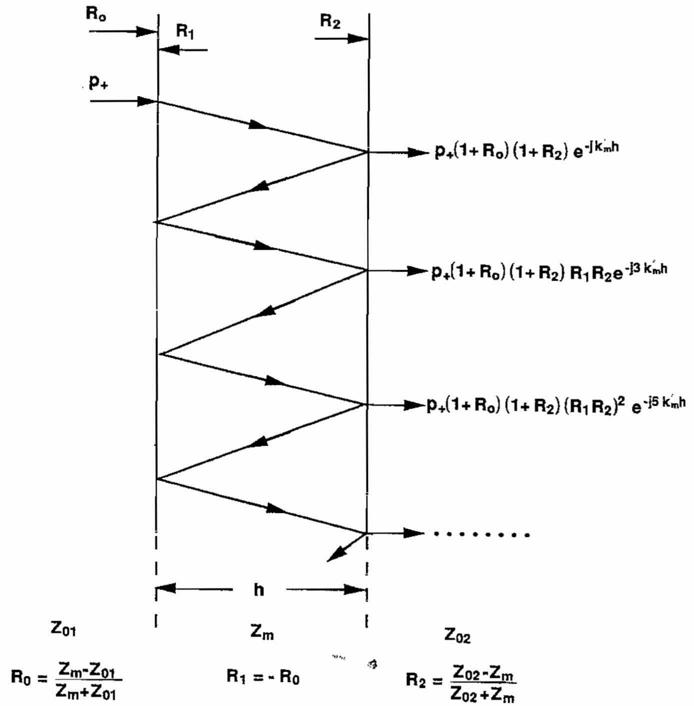

FIGURE 11.18 Transmission of a normally incident sound wave through a flat, homogeneous, isotropic plate. The transmitted pressure p_T is the sum of all the infinite components on the right. (See text for definition of symbols.)

entire surface of the plate, only compressional waves are excited. The sound wave of pressure amplitude p_+ propagates in a gas of characteristic plane-wave impedance $Z_{01} = \rho_{01}c_{01}$. It encounters the solid plate of characteristic impedance $Z_M = \rho c_L$ and on the transmitting side (right) will radiate sound into another gas of characteristic impedance $Z_{02} = \rho_{02}c_{02}$. The multiple reflection and transmission phenomena at the interfaces are governed by Eqs. (11.32) and (11.33). The amplitude of the transmitted sound pressure p_T in the receiver-side media is obtained by the summation of the transmitted components, as illustrated in Fig. 11.18, yielding[26]

$$p_T = p_+ \frac{(1 + R_0)(1 + R_2)e^{-jk_m h}}{1 - R_1 R_2 e^{-j2k_m h}} \quad \text{N/m}^2 \qquad (11.82)$$

where R_0, R_1, and R_2 are the reflection factors at the interfaces and directions indicated in Fig. 11.18 and h is the plate thickness. Propagation losses can be taken into account by a complex wavenumber $k'_m = k_m(1 + \frac{1}{2}j\eta)$, where $k_m = \omega/c_L$ is the wavenumber of compressional waves in the plate and η is the loss

factor. The normal-incidence sound transmission loss is defined as

$$R_N = 10 \log \frac{W_{\text{inc}}}{W_{\text{rad}}} = 10 \log \frac{p_+^2}{p_T^2} \quad \text{dB} \qquad (11.83a)$$

Assuming that the same gas is on both sides of the plate, Eq. (11.82) yields

$$R_N = 10 \log \left[\cos^2 k'_m h + 0.25 \left(\frac{Z_0}{Z_m} + \frac{Z_m}{Z_0} \right)^2 \sin^2 k'_m h \right] \quad \text{dB} \qquad (11.83b)$$

which for $|k'_m h| \ll 1$ yields the simple expression

$$R_N \cong 10 \log \left[1 + \left(\frac{\rho_s \omega}{2\rho_0 c_0} \right)^2 \right] \quad \text{dB} \qquad (11.83c)$$

known as the normal-incidence mass law. In Eq. (11.83c), $\rho_s = \rho h$ is the mass per unit area of the plate and $\rho_0 c_0 = Z_0$ is the characteristic impedance of the gas, assumed the same on both sides.

Figure 11.19 shows the computed normal-incidence sound transmission loss of a 0.6-m- (2-ft-) thick dense concrete wall. At low frequencies where the plate thickness is less than one-sixth of the compressional wavelength ($f < c_L/6h$) the sound transmission loss follows the normal-incidence mass law of Eq. (11.83c), increasing by approximately 6 dB for each doubling of the frequency or the mass per unit area. At high frequencies compressional wave resonances in the plate

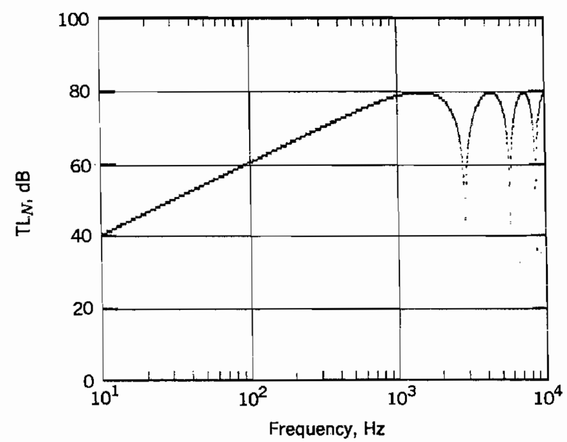

FIGURE 11.19 Normal-incidence sound transmission loss R_0 of a 0.6-m-thick dense concrete wall computed according to Eq. (11.83b) assuming $\eta = 0$.

occur and the R_N-versus-frequency curve exhibit strong minima at $f_n = nc_L/2h$, yielding

$$R_N^{\min} = 20 \log \left(1 + \frac{\pi}{4} \frac{Z_m}{Z_0} \eta n\right) \quad \text{dB} \tag{11.84a}$$

and the maximal achievable sound transmission loss can be approximated as

$$R_N^{\max} \cong 20 \log \frac{Z_m}{2Z_0} \quad \text{dB} \tag{11.84b}$$

Equation (11.84a) indicates complete transmission of the incident sound ($R_N^{\min} = 0$ dB) at compressional wave resonances if $\eta = 0$. However, Eq. (11.84a) indicates that even a small loss factor of $\eta = 0.001$ ensures that the normal-incidence transmission loss of a concrete partition does not dip below 24 dB at compressional wave resonances. Note, however, that no such dips are observed for random incidence because different incident angles correspond to different frequencies where such dips occur. As indicated in Eq. (11.84b), the maximum achievable normal-incidence sound transmission loss of homogeneous, isotropic single plates of any thickness is limited by the ratio of the characteristic impedances and is 80 dB for dense concrete, 94 dB for steel, and 68 dB for wood.

Transmission of Oblique-Incidence Plane Sound Waves through an Infinite Plate

The transmission of oblique-incidence sound through infinite plane plates can be formulated either in terms of shear and compressional waves, where the bending of the plate is considered as a superposition of these two wave types, or by utilizing the bending-wave equation of the plate. Both formulations are discussed below.

Combined Compressional and Shear Wave Formulation. The combined shear and compression wave formulation, which is valid also for thick plates, has been treated in Chapter 9 of the 1992 edition. It is too involved to present it here. The interested reader is referred to references 27 and 28 or to pages 248–288 of the 1992 edition of this book.

Separation Impedance Formulation. Sound transmission through plates can be conveniently characterized by the separation impedance Z_s defined as[1,26]

$$Z_s = \frac{p_s - p_{\text{rec}}}{v_n} \quad \text{N} \cdot \text{s/m}^3 \tag{11.85}$$

where p_s is the complex amplitude of the sound pressure at the source-side face of the plate representing the sum of the incident and reflected pressures ($p_s = p_{\text{inc}} + p_{\text{refl}}$), p_{rec} is the complex amplitude of sound pressure on the receiver-side face, and v_n is the complex amplitude of normal velocity of the receiver-side face of the plate. In the case of single panels, it is generally assumed that both faces of the panel vibrate in phase with the same velocity. The sound transmission coefficient of the plate τ and its sound transmission loss R are given by[1,26]

$$\tau(\phi) = \frac{I_{\text{trans}}}{I_{\text{inc}}} = \left|1 + \frac{Z_s \cos\phi}{2\rho_0 c_0}\right|^2 \tag{11.86}$$

$$R(\phi) = 10 \log \frac{1}{\tau(\phi)} = 10 \log \left(\left|1 + \frac{Z_s}{2\rho_0 c_0/\cos\phi}\right|^2\right) \quad \text{dB} \tag{11.87}$$

where ϕ is the angle of sound incidence ($\phi = 0$ for normal incidence).

The formulation of the sound transmission in terms of the separation impedance of Eq. (11.87) lends itself exceptionally well to predicting the sound transmission loss of multilayer partitions where the constituent layers may be thin plates separated by air spaces with and without porous sound-absorbing material (such as double and triple walls), windows, and so on. The reason for this is that the separation impedance of such multilayer partitions can be expeditiously obtained by appropriately combining the separation impedances of the constituent layers.

The separation impedance for a thick isotropic plate is obtained by solving the bending-wave equation of the plate as formulated by Mindlin[29]:

$$\left(\nabla^2 - \frac{\rho_M}{G}\frac{\partial^2}{\partial t^2}\right)\left(B\,\nabla^2 - \frac{\rho_M h}{12}\frac{\partial^2}{\partial t^2}\right)\xi(x,y) + \rho_M h \frac{\partial^2}{\partial t^2}\xi(x,y)$$
$$= \left(1 - \frac{B}{Gh}\nabla^2 + \frac{\rho_M h^2}{12G}\frac{\partial^2}{\partial t^2}\right)\Delta p\ (x,y,0) \tag{11.88}$$

where $\Delta p(x, y, 0)$ is the pressure differential across the plate, $\zeta(x, y)$ is the plate displacement in the z direction normal to the plate surface, $\nabla^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the Laplacian operator, ρ_M is the density, G is the shear modulus, B is the bending stiffness, and h is the thickness of the panel. The solution of Eq. (11.88) for a plane sound wave of incidence angle ϕ yields[30]

$$Z_s = \frac{j\left\{[\rho_M h + (\rho_M h^3/12 + \rho_M B/G)(\omega^2/c_0^2)\sin^2\phi]\omega - [(B/c_0^4)\sin^4\phi + \rho_M^2 h^3/(12G)]\omega^3\right\}}{1 + B\omega^2\sin^2\phi/(Gc_0^2 h) - \rho_M h^2\,\omega^2/(12G)} \quad \text{N} \cdot \text{s/m}^3 \tag{11.89}$$

Equation (11.89) can be approximated by

$$Z_s \cong Z_m + \left(\frac{1}{Z_B} + \frac{1}{Z_{\text{sh}}}\right)^{-1} \quad \text{N} \cdot \text{s/m}^3 \tag{11.90}$$

where $Z_m = j\omega\rho_M h$ is the mass impedance of the plate per unit area and $Z_B = -jB\omega^3\sin^4\phi/c_0^4$ and $Z_{\text{sh}} = -jGh\omega\sin^2\phi/c_0^2$ are the bending-wave and shear wave impedances of the plate per unit area.

If $|Z_{sh}| \ll |Z_B|$, the plate responds predominantly in shear and $Z_s \cong Z_m + Z_{sh}$. In this case, Eq. (11.89) yields

$$R_{sh}(\phi) = 20\log\left|1 + \frac{j\omega\rho_M h[1-(c_s/c_0)^2\sin^2\phi}{2\rho_0 c_0/\cos\phi}\right| \quad \text{dB} \tag{11.91}$$

Equation (11.91) indicates that trace coincidence between the incident sound wave and the free shear waves in the plate (which would lead to complete transmission) can be avoided at all incident angles provided that the panel is specifically designed to yield a low shear wave speed such that $c_s^2 = G/\rho < c_0^2 = P_0\kappa/\rho_0$. Unfortunately, this desirable condition cannot be met with homogeneous plates made of any construction-grade material. As we will discuss later, however, it is possible to satisfy the $c_s < c_0$ criterion with specially designed[31] inhomogeneous sandwich panels without compromising the static strength of the panel and thereby preserving the mass law behavior described by

$$R_{sh}(\phi) \cong R_{mass}(\phi) = 20\log\left(1 + \frac{\rho_2\ \omega\cos\phi}{2\rho_0 c_0}\right) \quad \text{dB} \tag{11.92}$$

which is representative of a limp panel of the same mass per unit area $\rho_s = \rho_M h$ as the shear panel.

Thin homogeneous panels are easier to bend than to shear so that $Z_B \ll Z_{sh}$. It follows that $Z_s \cong Z_m + Z_B$ and Eqs. (11.87) and (11.89) yield

$$R(\phi) = 10\log\frac{1}{\tau(\phi)} = 10\log\left|1 + \frac{j\rho_s\omega[1-(f/f_c)^2\sin^4\phi]}{2\rho_0 c_0/\cos\phi}\right|^2 \quad \text{dB} \tag{11.93}$$

where f_c is the critical frequency where the speed of the free bending waves in the plate, $c_B(f_c)$, equals the speed of sound in the media. It is given by

$$f_c = \left(\frac{\omega_c}{2\pi}\right) = \left(\frac{c_0^2}{2\pi}\right)\left(\frac{\rho_s}{B}\right)^{1/2} \quad \text{Hz(s)}^{-1} \tag{11.94}$$

where ρ_s = mass per unit are, $\rho_M h$ kg/m^2
h = plate thickness, m
B = bending stiffness of plate, $Eh^3/[12(1-\nu^2)]$ N · m

Consequently, the product $f_c\rho_s$ is a constant for a specific plate material and liquid (usually air). It is given by

$$f_c\rho_s = \left(\frac{c_0^2}{2\pi}\right)\sqrt{12(1-\nu^2)}\sqrt{\frac{\rho_M}{E}} \quad \text{Hz(s)}^{-1} \tag{11.95}$$

This product is listed in Table 11.2 for air as a surrounding medium. It is used to determine f_c as $f_c = \rho_s f_c/f_c$.

The coincidence frequency in air of homogeneous isotropic plates can be easily determined by cutting a narrow strip of length l in meters, supporting the two ends of the strip on a knife edge (to simulate simple supported edge conditions), and measuring the sag d in millimeters at the midpoint of the strip. The coincidence frequency is computed as

$$f_c = 1.65(10^2)\sqrt{\frac{d/\text{mm}}{l/\text{m}}} \quad \text{Hz(s)}^{-1} \tag{11.96}$$

Equation (11.93) indicates that above the critical frequency f_c given in Eq. (11.94), trace coincidence between the incident sound wave and the free bending waves in the plate occurs when $f = f_c/\sin^2\phi$ (which is called the coincidence frequency) and would result in complete transmission if the plate had no internal damping.

It is customary to account for internal damping in Eq. (11.88) by introducing a complex Young's modulus $E' = E(1 + j\eta)$ that results in complex wavenumbers $k_c' = k_c(1 + \frac{1}{2}j\eta)$ and $k_s' = k_s(1 + \frac{1}{2}j\eta)$ and yields the following modified form of the sound transmission loss:

$$\begin{aligned} R(\phi) &= 10\log\frac{1}{\tau(\phi)} \\ &= 10\log\left\{\left|1 + \frac{\rho_s\omega}{2\rho_0 c_0/\cos\phi}\right.\right. \\ &\qquad \left.\left.\left\{\eta\left(\frac{f}{f_c}\right)^2\sin^4\phi + j\left[1-\left(\frac{f}{f_c}\right)^2\sin^4\phi\right]\right\}\right|^2\right\} \quad \text{dB} \end{aligned} \tag{11.97}$$

Equation (11.97) indicates that in the vicinity of $f = f_c/\sin^2\phi$ the curves of sound transmission loss versus frequency exhibit a minimum that is controlled by the damping.

Figure 11.20 shows the curve of sound transmission loss versus frequency for a 4.7-mm-($\frac{3}{16}$-in.-) thick glass plate for normal ($\phi = 0°$), $\phi = 45°$, and near-grazing ($\phi = 85°$) angles of incidence computed according to Eq. (11.97). Figure 11.20 illustrates the decrease in sound transmission loss that occurs with increasing angle of incidence (owing to the $\cos\phi$ term) and the trace-matching dip that occurs at $f = f_c/\sin^2\phi$.

Transmission of Random-Incidence (Diffuse) Sound through an Infinite Plate

A plane wave impinging on the plate at one particular angle is not a typical problem. The sound field in a room is better modeled as a diffuse sound field, which is an ensemble of plane sound waves of the same average intensity traveling with equal probability in all directions. A region of unit area on the plate will be exposed, at any instant, to plane sound waves incident from all areas on

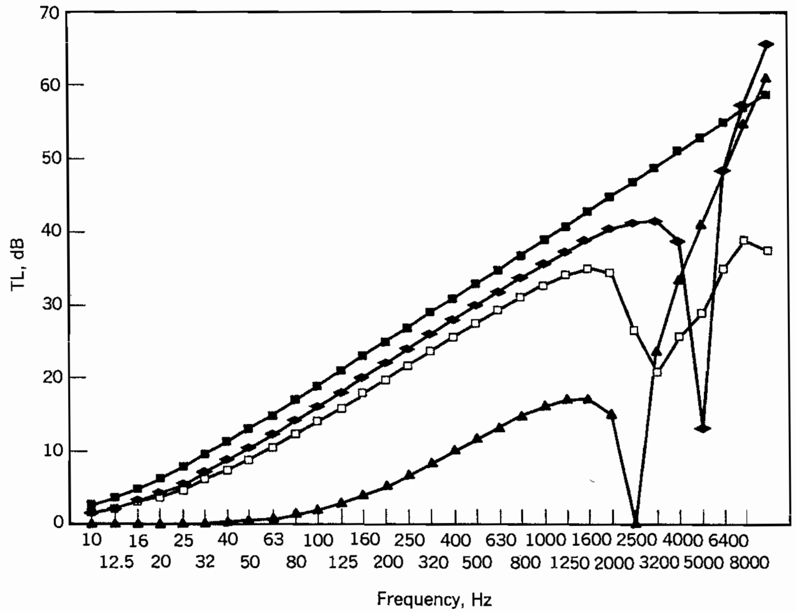

FIGURE 11.20 Computed TL-versus-frequency curve of a 3.7-mm-($\frac{3}{16}$-in.-) thick infinite glass plate for various angles of incidence: (■) normal ($\phi = 0°$); (♦) $\phi = 45°$; (►) $\phi = 85°$; (□) random.

a hemisphere whose center is the area on the plate. These waves are uncorrelated and have equal intensity. The sound intensity incident on the unit area of the plate from any particular angle will be the intensity of the plane wave at angle I_{inc} multiplied by the cosine of the angle of incidence. The total transmitted intensity is then

$$I_{\text{trans}} = \int_{\Omega} \tau(\phi) I_{\text{inc}} \cos\theta \, d\Omega \quad \text{W/m}^2 \tag{11.98}$$

The integration is over a hemisphere of solid angle Ω, where $d\Omega = \sin\phi \, d\phi \, d\theta$. Because I_{inc} is the same for all plane waves and τ is independent of the polar angle θ, an average transmission coefficient may be defined by

$$\overline{\tau} = \frac{\int_0^{\phi\,\text{lim}} \tau(\phi) \cos\phi \sin\phi \, d\phi}{\int_0^{\phi\,\text{lim}} \cos\phi \sin\phi \, d\phi} \tag{11.99}$$

where ϕ_{lim} is the limiting angle of incidence of the sound field. For random incidence, ϕ_{lim} is taken as $\frac{1}{2}\pi$, or 90°. The sound transmission coefficient $\tau(\phi)$ is that given in Eq. (11.97), and the random-incidence sound transmission loss is given by

$$R_{\text{random}} = 10 \log \frac{1}{\overline{\tau}} \quad \text{dB} \tag{11.100a}$$

At low frequencies ($f \ll f_c$) the random-incidence sound transmission loss (for $\text{TL}_N > 15$ dB) is found by averaging the argument of Eq. (11.97) over a range of ϕ from 0° to 90° to yield[32,33]

$$R_{\text{random}} \cong R_0 - 10 \log(0.23 R_0) \quad \text{dB} \tag{11.100b}$$

which is commonly referred to as the random-incidence mass law.

It has become common practice to use the *field-incidence mass law*, which is defined (for $R_0 \geq 15$ dB) as[34]

$$R_{\text{field}} \cong R_0 - 5 \quad \text{dB} \tag{11.101}$$

This result, which yields better agreement with measured data than Eq. (11.100b), approximates a diffuse incident sound field with a limiting angle ϕ_{lim} of about 78° in Eq. (11.99).[34]

The mass law transmission losses R_0, R_{field}, and R_{random}, valid for frequencies well below coincidence, are plotted versus $f\rho_s$ in Fig. 11.21.

Field-Incidence Sound Transmission for Thin Isotropic Plates, R_{field}. Equations (11.98) and (11.99) must be solved by numerical integration.

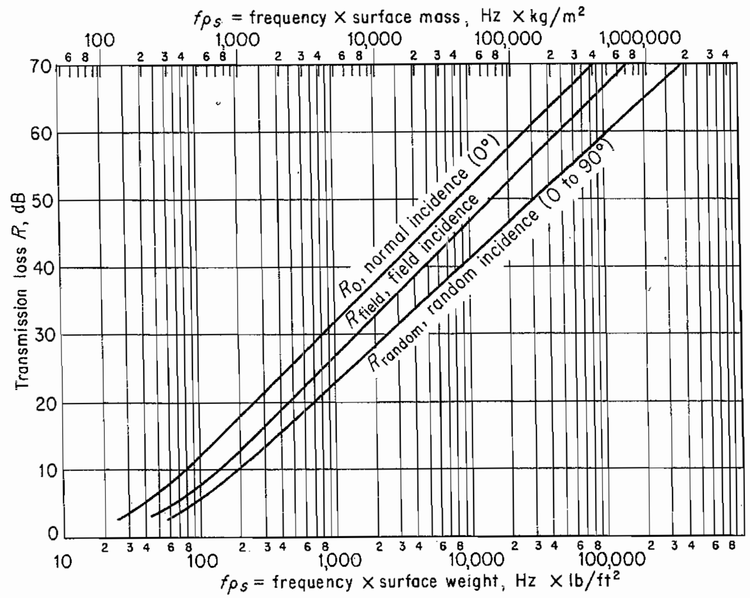

FIGURE 11.21 Theoretical sound transmission loss of large panels for frequencies well below coincidence ($f \leq 0.5 f_c$). Field incidence assumes a sound field that allows all angles of incidences up to 78° from normal.

The results of such an integration of the transmission coefficient between the angles 0° and 78° and application of Eq. (11.100a) to give the *field-incidence transmission loss* are presented in Fig. 11.22 for all values of f/f_c. The ordinate is the difference between the field-incidence transmission loss R_{field} and the normal-incidence mass law transmission loss at the critical frequency $R_0(f_c)$. The latter is easily determined from Eq. (11.83c) or from Fig. 11.21 when the mass per unit area and the critical frequency of the panel are known. Note that predicted transmission losses of less than about 15 dB for $f \ll f_c$ or less than 25 dB for $f \simeq f_c$ from Fig. 11.22 are not accurate.

Example 11.2. Calculate the normal-incidence mass law for an aluminum panel weighing 10 lb/ft^2 at a frequency of 500 Hz. Also determine the random-incidence and field-incidence mass laws. What is R_{field} at 2800 Hz when $\eta = 10^{-2}$?

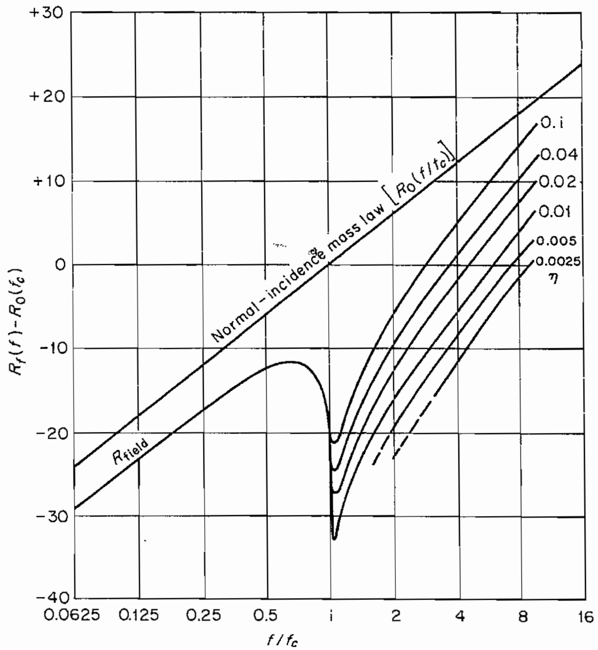

FIGURE 11.22 Field-incidence forced-wave transmission loss. The ordinate is the difference between the field-incidence transmission loss at the frequency f and the normal-incidence transmission loss at the *critical frequency* ($f/f_c = 1$). Note that for a predicted transmission loss of less than 15 dB or for the dashed areas on the figure, the transmission loss depends on both the surface weight and the loss factor, and the curves provide only a lower bound estimate to the actual transmission loss. Use of curve: (1) determine $\rho_s f_c$ from Table 11.2, (2) determined f_c, (3) determine $R_0(f_c)$ from Fig. 11.21 or Table 11.2, (4) read $R_f(f) - R_0(f_c)$ from Fig. 9.21 at the required η, and (5) $R_f(f) = [R_f(f) - R_0(f_c)] + R_0(f_c)$. Top curve is the normal-incidence mass law defined in Eq. (11.83c).

Solution The normal-incidence mass law is given by Eq. (11.83c) and the upper curve of Fig. 11.21. We have $f\rho_s = 500 \times 10 = 5000$ Hz · lb/ft^2. From Fig. 11.21, $R_0 = 45.5$ dB. The random-incidence mass law is given by Eq. (11.100b) and the lower curve of Fig. 11.21; that is, $R_{\text{random}} = 35$ dB. The field-incidence mass law is given by Eq. (11.101) and the middle curve of Fig. 11.21, that is, $R_{\text{field}} = 45.5 - 5 = 40.5$ dB.

From Table 11.2, $\rho_s f_c = 7000$ Hz · lb/ft^2; $f_c = 7000/10 = 700$ Hz and $R_0(f_c) = 48$ dB from Fig. 11.21. Evaluating Fig. 11.22 at $f/f_c = 2800/700 = 4$ and $\eta = 0.01$, we get $R_f(f) - R_0(f_c) = -6$ dB, yielding $R_r(f) = [R_r(f) - R_0(f_c)] + R_0(f) = -6 + 48 = 42$ dB.

Sound Transmission for Orthotropic Plates. Sound transmission for orthotropic plates differs from that of isotropic plates because orthotropic plates have markedly different bending stiffnesses in the different principal directions. The difference in bending stiffness for plane plates may result from the anisotropy of the plate material (such as for wood caused by grain orientation) or from the construction of the plate such as corrugations, ribs, cuts, and so on. Consequently, the speed of free bending waves is different for these two directions and the orthotropic panel has two coincidence frequencies given by[35]

$$f_{c1} = \frac{c_o^2}{2\pi}\sqrt{\frac{\rho_s}{B_x}} \quad \text{Hz} \tag{11.102a}$$

$$f_{c2} = \frac{c_o^2}{2\pi}\sqrt{\frac{\rho_s}{B_y}} \quad \text{Hz} \tag{11.102b}$$

where B_x is the bending stiffness for the stiffest direction and B_y the direction perpendicular to this. The random-incidence sound transmission loss of an orthotropic plate is predicted by[35]

$$R_{\text{random}} \cong \begin{cases} 10\log\left[\left(\dfrac{\rho_s\omega}{2\rho_0 c_0}\right)^2\right] - 5 & \text{for } f \ll f_{c1} \\ 10\log\left[\left(\dfrac{\rho_s\omega}{2\rho_0 c_0}\right)^2\right] - 10\log\left[\dfrac{1}{2\pi^3\eta}\dfrac{f_{c1}}{f}\sqrt{\dfrac{f_{c1}}{f_{c2}}}\left(\ln\dfrac{4f}{f_{c1}}\right)^4\right] & \text{for } f_{c1} < f < f_{c2} \\ 10\log\left[\left(\dfrac{\rho_s\omega}{2\rho_0 c_0}\right)^2\right] - 10\log\dfrac{\pi f_{c2}}{2\eta f} & \text{for } f > f_{c2} \end{cases} \tag{11.103}$$

where η is the loss factor. For corrugated plates, as shown in Fig. 11.23, the bending stiffnesses can be approximated by

$$B_y = \frac{Eh^3}{12(1 - \nu^2)} \quad \text{N} \cdot \text{m} \tag{11.104a}$$

$$B_x = B_y \left(\frac{s}{s'}\right) \quad \mathrm{N \cdot m} \tag{11.104b}$$

where s and s' are defined in Fig. 11.23. Note that the increase in bending stiffness caused by corrugations, ribs, and stiffeners always results in a reduction of the sound transmission loss, while measures such as partial-depth saw cuts, which decrease bending stiffness, result in an increase of the sound transmission loss of plates.

Sound Transmission Loss for Inhomogeneous Plates. Sound transmission loss for inhomogeneous plates, such as appropriately designed sandwich panels, can be substantially higher than for homogeneous panels of the same mass per unit area, provided that such plates favor the propagation of the free shear waves (with frequency-independent propagation speed) rather than free bending waves for which the propagation speed increases with increasing frequency. However, they must be designed such that the shear wave speed remains below the speed of sound in air so that no trace coincidence occurs. Consequently, the sound transmission loss of such so-called shear wall panels closely approximates the field-incidence mass law. Information for designing such panels is given in reference 31. However, ordinary sandwich panels are very poor sound barriers because

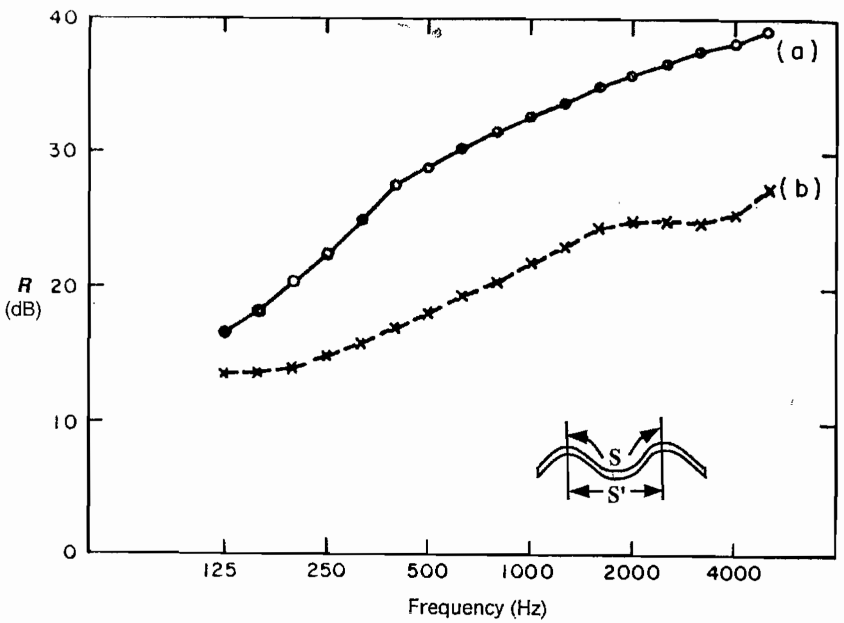

FIGURE 11.23 Measured sound transmission loss of steel plates (after Ref. 28): (*a*) plane plate, $\rho_s = 8$ kg/m^2; (*b*) corrugated plate, $\rho_s = 11$ kg/m^2; s, distance between corrugations along surface; s', distance along straight line.

of their low mass and high bending stiffness that result in a coincidence frequency that usually falls in the middle of the audio frequency range. Dilation resonance, which occurs at the frequency where the combined stiffness impedance of the face plate and that of the enclosed air equals the mass impedance of the plate, also leads to further deterioration of the sound transmission loss of sandwich panels.

Sound Transmission through a Finite-Size Panel

For most architectural applications, where the first resonance frequency of typical platelike partitions is well below the frequency range of interest and the plate size is much larger than the acoustical wavelength, Eq. (11.97) or Fig. 11.22 (which are strictly valid only for infinitely large panels) can be used to predict the sound transmission loss of finite panels. In many industrial applications, the finite size of the panel must be taken into account.[36]

In finite panels the sound-forced bending waves encounter the edges of the plate and generate free bending waves, such that the sum of the incident forced bending wave and the generated free bending wave satisfies the particular plate edge condition (e.g., zero displacement and angular displacement at a clamped edge). Consequently, the sound-forced bending waves continuously feed free bending wave energy into the finite panel and build up a reverberant, free bending wave field. The mean-square vibration velocity of this free bending wave field, $\langle v_{\mathrm{FR}}^2 \rangle$ can be obtained using a power balance for the finite plate. The power introduced into the finite plate at the edges equals the power lost by the plate owing to viscous losses in the plate material, energy flow into connected structures, and sound radiation. The transmitted sound radiated by the finite panel is given by

$$W_{\mathrm{rad}} = \langle v_{\mathrm{FO}}^2 \rangle\, \rho_0 c_0 S \sigma_{\mathrm{FO}} + \langle v_{\mathrm{FR}}^2 \rangle\, \rho_0 c_0 S \sigma_{\mathrm{FR}} \quad \mathrm{W} \tag{11.105}$$

where $\langle v_{\mathrm{FO}}^2 \rangle$ is the mean-square velocity of the sound-forced supersonic bending waves, $\sigma_{\mathrm{FO}} \geq 1$ is the radiation efficiency of the forced waves, S is the surface area of the panel, and σ_{FR} is the radiation efficiency of the free bending waves. Since $\sigma_{\mathrm{FR}} \ll 1$ below the critical frequency of the panel ($f \ll f_c$), it is frequently the case that the vibration response of the panel is controlled by the free bending waves (i.e., $\langle v_{\mathrm{FR}}^2 \rangle \gg \langle v_{\mathrm{FO}}^2 \rangle$) but the sound radiation is controlled by the less intense but more efficiently radiating forced waves.

The classical definition of sound transmission loss is $R = 10 \log(W_{\mathrm{inc}}/W_{\mathrm{trans}})$, where W_{inc} is the sound power incident at the source side and W_{trans} is that radiated from the receiver side of the panel. If the incident sound is a plane wave arriving at an incident angle ϕ ($\phi = 90°$ for grazing incidence), then it is assumed that

$$W_{\mathrm{inc}} = \frac{0.5 |\hat{p}_{\mathrm{in}}|^2 S \cos\phi}{\rho_0 c_0} \quad \mathrm{W} \tag{11.106}$$

This assumption leads to the dilemma that at grazing incidence ($\phi = 90°$) no power is incident on the panel. It is common knowledge that grazing incidence sound excites the panel to forced vibrations, and the panel radiates sound into the receiver room when the forced bending waves in the panel and the sound wave at the receiver side, which run parallel to the panel, encounter the edges of the finite panel. This unresolved conceptual problem has been avoided[34] by limiting the incident angle range to 78°, in computing the field incidence sound transmission loss for the infinite panel according to Eq. (11.101), so as to yield reasonable agreement with laboratory measurements for panel sizes typically employed in such tests.

Obviously, it is not the incident sound power but the mean-square sound pressure on the source side that is forcing the panel. Since this quantity is proportional to the sound energy density in the source room $E_s = \langle p_s^2 \rangle / \rho_0 c_0^2$, it has been suggested[37,38] that the sound transmission loss of a finite partition be defined as

$$R_E \equiv 10 \log \left(\frac{E_s}{E_R} \frac{S}{A} \right) \quad \text{dB} \qquad (11.107)$$

where $E_R = 4\ W_{\text{trans}}/c_0 A$ is the energy density in the receiver room, S is the surface area of the panel (one side), and A is the total absorption in the receiver room. The transmitted sound power $W_{\text{trans}} = \frac{1}{4} c_0 A E_R$ is owing to the velocity of the plate. The forced response is dominated by the mass-controlled separation impedance $Z_s \simeq j\omega\rho_s$. The sound radiation of the sound-forced finite plate is controlled by its radiation impedance $Z_{\text{rad}} \cong \text{Re}\{Z_{\text{rad}}\} = \rho_0 c_0 \sigma_F$. Consequently, the low-frequency sound transmission loss of the finite partition is predicted is predicted as[38]

$$R_E \cong R_0 - 3 - 10 \log \sigma_F \quad \text{dB} \qquad (11.108)$$

where R_0 is the normal-incidence mass law sound transmission loss given in Eq. (11.83c) and σ_F is the forced-wave radiation efficiency of the finite panel given in Table 11.8. Note that σ_F depends on panel size as well as on incidence angle and can be smaller or larger than unity. This implies that the sound transmission loss of finite panels can be larger than the normal-incidence mass law even for grazing incidence if the size of the panel is small compared with the wavelength. When the panel size is much larger than the acoustical wavelength, σ_F approaches $1/\cos\phi$. For predicting the sound transmission loss of finite partitions over the entire low-frequency range ($f \ll f_c$), Eq. (11.108) should be used.

According to reference 38, the classical sound transmission formulas for infinite panels can be used to approximate the sound transmission loss of finite partitions by substituting $1/\sigma_F$ instead of $\cos\phi$ and $\sqrt{1 - 1/\sigma_F^2}$ instead of $\sin\phi$ in Eq. (11.97) and carrying out the integration in Eq. (11.99) from $\phi = 0$ to $\phi = 90°$ to obtain an estimate of the random-incidence sound transmission loss that agrees well with laboratory measurements. There is no need to resort to limiting the incident angle range to 78°. The radiation efficiency for random-incidence (diffuse-field) sound-forced excitation is given in Table 11.8, and this expression

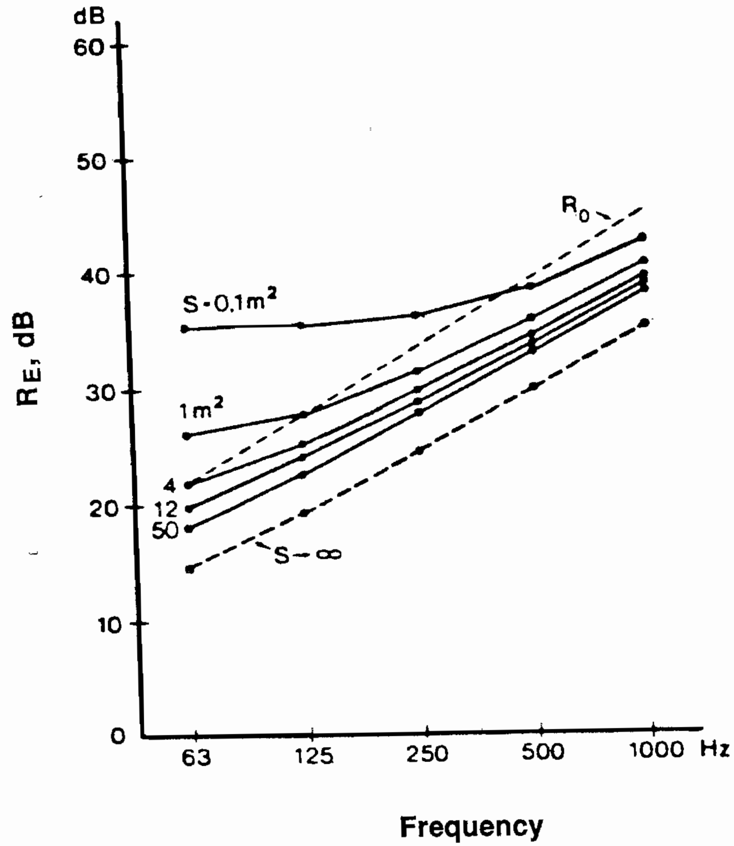

FIGURE 11.24 Random-incidence sound transmission loss of 25-kg/m² panels as a function of frequency with panel surface area S as a parameter, mass-controlled low-frequency region; computed according to Eq. (11.110). (After References 37 and 38.)

should be used in Eq. (11.108). As shown in Fig. 11.24, the random-incidence sound transmission loss of partitions of approximately 4 m² surface area, which are typically used in laboratory measurements, yield predicted values that are 5 dB below the normal-incidence mass law, giving theoretical justification for using the field-incidence mass law defined in Eq. (11.101) for partitions of this size. Note, however, that for small partitions Eq. (11.108) is more accurate. It should be pointed out that all of the sound transmission loss prediction formulas are valid only in the frequency region well above the first bending wave resonance of the panel where the forced response is mass controlled. For small, very stiff partitions the frequency range of interest may extend into the stiffness-controlled region below the frequency of the first bending wave resonance.* In this case,

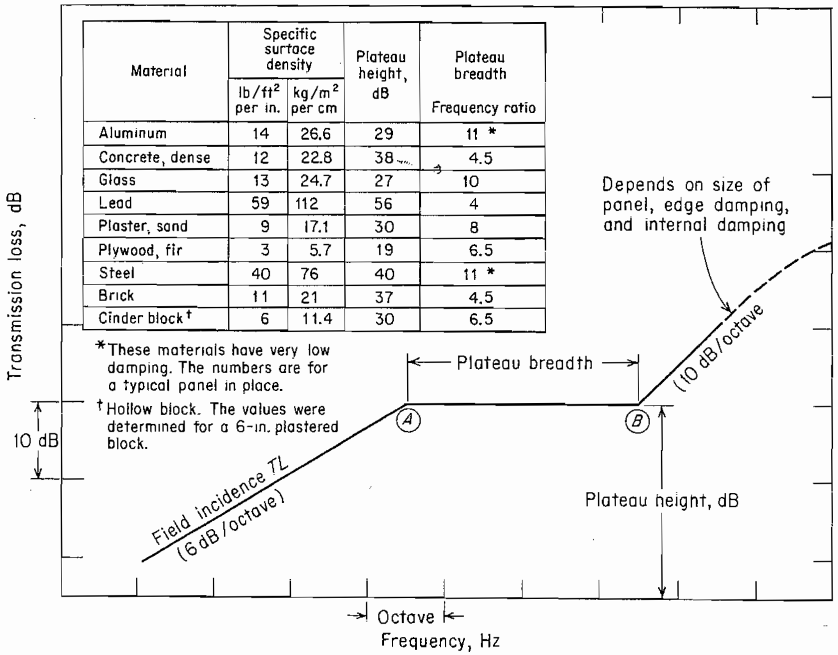
*For prediction in this frequency region use Eqs. (11.70)–(11.73).

the volume compliance of the panel, as described in the beginning of this section in Chapter 12, should be used to predict sound transmission.

Empirical Method for Predicting Sound Transmission Loss of Single Partitions. An alternate technique useful in preliminary design is illustrated in Fig. 11.25. In essence, it considers the loss factor of the material to be determined completely by the material selection and substitutes a "plateau" or horizontal line for the peak and valley of the forced-wave analysis in the region of the critical frequency.[34,39] Its use will be demonstrated in Example 11.3.

Example 11.3. Calculate the transmission loss of a $\frac{1}{8}$-in.- (3-mm-) thick, 5×6.5-ft (1.52×2-m) aluminum panel by the alternate (plateau) method.

Solution From Table 11.2, the product of surface mass and critical frequency is $\rho_s f_c = 34,700$ Hz $\cdot$ kg/m^2. The $\frac{1}{8}$-in.-thick aluminum plate has a surface density



Material	Specific surface density lb/ft^2 per in.	Specific surface density kg/m^2 per cm	Plateau height, dB	Plateau breadth Frequency ratio
Aluminum	14	26.6	29	11 *
Concrete, dense	12	22.8	38	4.5
Glass	13	24.7	27	10
Lead	59	112	56	4
Plaster, sand	9	17.1	30	8
Plywood, fir	3	5.7	19	6.5
Steel	40	76	40	11 *
Brick	11	21	37	4.5
Cinder block†	6	11.4	30	6.5

*These materials have very low damping. The numbers are for a typical panel in place.

†Hollow block. The values were determined for a 6-in. plastered block.

FIGURE 11.25 Approximate design chart for estimating the sound transmission loss of single panels. The chart assumes a reverberant sound field on the source side and approximates the behavior around the critical frequency with a horizontal line or plateau. The part of the curve to the left of A is determined from the field-incidence mass law curve (Fig. 11.21). The plateau height and length of the line from A to B are determined from the table. The part above B is an extrapolation. This chart is fairly accurate for large panels. Length and width of the panel should be at least 20 times the panel thickness.[34]

of 8.5 kg/m^2. From Fig. 11.21 we find that the normal-incidence transmission loss at the critical frequency is $R_0(f_c) = 48.5$ dB and that the field-incidence transmission loss at 1000 Hz is R_{field} (8500 Hz $\cdot$ kg/m^2) = 31.5 dB.

The procedure by the plateau method is as follows[34,39]:

1. Using semilog paper (with coordinates decibels versus log frequency), plot the field-incidence mass law transmission loss as a line with a 6-dB/octave slope through the point 31.5 dB at 1000 Hz.
2. From Fig. 11.25, the plateau height for aluminum is 29 dB. Plotting the plateau gives the intercept of the plateau with the field-incidence mass law curve at approximately 750 Hz.
3. From Fig. 11.25, the plateau width is a frequency ratio of 11. The upper frequency limit for the plateau is therefore 11×750 Hz = 8250 Hz.
4. From the point 29 dB, 8250 Hz, draw a line sloping upward at 10 dB/octave. This completes the plateau method estimate (see curve b in Fig. 11.34).

Sound Transmission through Double- and Multilayer Partitions

The highest sound transmission loss obtainable by a single partition is limited by the mass law. The way to "break this mass law barrier" is to use multilayer partitions such as double walls, where two solid panels are separated by an air space that usually contains fibrous sound-absorbing material and double windows where light transparency requirements do not allow the use of sound-absorbing materials.

The transmission of sound through a multilayer partition can be computed in a similar manner as the sound absorption coefficient of multilayer sound absorbers treated in Chapter 8. Figure 11.26 shows the situation where a plane sound wave of frequency $f = \omega/2\pi$ is incident at an angle ϕ on a panel that has N layers and $N+1$ interfaces. The important boundary conditions are that the wavenumber component parallel to the panel surface $k_x = k \sin\phi$ must be the same in all of the layers and that the acoustical pressure and particle velocity at the interfaces of the layers must be continuous.[40–42]

The layers are characterized by their wave impedance formula, which relates the complex wave impedance at the input-side interface Z_I with that at the termination-side interface Z_T and by their pressure formula that relates the complex sound pressure at the input-side interface p_I to that at the terminal-side interface p_T.

The impedance and pressure formulas for an impervious orthotropic thin plate are given by[42]

$$Z_I = Z_T + Z_S$$

$$= Z_T + j\left[\omega\rho_s - \frac{1}{\omega}(B_x k_x^4 + 2B_{xy}k_x^2k_y^2 + B_y k_y^4)\right] \quad \text{N} \cdot \text{s/m}^3 \qquad (11.109)$$

$$p_I = p_T \frac{Z_I}{Z_T} \quad \text{N/m}^2 \qquad (11.110)$$

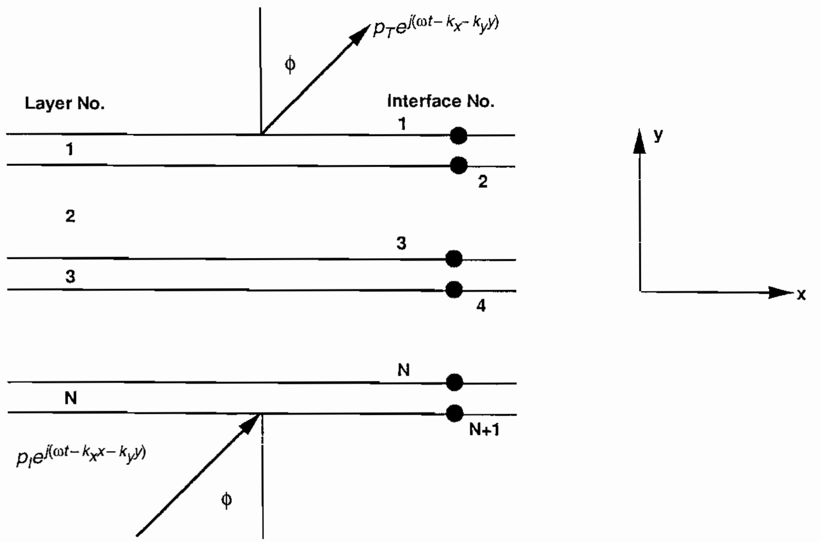


FIGURE 11.26 Transmission of a plane oblique incident sound wave through an infinite lateral dimension multilayer panel.

where ρ_s is the mass per unit area and B is the bending stiffness of the orthotropic plate.

For isotropic plates the second term in Eq. (11.109) reduces to $Z_s = Z_m + Z_B = j(\omega\rho_s - Bk_x^4/\omega)$. If the impervious layer is a composite of an isotropic homogeneous plate with a bonded damping material of thickness h_D, Young's modulus E_D, Poisson ratio ν_D, and damping loss factor η_D and the plate characteristics are thickness h_p, Young's modulus E_p, Poisson ratio ν_p, and loss factor η_p, then the complex bending stiffness $B = B_{\text{comp}}(1 + j\eta_{\text{comp}})$ is obtained[1,42] from

$$B_{\text{comp}} = \frac{E_p h_p^3}{12(1-\nu_p^2)} + \frac{E_D h_D (h_p + h_D)^2}{4(1-\nu_D^2)} \quad \text{Nm} \tag{11.111}$$

$$\eta_{\text{comp}} = \tfrac{1}{4} B_{\text{comp}} (\eta_p E_p h_p + \eta_D E_D h_D)(h_p + h_D)^2 \tag{11.112}$$

For a porous sound-absorbing layer of thickness h the impedance and pressure formulas are given by[42]

$$Z_I = Z_a \frac{k_a}{k_{ay}} \frac{(1 + Z_a\Gamma_a/Z_T\Gamma_{ay})e^{j\Gamma_{ay}h} + (1 - Z_a\Gamma_a/Z_T\Gamma_{ay})e^{-j\Gamma_{ay}h}}{(1 + Z_a\Gamma_a/Z_T\Gamma_{ay})e^{j\Gamma_{ay}h} - (1 - Z_a\Gamma_a/Z_T\Gamma_{ay})e^{-j\Gamma_{ay}h}} \quad \text{N} \cdot \text{s/m} \tag{11.113}$$

$$p_T = \frac{p_I}{2}\left[\left(1 + \frac{Z_a\Gamma_a}{Z_I\Gamma_{ay}}\right)e^{-j\Gamma_{ay}h} + \left(1 - \frac{Z_a\Gamma_a}{Z_I\Gamma_{ay}}\right)e^{j\Gamma_{ay}h}\right] \quad \text{N/m}^2 \tag{11.114}$$

where $Z_a = \rho_0 c_0 Z_{an}$ is the complex characteristic acoustical impedance of the porous bulk material for plane waves and Z_{an} is its normalized value while $\Gamma_a = \Gamma_{an} k_0$ is the complex wavenumber of plane sound waves in the bulk porous material; $\Gamma_{ay}^2 = \Gamma_a^2 - k_x^2$. Formulas for computing Γ_{an} and Z_{an} on the basis of the flow resistivity of the porous material R_1 are given in Chapter 8 [see Eqs. (8.22) and (8.19)]. The simpler approximate formulas for Γ_a and Z_a given in reference 42 are less accurate and their use is not recommended.

In the special case of an air layer without porous sound-absorbing material, substitute $Z_a = \rho_0 c_0$ and $k_a = k_0$ into Eqs. (11.113) and (11.114).

The computation of the sound transmission loss of a layered partition proceeds as follows:

1. Set the termination impedance at the receiver-side interface (interface 1 in Fig. 11.26) to $Z_T = \rho_0 c_0 / \cos\phi$.
2. Apply the appropriate impedance formula for layer 1 and compute the input impedance at interface 2.
3. Using the impedance computed in step 2 as the termination impedance for layer 2, compute the input impedance at interface 3 and proceed down the chain of impedance calculations until the input impedance at the source-side interface (interface $N+1$ in Fig. 11.26), Z_{N+1}, is obtained.
4. Compute the sound pressure at the source-side interface as the sum of the incident and reflected pressures $p_{N+1} = p_I[2\alpha/(\alpha+1)]e^{j(\omega t - k_x x - k_y y)}$, where $\alpha = Z_{N+1}/(\rho_0 c_0/\cos\phi)$.
5. Apply the appropriate pressure formulas in succession until the sound pressure at the receiver-side interface, p, is obtained.
6. Determine the transmission coefficient $\tau(\omega, \phi) = p_1^2/p_I^2$ for all frequencies of interest.
7. Perform computational steps 1–6 for the incident angle range from $\phi = 0°$ to $\phi = 90°$ in one-third-degree increments.
8. Compute the random-incidence sound transmission coefficient for isotropic layers (see ref. 42 for orthotropic impervious layers) as

$$\tau_R(\omega) = \int_0^{\pi/2} \tau(\omega, \phi) \sin 2\phi \, d\phi$$

9. Compute the random-incidence sound transmission loss of the infinite layered partition as

$$R_{\text{random}}(\omega) = 10 \log \frac{1}{\tau_R(\omega)}$$

Figure 11.27 shows the random-incidence sound transmission loss of an infinite three-layer partition as well as that of its constituent layers, computed according to Eqs. (11.109)–(11.114). The partition consists of two 1-mm-thick steel plates and a 100-mm-thick air space that may or may not contain a fibrous sound-absorbing material. Figure 11.27 illustrates the benefit of using sound-absorbing

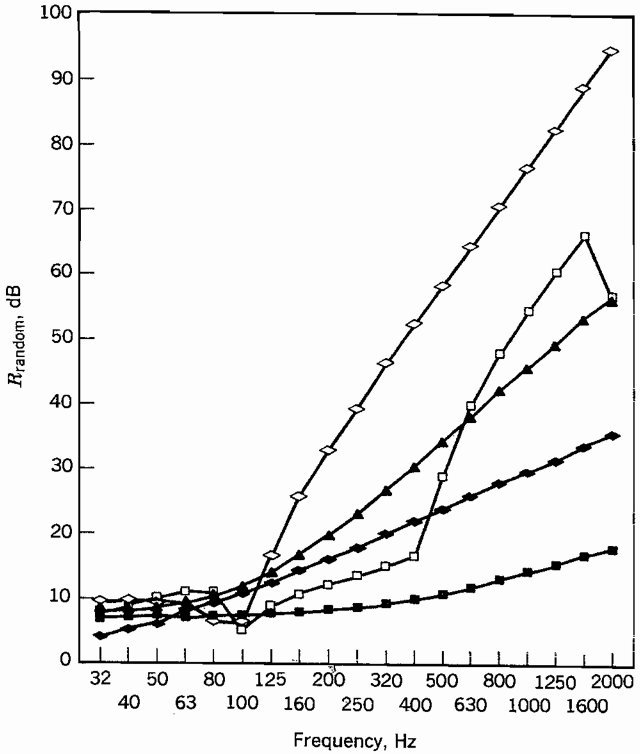

FIGURE 11.27 Computed random-incidence sound transmission loss of a double wall and its constituent layers: (■) 100-mm-thick fibrous absorber, flow resistivity $R_1 = 16{,}700$ N/s · m^4; (◆) 1-mm steel plate; (▲) 1-mm steel plate and 100-mm fibrous absorber. Double wall consisting of two 1-mm-thick steel plates: (□) 100-mm air space, no fibrous absorber; (◇) 100-mm air space with fibrous absorber.

layers. Note that below 500 Hz the double wall without sound-absorbing material in the air space provides substantially lower random-incidence sound transmission loss than a single 1-mm steel plate or the single plate combined with the sound-absorbing layer. The highest sound transmission loss is obtained when the air space is filled with the porous sound-absorbing material. In practical situations, leaks and structure-borne connections between the face plates at edges of the partition usually limit the maximally achievable sound transmission loss at high frequencies to a range of 40–70 dB. At low frequencies the finite size of the partition results in higher values than predicted for infinite partitions. The effect of the sound-absorbing material in the air space results in refraction of the oblique-incidence sound toward the normal, thereby reducing the dynamic stiffness of the air between the plates. The sound-absorbing material also prevents high sound energy buildup in the cavity. These result in a substantial

increase in sound transmission loss. The flow resistivity of the sound-absorbing material should be about $R_1 = 5000$ N · s/m^4.[43] Higher values of R_1 yield only diminishing returns.

The filling of the air space with a gas of 50% lower speed of sound than air (such as SF_6 or CO_2) has the same effect as the sound-absorbing material,[44,45] as illustrated in Fig. 11.28. Using a light gas such as helium, which has three times higher speed of sound than air, also improves sound transmission loss to the same extent as a heavy-gas fill. In this case, the improvement is due to the higher speed of sound in the gas fill, which makes it easier to push the gas tangentially than to compress it. Double windows, which can be hermetically sealed and must be light transparent, are partitions where this beneficial effect can be exploited.

Empirical Method for Predicting Sound Transmission Loss of Double Partitions. Goesele[46] has proposed a simplified method to predict the sound transmission loss R of a double partition when the measured sound transmission losses of the two constituent single partitions R_{I} and R_{II} are available, there are no structure-borne connections, and the gap is filled with porous sound-absorbing material. The prediction is given as

$$R \cong R_{\mathrm{I}} + R_{\mathrm{II}} + 20\log\left(\frac{4\pi f \rho_0 c_0}{s'}\right) \quad \text{dB} \tag{11.115}$$

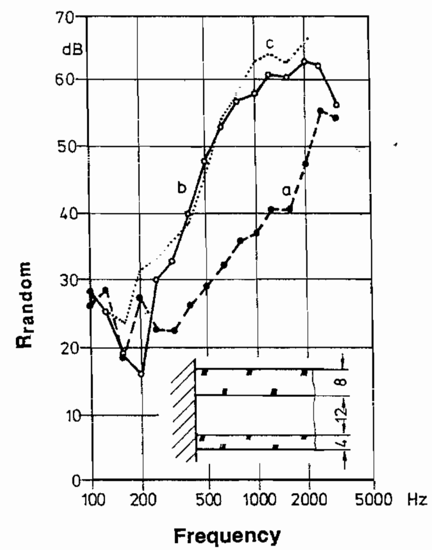

FIGURE 11.28 Improvement of the sound transmission loss of a double glass partition (no contact at the edges) owing to heavy gas (SF_6) fill of the gap: a, measured with air-filled gap; b, measured with SF_6-filled gap; c, computed for mineral wool fill. (After Ref. 44.)

where

$$s' = \begin{cases} \dfrac{\rho_0 c_0^2}{d} & \text{for } f < f_d = \dfrac{c_0}{2\pi\, d} \quad \text{N/m}^3 \quad (11.116\text{a}) \\ 2\pi f \rho_0 c_0 & \text{for } f > f_d \quad \text{N/m}^3 \quad (11.116\text{b}) \end{cases}$$

is the dynamic stiffness per unit area of the gap and d is the gap thickness.

If no measured sound transmission loss data for the constituent single partitions are available, the sound transmission loss of the double wall made of two identical panels can be predicted on the basis of material properties as

$$R(f_R < f < f_c) \cong 20 \log \frac{\pi f \rho_{s1}}{\sqrt{2}\rho_0 c_0} + 40 \log \left(\frac{\sqrt{2} f}{f_R} \right) \quad \text{dB} \qquad (11.117\text{a})$$

$$R(f > f_R, f > f_c) \cong 40 \log \left[\frac{\pi f \rho_{s1}}{\rho_0 c_0} \sqrt{2\eta} \left(\frac{f}{f_c} \right)^{1/4} \right] + 20 \log \frac{4\pi f \rho_0 c_0}{s'} \quad \text{dB} \qquad (11.117\text{b})$$

where f_c is the critical frequency of the panels and f_R is the double-wall resonance frequency

$$f_R = \frac{1}{2\pi} \sqrt{\frac{2\sqrt{2} s'}{\rho_{s1}}} \quad \text{Hz} \qquad (11.118)$$

Figure 11.29 shows that Eq. (11.115) yields good agreement with measured data in the entire frequency region, while Eqs. (11.117a) and (11.117b) give good agreement only well below and well above the critical frequency but fail in the frequency region near the critical frequency. Prediction methods for the sound transmission loss of double walls with point and line bridges are given by reference 30 and by Bies and Hansen (see Bibliography).

Sound Transmission Loss of Ducts and Pipes

Pipes and ducts that carry high-intensity internal sound are excited into vibration and radiate sound to the outside. This sound transmission in the breakout direction (i.e., from inside to outside) is characterized by breakout sound transmission loss R_{io}, which is a measure of the rate at which sound energy from the interior of the duct radiated to the outside. When pipes and ducts traverse areas of high-intensity sound such as found in mechanical equipment rooms, the exterior sound field excites ductwall vibrations and the vibrating walls generate an internal sound field that can travel to distant quiet areas. This sound transmission from the outside to the inside direction is characterized by the breakin sound transmission loss R_{oi}, which is a measure of the rate at which sound energy from the exterior sound field enters the duct.

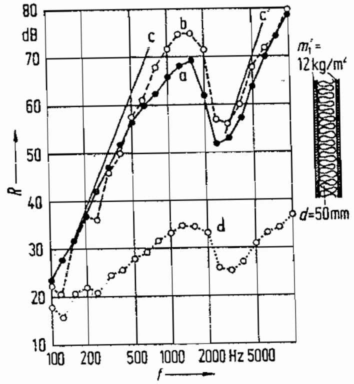

FIGURE 11.29 Sound transmission loss of a double partition consisting of two identical, 12.5-mm-thick gypsum boards separated by a 50-mm-thick gap filled with fibrous sound-absorbing material: *a*, measured values; *b*, predicted by Eq. (11.117); *c*, predicted by Eqs. (11.116a) and (11.116b); *d*, measured sound transmission loss of a single gypsum board wall. (After reference 46.)

The sound power level radiated by a duct or pipe of length l, L_w^{io}, is predicted as[47]

$$L_w^{io}(l) = L_w^i(0) - R_{io} + 10 \log \left(\frac{Pl}{S} \right) + 10 \log(C) \quad \text{dB re} 10^{-12} \text{ W} \qquad (11.119\text{a})$$

where

$$C = \frac{1 - e^{-(\tau + \beta)l}}{(\tau + \beta)l} \qquad (11.119\text{b})$$

$$\tau = \frac{P}{S} \times 10^{-R_{io}/10} \qquad (11.119\text{c})$$

$$\beta = \frac{\Delta L_1}{4.34} \qquad (11.119\text{d})$$

where $L_w^i(0)$ is the sound power level in the duct at the source side, S is the cross-sectional area in square meters, P is the perimeter of the duct cross section in meters, and ΔL_1 is the sound attenuation in decibels per unit length inside the duct due to porous lining. Equation (11.119a) contains only measurable quantities and is used as a basis for the experimental evaluation of the breakout sound transmission loss R_{io}, by measuring the sound power $W_{io}(l)$ radiated by a test duct of length l into a reverberation room, the sound power in the duct at the source side, $W_i(0)$, and the sound attenuation inside the duct, ΔL_1, and solving Eq. (11.119a) for R_{io} by iteration.

The sound power level of the sound propagating in one direction, $L_w^{io}(l)$ when a duct of length l traverses through a noisy area (and sound breaks into the duct is predicted by[47]

$$L_w^{io}(l) = L_w^{\text{inc}} - R_{io} - 3 + C \quad \text{dB re}10^{-12}\ \text{W} \tag{11.120}$$

where L_w^{inc} is the sound power level of the sound incident on the duct of length l, R_{io} is the breakin sound transmission loss, and C is as defined in Eq. (11.119b). On the basis of reciprocity,[48] the following relationship exists between breakout and breakin sound transmission loss:

$$R_{oi} \cong R_{io} - 10\log\left\{4\gamma\left[1 + 0.64\frac{a}{b}\left(\frac{f_{\text{cut}}}{f}\right)^2\right]\right\} \quad \text{dB} \tag{11.121}$$

where a and b are the larger and smaller sides of a rectangular duct cross section, f is the frequency, f_{cut} is the cutoff frequency of the duct, and γ is 1 below cutoff and 0.5 above cutoff. Empirical methods for predicting the breakout sound transmission loss of unlined, unlagged rectangular sheet metal ducts are given in references 48–50. Chapter 17 contains predicted values of octave-band breakout sound transmission loss versus frequency for rectangular sheet metal ducts of sizes most frequently used in low-velocity HVAC systems. Sound transmission loss predictions for round and flat-oval ducts are given elsewhere.[49,50] Figure 11.30 shows the breakin sound transmission loss of an unlined, unlagged

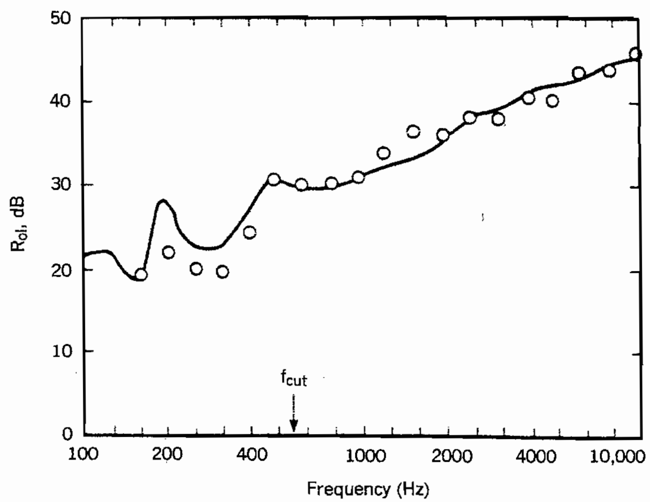

FIGURE 11.30 Breakin sound transmission loss R_{io} of a 0.3 m × 0.91 mm thick sheet metal duct (after Ref. 48): (——) measured: (○ ○ ○) predicted from measured R_{io} using Eq. (11.121).

sheet metal duct. The solid curve was obtained by directly measuring the breakin sound transmission loss while the open circles represent data points obtained by applying the reciprocity relationship embodied in Eq. (11.121) for the measured breakout sound transmission loss. The importance of Eq. (11.121) is that it makes it unnecessary to measure both R_{oi} and R_{io} separately because if one has been measured, the other can be predicted.

Sound Transmission through a Composite Partition

Partitions that separate adjacent rooms frequently consist of areas that have different sound transmission losses, such as a wall that contains a door with an uncovered key hole. If all parts of the composite partition are exposed to the same average sound intensity, I_{inc}, on the source side, then the sound power transmitted is

$$W_{\text{trans}} = I_{\text{inc}} \sum_{i=1}^{n} S_i \times 10^{-R_i/10} = I_{\text{inc}} \sum_{i=1}^{n} S_i \tau_i \quad \text{W} \tag{11.122a}$$

and the transmission loss of the composite partition is

$$R_{\text{comp}} = 10\log\frac{W_{\text{inc}}}{W_{\text{trans}}} = -10\log\sum_{i=1}^{n}\frac{S_i}{S_{\text{tot}}} \times 10^{-R_i/10} \quad \text{dB} \tag{11.122b}$$

where S_i is the surface area of each component, S_{tot} is the total area of all components, and R_i is the sound transmission loss of the ith component. The sound transmission loss of a small hole radius $a \ll \lambda_0$ in a thin plate of thickness h is well approximated by[26]

$$R_{\text{hole}} \cong 20\log\frac{h + 1.6a}{\sqrt{2}a} \quad \text{dB} \tag{11.123}$$

indicating that small holes in thin partitions ($h < a$) yield a frequency-independent sound transmission loss of $R_{\text{hole}} \simeq 0$ dB. Note, however, that Eq. (11.123) is valid only for small round holes. Long narrow slits can have a "negative sound transmission loss."[51] The sound transmission loss of holes and slits can be increased substantially by sealing them with either porous sound-absorbing material or an elastomeric material or designing them as silencer joints. Prediction of the sound transmission loss of such acoustically sealed openings are given in references 52 and 53.

Flanking Sound Transmission

The sound transmission loss of partitions is measured in acoustical laboratories where sound transmission from the source room to the receiver room occurs only through the partition under test. However, if the same partition constitutes a part of a building, then sound can be transmitted through many paths, as shown schematically in Fig. 11.31. Path 1 represents the primary path, which is

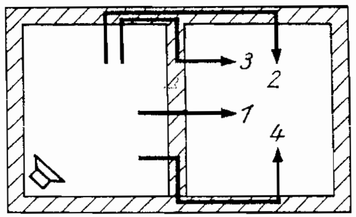

FIGURE 11.31 Sound transmission paths between two adjacent rooms in a typical building (after Reference 54): 1, primary path; 2–4, flanking paths.

characterized by sound transmission loss of the separating partition R_1, usually available from laboratory measurements. The sound transmission loss for each of the $n = 4$ paths (1 the direct and 2, 3, and 4 the flanking paths) is defined as[54]

$$R_n \equiv 10 \log \frac{W_1^{\text{inc}}}{W_{\text{trans}}^n} \quad \text{dB} \tag{11.124}$$

and the composite sound transmission loss, which combines sound transmission along each of the four paths, as

$$R_{\text{comp}} \equiv -10 \log \left(10^{-R_1/10} + \sum_{n=2}^{4} \sum_{m=1}^{4} 10^{-R_{mn}/10} \right) \quad \text{dB} \tag{11.125}$$

where $m = 4$ represents the four sound-excited flanking partitions (i.e., the two sidewalls, floor, and ceiling of the receiver room) each of which transmit sound along each of the three flanking paths $n = 2$, 3, 4. Usually flanking path $n = 2$ contributes as much to the receiver room sound power as do the two other flanking paths $n = 3$ and $n = 4$ together. The contribution of the back wall of the source and receiver room is usually negligible. The process of flanking transmission along flanking paths $n = 2$, 3, 4 is as follows: (1) the sound field in the source room excites the flanking walls to vibration, (2) the vibration is transmitted through the wall junctions to the receiver room walls, and (3) the receiver room walls radiate sound power into the receiver room that adds to that transmitted by the separating partition through the direct path. If the source and receiver rooms have no common wall, the entire sound transmission takes place through flanking paths. For adjacent rooms with a common wall, the composite sound transmission loss given in Eq. (11.125) should be used to predict the sound pressure level in the receiver room. The component flanking transmission losses R_{mn} for homogeneous isotropic single-wall construction can be approximated by[54]

$$R_{mn} = 10 \log \left[\frac{1}{4\pi\sqrt{12}} \left(\frac{\rho_M}{\rho_0} \right)^2 \frac{c_L h^3}{c_0^4} \frac{\omega^2}{} \eta_m \right] + \Delta L_{\text{junct}}$$

$$+ 10 \log \frac{S_1}{S_{\text{rad}}} - 10 \log(\sigma_m \sigma_{\text{rad}}) \quad \text{dB} \tag{11.126}$$

where ρ_M is density and c_L the longitudinal wave speed of the wall material, h is the thickness, η_m is the composite loss factor of the mth partition in the source room, and ΔL_{junct} is the attenuation of the structure-borne sound amplitude at the wall junction along the transmission path n. The symbol S_1 is the surface area of the separating partition and S_{rad} is the surface area of the partition in the receiver room involved in the transmission along path n. The symbols σ_m and σ_{rad} are the radiation efficiencies of the mth partition in the source room and the radiation efficiency of the partition in the receiver room that radiates sound owing to the sound-induced vibration of the mth partition in the source room transmitted through the nth path. A more accurate prediction of the effect of flanking paths on sound transmission loss can be made utilizing the statistical energy analysis method discussed in the next section.

11.8 STATISTICAL ENERGY ANALYSES

Statistical energy analysis (SEA) is a point of view in dealing with the vibration of complex resonant systems. It permits calculation of the energy flow between connected resonant systems, such as plates, beams, and so on, and between plates and the reverberant sound field in an enclosure.[55–59]

System of Modal Groups

In respect to the energy E stored in a structure or in an acoustical volume, may be thought of as a *system of* resonant modes or resonators. First, let us consider the power flow between two groups of resonant modes of two coupled structures having their modal resonance frequencies within the same narrow frequency band $\Delta\omega$ (see Fig. 11.32).

We assume that each resonant mode of the first system (box 1 in Fig. 11.32) has the same energy. Also, assume that the coupling of the individual resonant modes of the first system with each resonance mode of the second system is approximately the same.

If we further assume that the waves carrying the energy in one system are uncorrelated with the waves carrying the energy gained through coupling to the

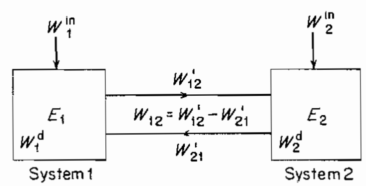

FIGURE 11.32 Block diagram illustrating power flow between two nondissipatively coupled systems.

other system, we can separate the power flow (each equation is written for a narrow frequency band $\Delta\omega$) as

$$W'_{12} = E_1\omega\eta_{12} \quad \text{W} \tag{11.127}$$

$$W'_{21} = E_2\omega\eta_{21} \quad \text{W} \tag{11.128}$$

where W'_{12} = power system 1 transmits to system 2, W
W'_{21} = power system 2 transmits to system 1, W
E_1 = total energy in system 1, m · kg/s
E_2 = total energy in system 2, m · kg/s
ω = center frequency of band, rad/s
η_{12} = coupling loss factor from system 1 to system 2, as defined in Eq. (11.127)
η_{21} = coupling loss factor from system 2 to system 1, as defined in Eq. (11.128)

The net power flow between the two systems is, accordingly,

$$W_{12} = W'_{12} - W'_{21} = E_1\omega\eta_{12} - E_2\omega\eta_{21} \quad \text{W} \tag{11.129}$$

Modal Energy E_m

Let us define modal energy as

$$E_m = \frac{E(\Delta\omega)}{n(\omega)\ \Delta\omega} \quad \text{W} \cdot \text{s/Hz} \tag{11.130}$$

where $E(\Delta\omega)$ = total energy in system in angular frequency band $\Delta\omega$
$n(\omega)$ = modal density, = number of modes in unit bandwidth ($\Delta\omega = 1$) centered on ω, the angular frequency
$\Delta\omega$ = bandwidth, rad/s

If the previously made assumptions about the equal distribution of energy in the modes and the same coupling loss factor are valid, then it may be shown that

$$\frac{\eta_{21}}{\eta_{12}} = \frac{n_1(\omega)}{n_2(\omega)} \tag{11.131}$$

where $n_1(\omega)$ = modal density of system 1 at frequency ω, s
$n_2(\omega)$ = modal density of system 2 at frequency ω, s

Equation (11.131) implies that for equal total energies in the two systems, $E_1 = E_2$, the system that has the *lower* modal density [lower $n(\omega)$] transfers more energy to the second system than is transferred from the second to the first system.

Combining Eqs. (11.129) and (11.131) yields*

$$W_{12} = \omega\eta_{12}n_1(\omega)[E_{m1} - E_{m2}]\ \Delta\omega \quad \text{W} \tag{11.132}$$

where W_{12} = net power flow between systems 1 and 2 in band $\Delta\omega$, centered at ω, W
E_{m1}, E_{m2} = modal energies for systems 1 and 2, respectively [see Eq. (11.130)], W · s/Hz

This equation is positive if the first term in the brackets is greater than the second.

The principle of the SEA method is given by Eq. (11.132), which is a simple algebraic equation with energy as the independent dynamic variable. It states that *the net power flow between two coupled systems in a narrow frequency band, centered at frequency ω, is proportional to the difference in the modal energies of the two systems at the same frequency. The flow is from the system with the higher modal energy to that with the lower modal energy.*

It may help to understand Eq. (11.132) if we use the thermodynamical analogy of heat transfer between two connected bodies of different temperature, where the heat flow is from the body of higher temperature to that of lower temperature and the net heat flow is proportional to the difference in temperature of the two bodies. Consequently, the modal energy E_m is analogous to temperature, and the net power flow W_{12} is analogous to heat flow. The case of equal modal energies of the two systems where the net power flow is zero is analogous to the equal temperature of the two bodies.

Equal Energy of Modes of Vibration

Equal energy of the modes within a group will usually exist if the wave field of the structure is diffuse. Also, since the frequency-adjacent resonance modes of a structure are coupled to each other by scattering and damping, there is always a tendency for the modal energy of resonant modes to equalize within a narrow frequency band even if the wave field is not diffuse.

Noncorrelation between Waves in the Two Systems

In sound transmission problems usually only one system is excited. The power W'_{12} transmitted to the nonexcited system builds up a semidiffuse vibration field in that system. Accordingly, the waves that carry the transmitted power W'_{21} back to the excited system are almost always sufficiently delayed and randomized in phase with respect to the waves carrying the incident power W'_{12} that there is little correlation between the two wave fields.

*Note that Eq. (11.131) is a necessary requirement if Eq. (11.132) is to obey the consistency relationship $W_{12} = -W_{21}$.

Realization of Equal Coupling Loss Factor

Equality of the coupling loss factors between individual modes within a group is a matter of grouping modes of similar nature. If the coupled system is a plate in a reverberant sound field, the *acoustically slow edge and corner modes* and *acoustically fast surface modes* are grouped separately.

Composite Structures

Composite structures generally consist of a number of elements such as plates, beams, stiffeners, and so on. We may divide a complex structure into its simpler member provided the wavelength of the structure-borne vibration is small compared with the characteristic dimensions of the elements. Where this is true, the modal density of a complex structure is approximately that of the sum of the modal densities of its elements. If the power input, the various coupling loss factors, and the power dissipated in each element are known, the power balance equations will yield the vibrational energy in the respective elements of the structure.

The dissipative loss factor for an element of a structure is obtained by separating that element from the rest of the structure and measuring its decay rate, as discussed in Chapter 14. The coupling loss factor can be determined experimentally from Eq. (11.132); however, the procedure is difficult. Theoretical solutions are available for the coupling loss factors of a few simple structural connections.[59] When the coupling loss factor between a sound field and a simple structure is desired, such a loss factor can be calculated from Eq. (11.131) if the radiation ratio of the structure is known, as shown in the next section.

Power Balance in a Two-Structure System

The power balance of the simple two-element system of Fig. 11.32 is given by the following two algebraic equations:

$$W_1^{\text{in}} = W_1^d + W_{12} \quad \text{W} \tag{11.133}$$

$$W_2^{\text{in}} = W_{12} + W_2^d \quad \text{W} \tag{11.134}$$

where W_1^{in} = input power to system 1, W
W_1^d = power dissipated in system 1, W
W_{12} = net power lost by system 1 through coupling* to system 2, = W'_{12} - W'_{21}, W
W_2^{in} = input power to system 2, W
W_2^d = power dissipated in system 2, W

*As in our previous analysis, we assume that the coupling is nondissipative.

The power dissipated in a system is related to the energy stored by that system, E_i, through the dissipative loss factor η_i, namely,

$$W_i^d = E_i \omega \eta_i \quad \text{W} \tag{11.135}$$

where E_i is energy stored in system i in newton-meters.

Assuming that the second system does not have direct power input ($W_2^{\text{in}} = 0$), the combination of Eqs. (11.130)–(11.132), (11.134), and (11.135) (with $i = 2$) yields the ratio of the energies stored in the two respective systems:

$$\frac{E_2}{E_1} = \frac{n_2}{n_1} \frac{\eta_{21}}{\eta_{21} + \eta_2} \tag{11.136}$$

If the coupling loss factor is very large compared to the loss factor in system 2, that is, if $\eta_{21} \gg \eta_2$, Eq. (11.136) yields the equality of the modal energies ($E_1/n_1\ \Delta\omega = E_2/n_2\ \Delta\omega$).

Diffuse Sound Field Driving a Freely Hung Panel

Let us now examine the special case of the excitation of a homogeneous panel (system 2) that hangs freely, exposed to the diffuse sound field of a reverberant room (system 1).

For this case, the total energies for each system are given by

$$E_1 = DV = \frac{\langle p^2 \rangle}{\rho_0 c_0^2} V \quad \text{N} \cdot \text{m} \tag{11.137}$$

$$E_2 = \langle v^2 \rangle \rho_s S \quad \text{N} \cdot \text{m} \tag{11.138}$$

where D = average energy density in reverberant room, N/m^2
$\langle p^2 \rangle$ = mean-square sound pressure (space–time average), N^2/m^4
V = room volume, m^3
$\langle v^2 \rangle$ = mean-square plate vibration velocity (space–time average), m^2/s^2
S = plate surface area (one side), m^2
ρ_s = mass per unit area of panel, kg/m^2

To find the coupling loss factor η_{21}, we must first recognize that W'_{21} equals the power that the plate, having been excited into vibration, radiates back into the room. Thus

$$W_{\text{rad}} = W'_{21} = 2\langle v^2 \rangle \rho c \sigma_{\text{rad}} S \equiv E_2\ \omega\eta_{21} = \langle v^2 \rangle \rho_s S \omega \eta_{21} \quad \text{W} \tag{11.139}$$

where σ_{rad} = radiation ratio for plate, dimensionless
W_{rad} = acoustical power radiated by both sides of plate, which accounts for factor 2, W

Solving for η_{21} yields

$$\eta_{21} = \frac{2\rho_0 c_0 \sigma_{\text{rad}}}{\rho_s \omega} \tag{11.140}$$

The modal density of the reverberant sound field in the room $n_1(\omega)$ and that of the thin homogeneous plate $n_2(\omega)$ are given in Table 11.7, namely,

$$n_1(\omega) \simeq \frac{\omega^2 V}{2\pi^2 c_0^3} \quad \text{s} \tag{11.141}$$

$$n_2(\omega) = \frac{\sqrt{12}\, S}{4\pi c_L h} \quad \text{s} \tag{11.142}$$

where c_L = propagation speed of longitudinal waves in plate material, m/s
h = plate thickness, m

Inserting Eqs. (11.137)–(11.142) into Eq. (11.135) yields the desired relation between the sound pressure and plate velocity:

$$\langle v^2 \rangle = \langle p^2 \rangle \frac{\sqrt{12}\pi c_0^2}{2\rho_0 c_0 h c_L \rho_s \omega^2} \frac{1}{1 + \rho_s \omega \eta_2 / 2\rho c \sigma_{\text{rad}}} \quad \text{m}^2/\text{s}^2 \tag{11.143}$$

The mean-square (space–time average) acceleration of the panel is simply

$$\langle a^2 \rangle = \omega^2 \langle v^2 \rangle = \langle p^2 \rangle \frac{\sqrt{12}\pi c_0^2}{2\rho_0 c_0 h c_L \rho_s} \frac{1}{1 + \rho_s \omega \eta_2 / 2\rho_0 c_0 \sigma_{\text{rad}}} \quad \text{m}^2/\text{s}^4 \tag{11.144}$$

It can be shown that as long as the power dissipated in the plate is small compared with the sound power radiated by that plate ($\rho_s \omega \eta_2 \ll 2\rho_0 c_0 \sigma_{\text{rad}}$), the equality of the modal energies of the sound field and the plate yields the proper plate velocity and acceleration. Also, under this condition, the ratio of the mean-square plate acceleration to the mean-square sound pressure is independent of frequency.

In general, *the plate response is always smaller than that calculated by the equality of the modal energies by the last factor on the right of Eq. (11.143) or (11.144), which equals the ratio of the power loss by acoustical radiation to the total power loss.* In dealing with the excitation of structures by a sound field, the concept of equal modal energy often enables one to give a simple estimate for the upper bound of the structure's response.

Example 11.4. Calculate the rms velocity and acceleration of a 0.005-m- ($\frac{1}{10}$-in.-) thick homogeneous aluminum panel resiliently suspended in a reverberant room. The space-averaged sound pressure level $\overline{L}_p = 100$ dB ($\sqrt{\langle p^2 \rangle} = 2$ N/m^2) as measured in a one-third-octave band centered at a frequency $f = \omega/2\pi = 1000$ Hz. The appropriate constants of the panel and surrounding media are $\rho_s = 13.5$ kg/m^2; $c_L = 5.2 \times 10^3$ m/s; $h = 5 \times 10^{-3}$ m; $\rho_0 = 1.2$ kg/m^3; $c_0 = 344$ m/s; and $\eta_2 = 10^{-4}$.

Solution First, calculate the factor

$$\frac{\rho_s \omega \eta_2}{2\rho_0 c_0 \sigma_{\text{rad}}} = \frac{13.5 \times 2\pi \times 10^3 \times 10^{-4}}{2 \times 1.2 \times 344 \times \sigma_{\text{rad}}} = \frac{8.5}{820\sigma_{\text{rad}}} \ll 1$$

According to the above inequality the mean-square acceleration of the panel given by Eq. (11.144) simplifies to

$$\langle a^2 \rangle \approx \langle p^2 \rangle \frac{\sqrt{12}\pi c_0^2}{2\rho_0 c_0 h c_L \rho_s} = 19 \quad \text{m}^2/\text{s}^4$$

or $a_{\text{rms}} = \sqrt{\langle a^2 \rangle} = 4.34$ m/s^2, an acceleration level of 113 dB re 10^{-5} m/s^2.

The mean-square velocity is

$$\langle v^2 \rangle = \frac{\langle a^2 \rangle}{\omega^2} = \frac{19}{4\pi^2 \times 10^6} = 4.76 \times 10^{-7} \ \text{m}^2/\text{s}^2$$

or $v_{\text{rms}} = \sqrt{\langle v^2 \rangle} = 6.9 \times 10^{-4}$ m/s, a velocity level of 97 dB re 10^{-8} m/s.

Sound Transmission Loss of a Simple Homogeneous Structure by the SEA Method

The SEA method may be used to analyze the transmission of sound between two rooms coupled to each other by a single common, thin homogeneous wall.[58] (i.e., there are no flanking paths). System 1 is the ensemble of modes of the diffuse, reverberant sound field in the source room, resonant within the frequency band $\Delta\omega$. System 2 is an appropriately chosen group of vibration modes of the wall. System 3 is the ensemble of modes of the diffuse reverberant sound field in the receiving room, resonant within the frequency band $\Delta\omega$. A loudspeaker in the source room is the only source of power, and the power dissipated in each system is assumed to be large compared with the power lost to the other two systems through the coupling (see Fig. 11.33).

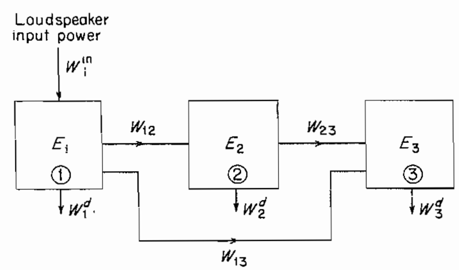

FIGURE 11.33 Block diagram illustrating the power flow in three-way coupled systems: W_{13}, transmission of sound by those modes whose resonance frequency lies outside the source band. The "nonresonant" modes are important below the critical frequency.

The procedure is as follows:

1. Relate W_1^{in} to the power lost by sound absorption in the room. This yields $\langle p_1^2 \rangle$, the space-averaged mean-square sound pressure in the source room.
2. Calculate $E_1 = \langle p_1^2 \rangle V_1/\rho c^2$, where V_1 is the volume of the source room.
3. The reverberant sound power incident on the dividing wall of area S_2 is $W_{\text{inc}} = E_1 c S_2/4V_1 = p_1^2/4\rho c$.
4. From the power balance of the wall for resonant modes within the bandwidth, $\Delta\omega$ is next determined, that is, $W_{12} = W_2^d + W_{23}$, so that

$$W_{12} = \text{Eq.}(11.135) + 0.5\ [\text{Eq.}(11.139)]$$

This sum equals Eq. (11.132). Because η_{12} of Eq. (11.32) is not well known, it is replaced by using Eq. (11.131) and the definition of loss factor η_{21}, which yields $\eta_{21} = \rho_0 c_0 \sigma_{\text{rad}}/\rho_s \omega$.

5. The vibrational energy of the wall is $E_2 = \langle v^2 \rangle \rho_s S_2$.
6. Combining steps 3, 4, and 5 yields the mean-square wall velocity $\langle v^2 \rangle$ as a function of mean-square source room pressure $\langle p_1^2 \rangle$.
7. The power radiated into the receiving room is

$$W_{23} = \rho_0 c_0 S_2 \sigma_{\text{rad}} \langle v^2 \rangle$$

8. Finally, the resonance transmission coefficient τ_r is found by dividing step 7 by step 3.
9. The *resonance transmission loss*, defined as $R_r = 10\log(1/\tau_r)$, is computed from step 8 using Eq. (11.97) and assuming that $\rho_s \omega \eta_2 \gg 2\rho_0 c_0 \sigma_{\text{rad}}$ to yield

$$R_r = 20\log\left(\frac{\rho_s \omega}{2\rho_0 c_0}\right) + 10\log\left(\frac{f}{f_c}\frac{2}{\pi}\frac{\eta_2}{\sigma_{\text{rad}}^2}\right) \quad \text{dB} \tag{11.145}$$

The first term in Eq. (11.145) is approximately the normal-incidence mass law transmission loss R_0, so that Eq. (11.145) becomes

$$R_r = R_0 + 10\log\left(\frac{f}{f_c}\frac{2}{\pi}\frac{\eta_2}{\sigma_{\text{rad}}^2}\right) \quad \text{dB} \tag{11.146}$$

where f_c = critical frequency [see Eq. (11.94)], Hz
η_2 = total loss factor of wall, dimensionless
σ_{rad} = radiation efficiency for wall, dimensionless

Thus we have obtained the transmission loss between two rooms separated by a common wall using the SEA method.

Below the critical frequency and when the dimensions of the wall are large compared with the acoustical wavelength, the radiation factor σ_{rad} can be taken from Table 11.8.

It is important to note that if the sound transmission loss of an equivalent *infinite* wall is compared with the data measured and predicted by the SEA method, it is found that *above the critical frequency*, the transmission loss R for the infinite wall yields the same results as Eq. (11.146), which takes into account only the resonance transmission of a finite wall.

Below the critical frequency the sound transmission loss of a finite panel is more controlled by the contribution of those modes that have their resonance frequencies outside of the frequency band of the excitation signal than by those with resonance frequencies within that band. Since only the contributions of the latter are included in the previous SEA calculation, Eq. (11.146) usually overestimates the sound transmission loss of a finite panel below the critical frequency. Figure 11.34 shows that below the critical frequency for a $\frac{1}{8}$-in.-thick aluminum panel the sound transmission loss of the resonant modes alone (curve a) is approximately 10 dB higher than that measured on the actual panel (curve d).

A *composite transmission factor* that approximately takes into account both the forced and resonance waves is closely approximated by

$$\begin{aligned}\frac{1}{\tau} &= \frac{W_{\text{inc}}}{W_{\text{forced}} + W_{\text{res}}} \\ &= \frac{(\langle p^2 \rangle/4\rho c)S_2}{\langle p^2 \rangle(\pi\rho c S_2/\rho_s^2\,\omega^2) + \langle p^2 \rangle(\sqrt{12}\pi c^3 \rho \sigma_{\text{rad}}^2 S_2/2\,\omega^3 \rho_s^2 c_L h \eta_2)}\end{aligned} \tag{11.147}$$

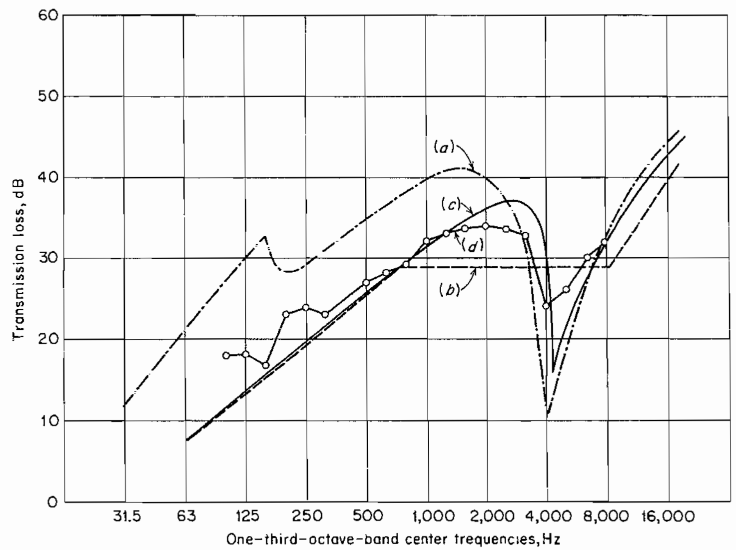

FIGURE 11.34 Comparison of experimental and theoretical transmission loss of a 5 ft × 6.5 ft × $\frac{1}{8}$ in. aluminum panel. The theoretical calculations are based on (a) resonance mode calculation, (b) plateau calculation, and (c) forced-wave calculation. Curve d shows the experimental results. (After Reference 58.)

At low frequencies where the first term in the denominator dominates, the transmission factor becomes

$$\frac{1}{\tau} \approx \frac{1}{\pi}\left(\frac{\rho_s \omega}{2\rho c}\right)^2 \qquad (11.148)$$

and the sound transmission loss is [see Eq. (11.101)]

$$R = 10 \log \frac{1}{\tau} \approx R_0 - 5 = R_{\text{field}} \quad \text{dB} \qquad (11.149)$$

At high frequencies where the second term in the denominator becomes dominant, the sound transmission loss is given by Eq. (11.146).

11.9 EQUIVALENCY BETWEEN THE EXCITATION OF A STRUCTURE SOUND FIELD AND POINT FORCE

In the mechanical equipment room of buildings, ships, and engine compartment of vehicles the boundaries (such as the walls, floor, and ceiling) are excited simultaneously by airborne noise and by dynamic forces. The airborne noise might emanate from the casing of machines and the dynamic forces might be those acting at the rigid or resilient attachment points of the machine to the floor or at the attachment points of pipes, conduits, or ducts (which are rigidly connected to the vibrating machine) to the wall or to the ceiling.

The noise control engineer is faced with the dilemma of predicting whether the airborne noise or the dynamic forces at the attachment points control the vibration response of the structure. The type of excitation that controls the vibration response of the structure will also control the airborne noise and vibration at distant noise- and vibration-sensitive receiver locations.

In his noise control engineering practice the author has been called upon to predict whether the ramble (low-frequency random noise) generated by the passage of subway trains in a nearby tunnel will be above or below the threshold of human hearing in a planned concert hall. In another project, he had to predict whether eye surgeons would be able to perform retina operations in a hospital located near another subway tunnel.

The dynamic forces acting in the tunnel floor owing to the wheel–rail interaction can be reduced substantially by mounting the track on a "floating slab" consisting of a thick concrete slab that is supported by resilient rubber mounts laid on the tunnel floor. However, the floating slab has no beneficial effect on reducing the airborne noise exposure of the walls and the roof of the tunnel. Actually, the floating slab results in an increase of the airborne noise, especially in the frequency range near its coincidence frequency where the propagation speed of bending waves in the floating slab coincides with the propagation speed of sound in air and the slab becomes a very efficient sound radiator. Consequently, the airborne sound excitation of the tunnel structure might be controlling the low-frequency vibration response of the tunnel walls and the noise and vibration at a distant observer location.

To enable him to make a quantitative judgment on the relative importance of the airborne noise versus the force excitation of a platelike structure, the author has derived the relationship[60]

$$F_{\text{eq}} = p\left(\frac{c_0}{f}\right)\sqrt{\frac{\sigma_{\text{rad}} S_f}{\pi}} = p\lambda\sqrt{\frac{\sigma_{\text{rad}} S_f}{\pi}}[2(10^{-5})]10^{L_p/20} \quad \text{N} \qquad (11.150)$$

where F_{eq} is the point force in newtons that generates the same free bending wave response on a partition of surface area S_f as a random-incidence sound field with a space–time average sound pressure p. The symbol σ_{rad} is the radiation efficiency of the partition. It is unity at frequencies above the coincidence frequency. The principle of reciprocity requires that σ_{rad} is also a measure of the degree of coupling of the sound waves to the vibration response of the structure. The symbol $\lambda = c_0/f$ is the acoustical wavelength in meters, c_0 is the speed of sound in air in meters per second, and f is the frequency in hertz (reciprocal seconds). The symbol L_p is the sound pressure level in decidels re 2×10^{-5} N/m^2.

Equation (11.150) can be written in a form that is easy to remember:

$$F_{\text{eq}}^2 = \left(\frac{4}{\pi}\right)\left(\frac{(pS)^2}{S/(\lambda/2)^2}\right) \simeq \left(\frac{(pS)^2}{S/(\lambda/2)^2}\right) \quad \text{N}^2 \qquad (11.151)$$

The numerator of Eq. (11.151) is a force squared (the product sound pressure and the area) and the denominator is the number of areas, each a half wavelength squared, that would fill the entire surface area S. The area $(\lambda/2)^2$ is where the sound pressure on the surface of the partition is in phase.

Equations (11.150) and (11.151) are extremely simple and universally useful because:

1. The force/sound pressure equivalency does not implicitly depend on the material properties of the partition such as the density, Young's modulus, loss factor, and geometry.
2. They do not depend on the density of the fluid:
3. They are also valid for partitions with fluid loading such as concrete slabs embedded in soil or steel plates with a liquid on the other side.

The reason for these unique properties of Eqs. (11.150) and (11.151) is that the vibration response to both sound and point force depends the same way on these properties. For example, a lightly damped structure will respond equally vigorously to sound and point force excitation, a plate made out of a material with high density will respond equally less vigorously to both sound and force excitation than one that is made of a less dense material, and so on. Equations (11.150) and (11.151) have been derived by assuming that the partition is large compared with the bending wavelength and the room where the sound field is generated is large compared with the acoustical wavelength. Both the structure and the sound field respond in a multimodal fashion and their response is dominated by the resonant modes.

In noise control design the airborne noise strength of machines and equipment is given in the form of their sound power $W(f)$ or sound power level spectrum $L_w(f)$. The diffuse-field sound pressure in a room, resulting from the injected sound power, is given by

$$\frac{p^2}{4\rho_0 c_0} S_{\text{tot}}\overline{\alpha} = W_f \quad \text{N/m}^2 \tag{11.152}$$

Combining Eqs. (11.150) and (11.152) yields

$$F_{\text{eq}}(f) = W(f)\frac{\rho_0 c_0^3 \sigma_{\text{rad}}(f)}{f^2}\left(\frac{1}{\alpha}\right)\left(\frac{S_i}{S_{\text{tot}}}\right)\left(\frac{4}{\pi}\right) \quad \text{N}^2 \tag{11.153}$$

where $W(f)$ = sound power of machine, W

$F_{eq}(f)$ = equivalent point force acting on solid boundary that produces same resonant (i.e., free bending wave) vibration response of boundary as the sound field produced in room owing to sound power output of the machine, N/m^2,

S_i = surface area (one side) of boundary directly excited by force, m^2,

S_{tot} = total surface area of all boundaries of room, m^2,

α = sound absorption coefficient of internal boundary surfaces

The validity of Eqs. (11.150), (11.151), and (11.153) have been briefly checked[61] experimentally by exciting the boundaries of an underground fan room. First one wall was excited with a shaker and the point force $F(f)$ was measured with a force gauge built into the impedance head that connected the shaker to the fan room wall. Then, a sound field was generated in the fan room by a loudspeaker and the sound pressure level SPL(f) was measured with a calibrated microphone. For both types of excitation the force and the sound pressure level was generated at an identical series of pure-tone frequencies to maximize the signal–noise ratio. The response was measured by a geophone in the form of the ground vibration at a distant location.

Example 11.5. Predict whether a planned concert hall can be located on a site near an existing subway line without imposing speed limits on the subway train and without supporting the entire concert hall on resilient vibration isolation pads. The design goal is to keep the ramble noise in the concert hall below the threshold of human hearing, which is 35 dB in the 63-Hz center-frequency octave band.

The subway tunnel has a 10 ft × 10 ft cross section and the subway train is 100 ft long. The tunnel walls, roof, and floor are poured concrete of 0.4 m thickness. Analytical predictions carried out have indicated that mounting the

rails on a floating slab would reduce the total force acting on the tunnel floor to 200 N in the 63-Hz center-frequency octave band and that this dynamic force was expected to produce a sound pressure level of 30 dB in the concert hall. This is 5 dB lower than the human threshold of hearing. Sound-level measurements carried out in the tunnel during the passage of a subway train yielded a sound pressure level of 110 dB in the 63-Hz center-frequency octave band. Predict whether this airborne excitation will produce noise levels in the concert hall above the 35-dB threshold of hearing.

Solution The critical frequency f_c is predicted from Table 11.2. The density of concrete $\rho = 2300$ kg/m^3, the mass per unit area $\rho_s = \rho h = 2300 \times 0.4 = 920$ kg/m^2, $f_c\rho_s = 43,000$, and $f_c = 43,000/920 = 47$ Hz; consequently, $\sigma_{\text{rad}(f=63\text{ Hz})} \simeq 1$. The surface area ot the tunnel exposed to the high-level airborne noise excitation $S_{\text{tot}} = 10 \times 10 \times 100 = 10,000\ \text{ft}^2 = 929\ \text{m}^2$. With these values Eq. (11.150) yields

$$F_{\text{eq}} = \left(\frac{c_0}{f}\right)\sqrt{\frac{S_{\text{tot}}}{\pi}}2(10^{-5})10^{\text{SPL}/20} = \left(\frac{340}{63}\right)\sqrt{\frac{929}{\pi}}2(10^{-5})10^{110/20} = 586\ \text{N}$$

Consequently, the noise level in the concert hall that is attributable to the airborne sound excitation of the tunnel walls is predicted to be

$$\text{SPL}_{\text{Hall}}(f = 63\ \text{Hz}) = 30 + 20\log\left(\frac{586}{200}\right) \simeq 39\ \text{dB}$$

This is 4 dB above the design goal, indicating that the design goal cannot be achieved without restricting the train speed or putting the concert hall on vibration isolators that would need to provide a high degree of isolation at 63 Hz.

11.10 RECIPROCITY AND SUPERPOSITION

The principles of reciprocity and superposition apply to linear systems with time-invariant parameters. Not only solid structures but fluid volumes at rest fall into this category. Consequently, reciprocity and superposition apply to systems that consist of solid structures surrounded by acoustical spaces and can be used to great advantage not only in structure-borne noise and airborne noise but also in structural acoustics, which deals with the interaction of sound waves with solid structures.

The principle of superposition, illustrated in Fig. 11.35, allows the use of the simplest excitation sources such as a point force source or a point-monopole sound source to explore the response to more complex excitation sources such as a moment acting on a structural element or an acoustical dipole radiating into an acoustical volume. The principle of reciprocity, which can be traced back to Lord Rayleigh,[62] is illustrated in the upper three sketches in Fig. 11.36. It states that

$$F_2 v_2 = F_1 v_1 \quad \text{W} \tag{11.154a}$$

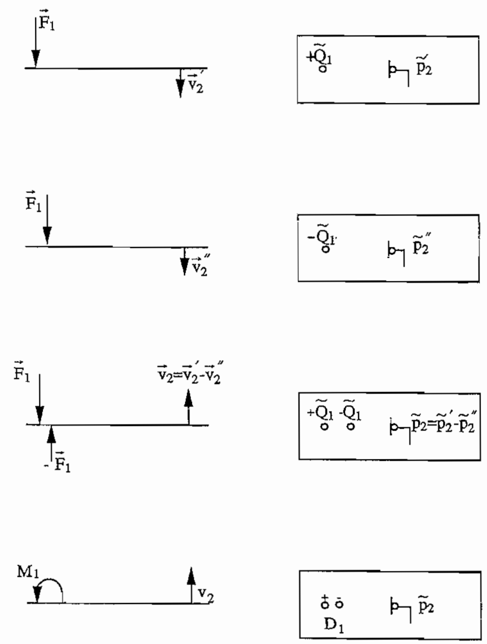

FIGURE 11.35 Use of superposition to predict the response of structures and acoustical spaces (v_2 and p_2) to complex excitation sources such as moments (M_1) and dipoles (D_1) on the basis of point force (F_1) and acoustical monopole (Q_1). Note that the structure and the acoustical space may be of arbitrary shape and the acoustical space may be unbound or bound by elastic or sound-absorbing boundaries and may contain an arbitrary number and size of rigid or elastic scatterers.

The symbol F_1 is (generalized) force when point 1 is source and point 2 is receiver and v_1 is (generalized) velocity when point 1 is receiver and point 2 is source. The vector product $F_1 v_1$ must yield the instantaneous power, or in complex notation $\text{Re}\{\frac{1}{2}F_1 v_1^*\} = \text{Re}\{\frac{1}{2}F_2 v_2^*\}$ must yield the time-averaged power. Note that F and v are vector quantities as signified in the figure by the arrow above the symbols. If v_1 and F_1 and v_2 and F_2 are measured or applied in the same direction, as illustrated by the sketch in the lower left side of Fig. 11.36, the vector notation can be exchanged for the less complicated scalar notation, where force and velocity are characterized by a magnitude and phase (i.e., $\tilde{F} = Fe^{j\phi f}$, $\tilde{v} = ve^{j\phi r}$). In this case, the reciprocity takes the form of the equality of transfer functions

$$\frac{\tilde{v}_2}{\tilde{F}_1} = \frac{\tilde{v}_1}{\tilde{F}_2} \quad \text{m/N} \cdot \text{s} \tag{11.154b}$$

This should be kept in mind in our latter deliberations, where the special vector notation is not carried through. Since monopole strength $\tilde{Q}$ and sound pressure

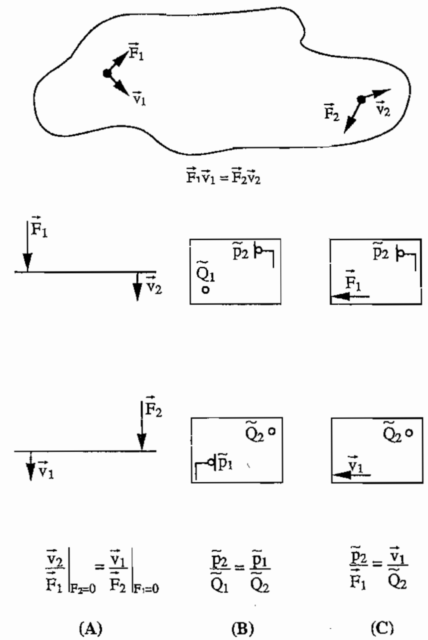

FIGURE 11.36 Principle of reciprocity as applied to a complex structure. Top sketch illustrates general principle. Lower sketches apply in special situations: (a) structure; (b) an acoustical space; (c) a structure coupled to an acoustical space. Symbols: F, point force vector; v, velocity response vector (measured by the same direction as F); $\tilde{Q}$, volume velocity of acoustical point source; $\tilde{p}$, sound pressure.

$\tilde{p}$ are scalar quantities (defined by their magnitude and phase), no directional restraints exist in the acoustical case illustrated in Fig. 11.36b.[63,64] However, dipole and quadrupole sound sources (constructed from adjacent out-of-phase monopoles) have highly directional radiation characteristics and must be connected to directional quantities of the sound field such as pressure gradients dp/dx and d^2p/d^2x measured in the same direction relative to the orientation of the dipole or quadrupole sound source for the reciprocity to apply.

Table 11.9 contains useful reciprocity relationships applicable to higher order excitation sources and responses. These relationships automatically follow from the joint application of superposition and reciprocity to the appropriate combination of simple sources such as point forces and acoustical monopoles.

The principle of reciprocity can be used to considerable advantage in both experimental and analytical work. In experimental work it is difficult and cumber some to excite complex structures by point forces and moments and to measure the sound pressure such excitation causes in the interior of a vehicle. It is almost always easier to obtain the sought transfer function between the acoustical pressure and the exciting force or moment by placing a small acoustical source of known volume velocity at the microphone location and measuring the vibration response at the position and in the direction of the applied force and applying the reciprocity relationship illustrated in Fig. 11.36*c*.

The form of reciprocity illustrated in Fig. 11.36*c* is the most useful in structural acoustics. Its practical application is described in reference 64. In the direct experiment the force $\tilde{F}_1$ is applied to the structure by a shaker (and its magnitude and phase are measured by a force gauge inserted between the shaker and the structure), and the magnitude and phase of the sound pressure p_2 are measured by a microphone. The phase of F_1 and p_2 are referenced to the voltage U applied to the shaker. In the reciprocal experiment—which is much easier to perform than the direct experiment—a small omnidirectional sound source (an enclosed loudspeaker whose diameter is smaller than one-quarter acoustical wavelength) with calibrated volume velocity response Q is placed at the former microphone location and the velocity response of the structure at the former excitation point v_2 is measured (in the same direction as the force was applied) by a small accelerometer. The phases of Q and v_2 are referenced to the voltage U applied to the loudspeaker sound source. The volume velocity calibration of the sound source (Q/U) is obtained by placing it in an anechoically terminated rigid tube, baffling it so it radiates only toward the anechoic termination, sweeping the loudspeaker voltage through the frequency range of interest, and measuring the transfer function (p/U), where U is the voltage applied to the loudspeaker and p is the sound pressure measured by a microphone located two tube diameters or further away from the source. The sought volume velocity calibration of the source is then computed as[65] $|Q/U| = |P/U|(S/\rho_0 c_0)$, where S is the cross-sectional area of the tube, ρ_0 is the density of air, and c_0 is the speed of sound in air. When phase information is important, the sound source can be calibrated in an anechoic chamber by measuring the sound pressure $p(r)$ at a large distance $r \gg \lambda_0$ away from the source and computing the volume velocity calibration $Q/U = [p(r)/U](4\pi r^2/\rho_0 c_0)e^{-j2\pi f r/c_0}$.

Figure 11.37 illustrates the application of reciprocity on a complex structural acoustical problem, namely, the prediction of the interior noise of an automobile to point force excitation of the shock tower. First, the shock tower was excited by a point force, and sound pressure generated at the driver's head position was measured to obtain the direct transfer function $\tilde{p}/F$ identified by the solid line. Next, the reciprocal experiment was carried out by placing a point sound source of known volume velocity $\tilde{Q}$ at the former location of the microphone and measuring the vibration velocity response of the shock tower. The transfer function $v/\tilde{Q}$ obtained this way is shown as the dotted curve in Fig. 11.37*a*. Referencing the phases of $\tilde{p}$ and F to the voltage applied to the shaker and that of v and $\tilde{Q}$ to the voltage applied to the loudspeaker source, not only the magnitude but also the phase of the reciprocal transfer functions $\tilde{p}/F$ and $v/\tilde{Q}$ can be retained so that the interior noise caused by many simultaneously acting forces and moments can be predicted. Figure 11.37*b* shows the unrolled phase of the transfer function pair.

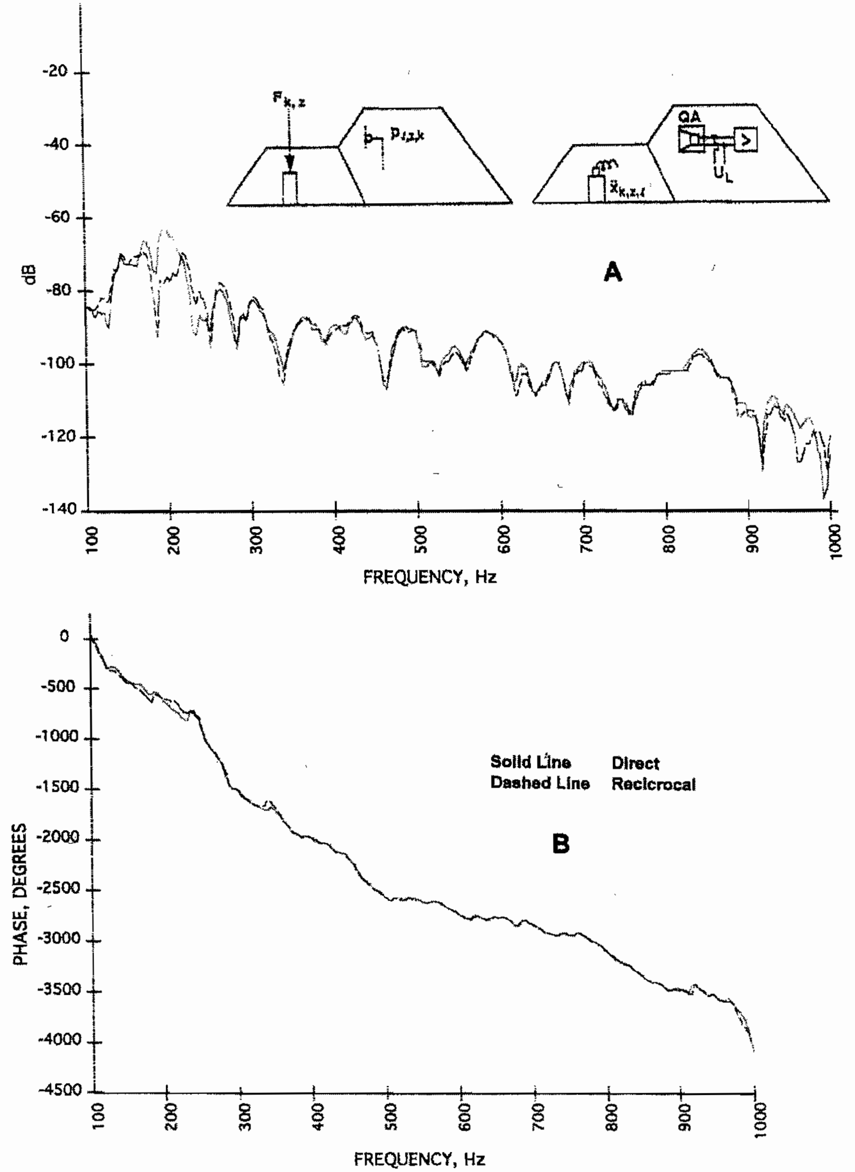

FIGURE 11.37 Pair of reciprocal transfer functions measured in a passenger vehicle: (*a*) direct, $\tilde{p}/\tilde{F}$; (*b*) reciprocal, $\tilde{v}/\tilde{Q}$.

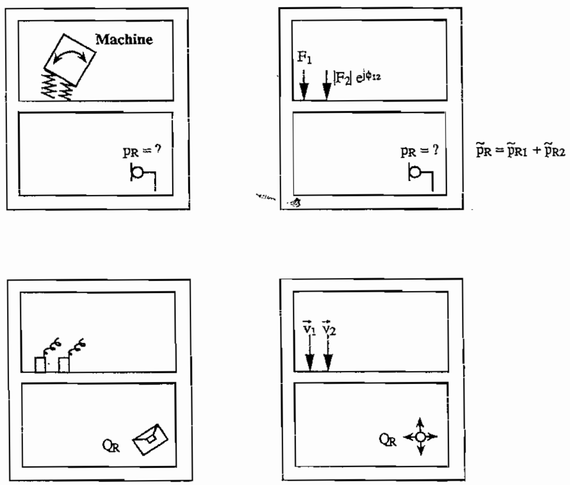
Prediction of Noise Caused by Multiple Correlated Forces

The use of reciprocity and superposition in the case of multiple correlated force input is illustrated in Fig. 11.38. The problem is to predict the sound pressure p_R in the receiver room below after installation of a vibrating machine in the source room above. The building is constructed, and the machine manufacturer provides the magnitude, the direction, and the mutual phase ϕ_{12} of forces F_1 and F_2 the machine—when installed on soft springs—will impart to the floor. The prediction of p_R proceeds as illustrated in the lower part of Fig. 11.38 by measuring the reciprocal transfer functions $-v_1/\tilde{Q}_R = \tilde{p}_R/F_1$ and $-v_2/\tilde{Q}_R = \tilde{p}_{R2}/F_2$ and utilizing the principle of superposition. The forces and velocities must be measured in the same direction. Performing the reciprocity prediction for a number of different loudspeaker positions in the receiver room, the spatial



$$-\frac{p_{R1}}{\vec{F}_1} = \frac{\vec{v}_1}{Q_R}, \quad -\frac{p_{R2}}{\vec{F}_2} = \frac{\vec{v}_2}{Q_R}$$

$$-p_R = \left\{ |F_1| \frac{|v_1|}{|Q_R|} e^{j\phi_{1Q}} + |F_2| e^{j\phi_{12}} \frac{|v_2|}{|Q_R|} e^{j\phi_{2Q}} \right\}$$

FIGURE 11.38 Use of reciprocity and superposition to predict the sound pressure in a room caused by two correlated forces $\tilde{F}_1$ and $\tilde{F}_2$ acting on the building structure. Top sketch represents actual situation and lower sketch the reciprocity prediction: ϕ_{1Q} and ϕ_{2Q} represent the phases of the transfer functions $\tilde{v}_1/\tilde{Q}_R$ and $\tilde{v}_2/\tilde{Q}_R$, respectively; each is conveniently referenced to the excitation voltage of the loudspeaker sound source.

variation of p_R can also be predicted. The methodology can be easily extended to more than two simultaneously acting, correlated forces.[66]

The reciprocity is most useful in the early stages of design of aircraft and ground vehicles, well before a flightworthy version of the aircraft or a roadworthy version of the ground vehicle is available. Reciprocity helps the noise control engineer to find answers to some difficult questions:

1. What will be the contribution of the structure-borne noise at the engine firing rate to the noise in the passenger compartment?
2. Which engine mount transmits most of the structure-borne noise?
3. Which direction of vibration force is most critical?
4. Which mutual phasing of forces acting on the individual engine-mounting points is most critical?
5. Most importantly, what is the effect of changing the design of engine-mounting brackets on cabin noise?

All these questions can be answered without applying known forces in three orthogonal directions to each of the engine-mounting brackets.

Source Strength Identification by Reciprocity

When it is not feasible to measure directly the strength of noise and vibration sources during the operation of vehicles, equipment, and machinery, reciprocity can be used to obtain them indirectly. This is accomplished by measuring the noise or vibration during the operation of the equipment at a distant, accessible receiver location and—when the equipment is not operating—exciting it at these distant receiver locations and measuring the acoustical or structural response at the source location, which is now accessible. The principle is illustrated in Fig. 11.39. Common in the three problems shown in Fig. 11.39 is the knowledge of the location and nature of the excitation sources. Unknown are their magnitude and mutual phase, which must be determined by observation of response to these sources at distant locations and by reciprocity experiments as described below.

The upper left-hand side of Fig. 11.39 represents the case where the sound field in an enclosure is excited by two monopole sound sources of unknown strength and mutual phase $\tilde{Q}_1(?)$ and $\tilde{Q}_2(?)$ (e.g., the openings of the inlet pipe leading to two cylinders of a reciprocating compressor). The first experiment, illustrated in the upper sketch, is the measurement of the magnitude and mutual phase of the sound pressure $\tilde{p}_3$ and $\tilde{p}_4$ at accessible distant locations 3 and 4 obtained when both sources were operating simultaneously. The reciprocal experiments, illustrated in the two lower sketches, are performed when the sources are not operational by placing a monopole sound source of known volume velocity Q at the former microphone locations 3 and 4 and measuring the magnitude and phase of the sound pressure produced at the two former source locations $\tilde{p}_{13}$, $\tilde{p}_{23}$,

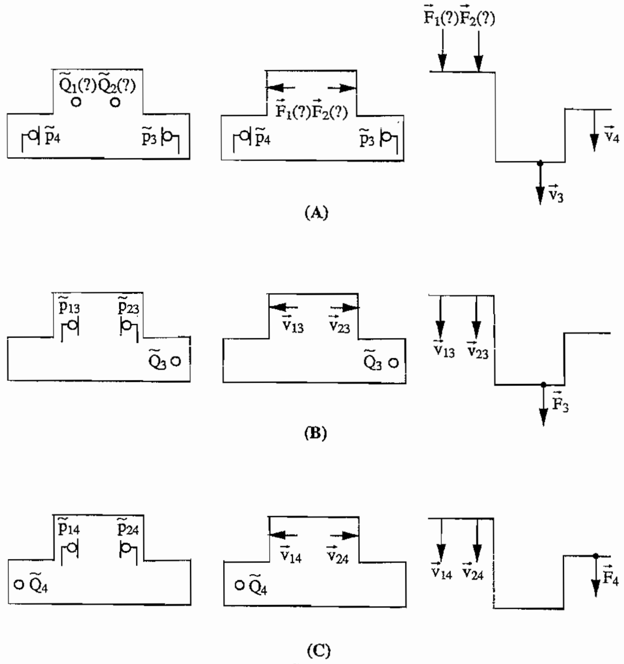


FIGURE 11.39 Source strength identification utilizing reciprocity and superposition: (*a*) response measurements at distant locations with sources active and (*b, c*) reciprocity measurements, sources inactive. (See text for explanation of symbols.)

$\tilde{p}_{14}$, and $\tilde{p}_{24}$. The phase of the sound pressure is referenced to the loudspeaker voltage.

The sketches in the middle column in Fig. 11.39 illustrate a case where the sound field in an enclosure is produced by two forces $\tilde{F}_1$ and $\tilde{F}_2$ of known location and direction but unknown magnitude and mutual phase, both acting simultaneously at the enclosure wall (e.g., forces caused by a vibration isolation-mounted reciprocating or rotating machine). In this case, the reciprocal experiment yields the vibration velocity responses at the former force application points $\tilde{v}_{13}$, $\tilde{v}_{23}$, $\tilde{v}_{14}$, and $\tilde{v}_{24}$, measured in the same direction as the force.

The situation shown in the sketch on the upper right-hand side in Fig. 11.39 illustrates the situation when the determination of the unknown magnitude and mutual phase of the two forces $\tilde{F}_1(?)$ and $\tilde{F}_2(?)$ must be diagnosed (e.g., forces transmitted to a structural floor by a vibration-isolated machine). In this case, the reciprocal experiment is carried out by exciting the building structure at the two distant observation points 3 and 4 by known forces $\tilde{F}_3$ and $\tilde{F}_4$ and measuring the velocity responses $\tilde{v}_{13}$, $\tilde{v}_{23}$, $\tilde{v}_{14}$, and $\tilde{v}_{24}$ at the former force excitation points 1 and 2. Utilizing the principle of reciprocity and superposition yields the following pairs of linear equations:

$$\tilde{p}_3 = \tilde{Q}_1(?)\left[\frac{\tilde{p}_{13}}{\tilde{Q}_3}\right] + \tilde{Q}_2(?)\left[\frac{\tilde{p}_{23}}{\tilde{Q}_3}\right] \quad \text{N/m}^2 \tag{11.155a}$$

$$\tilde{p}_4 = \tilde{Q}_1(?)\left[\frac{\tilde{p}_{14}}{\tilde{Q}_4}\right] + \tilde{Q}_2(?)\left[\frac{\tilde{p}_{24}}{\tilde{Q}_4}\right] \quad \text{N/m}^2 \tag{11.155b}$$

which can be solved for the two unknowns $\tilde{Q}_1(?)$ and $\tilde{Q}_2(?)$. Similarly, the set of equations for obtaining $\tilde{F}_1(?)$ and $\tilde{F}_2(?)$ in the situation illustrated in the center sketches in Fig. 11.39 are

$$\tilde{p}_3 = \tilde{F}_1(?)\left[\frac{\tilde{v}_{13}}{\tilde{Q}_3}\right] + \tilde{F}_2(?)\left[\frac{\tilde{v}_{23}}{\tilde{Q}_3}\right] \quad \text{N/m}^2 \tag{11.155c}$$

$$\tilde{p}_4 = \tilde{F}_1(?)\left[\frac{\tilde{v}_{14}}{\tilde{Q}_4}\right] + \tilde{F}_2(?)\left[\frac{\tilde{v}_{24}}{\tilde{Q}_4}\right] \quad \text{N/m}^2 \tag{11.155d}$$

and for that illustrated in the sketches on the right

$$\tilde{p}_3 = \tilde{F}_1(?)\left[\frac{\tilde{v}_{13}}{\tilde{F}_3}\right] + \tilde{F}_2(?)\left[\frac{\tilde{v}_{23}}{\tilde{F}_3}\right] \quad \text{N/m}^2 \tag{11.155e}$$

$$\tilde{p}_4 = \tilde{F}_1(?)\left[\frac{\tilde{v}_{14}}{\tilde{F}_4}\right] + \tilde{F}_2(?)\left[\frac{\tilde{v}_{24}}{\tilde{F}_4}\right] \quad \text{N/m}^2 \tag{11.155f}$$

In the case of n unknown excitation sources, the prediction equations represent an $n \times n$ matrix.

Extension of Reciprocity to Sound Excitation of Structures

As illustrated in Fig. 11.40, the reciprocity relationship can be extended for surface excitation of structures (e.g., by an incident sound wave). Consider first a small part of the surface of a cylindrical body (such as an aircraft fuselage) with surface area dA exposed to a local sound pressure of $\tilde{p}_1$ as illustrated in the upper left sketch in Fig. 11.40 resulting in a local force of $\tilde{F}_1 = \tilde{p}_1\, dA$. For this force the reciprocity relationship shown in Fig. 11.36*c* yields $\Delta\tilde{p}_{R1}/\tilde{F}_1 = \Delta\tilde{v}_{1R}/Q_R$, which for $\tilde{F}_1 = \tilde{p}_1\, dA$ and $\Delta\tilde{Q}_{1R} = \Delta\tilde{v}_{1R}\, dA$ becomes

$$\frac{\Delta\tilde{p}_R}{\tilde{p}_1} = \frac{\Delta\tilde{Q}_{1R}}{\tilde{Q}_R} \tag{11.156a}$$

When the structure is exposed to a complex sound field distribution $\tilde{p}_1, \tilde{p}_2, \ldots, \tilde{p}_n$, as illustrated in the lower sketch, the resulting interior sound pressure at the receiver location, $\tilde{p}_R$, is given by

$$\tilde{p}_R = \sum_{i=1}^{n} \tilde{p}_i \left(\frac{\Delta\tilde{Q}_{iR}}{\tilde{Q}_R}\right) \quad \text{N/m}^2 \tag{11.156b}$$

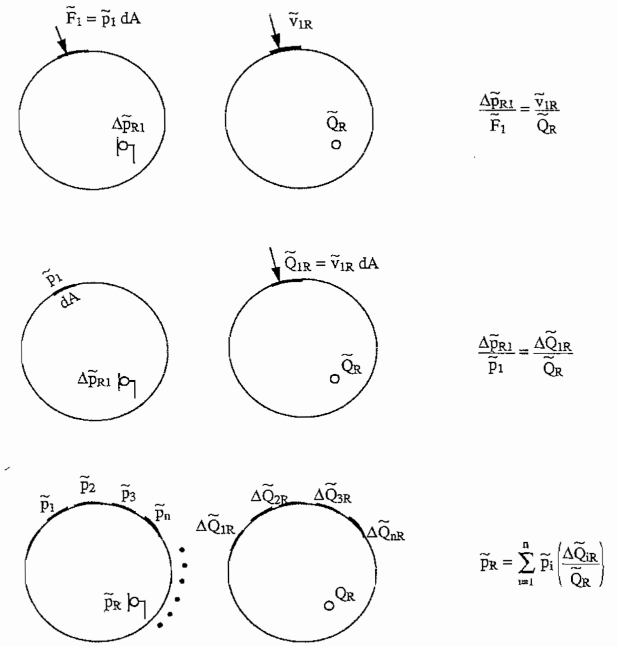

FIGURE 11.40 Extension of reciprocity to sound excitation of structures. Top: Reciprocity relationship for external pressure, $\tilde{p}_1$, acting on a small area (dA) of the structure and the resulting internal sound pressure, $\Delta\tilde{p}_{R1}$, and structural response v_{1R} produced by an internal point sound source of volume velocity Q_R located at the former receiver position. Middle: Substitution of volume velocity response $\Delta\tilde{Q}_{1R} = d\tilde{v}_{1R}\,dA$ into the reciprocity relationship. Bottom: Reciprocity relationship for external incident sound excitation p_i and internal sound pressure $\tilde{p}_R$ and volume velocity responses of the structure $\Delta\tilde{Q}_{1R}$ produced by an internal point sound source of volume velocity $\tilde{Q}_R$.

where the transfer functions $\Delta\tilde{Q}_{1R}/\tilde{Q}_R$ represent the reciprocity calibration of the structure as a transducer. This extension of reciprocity by Fahy[67] has the advantage that the reciprocity calibration of the structure (in the form of discretized transfer functions $\Delta\tilde{Q}_{iR}/\tilde{Q}_R$) can be carried out with a capacitive transducer that directly measures the structure's local volume displacement $\Delta\tilde{Q}_{iR}/j\omega$. To obtain sufficient resolution, the side length of the square-shaped capacitive transducer used in measuring the volume displacement must not exceed one-eighth of the acoustical wavelength. Note that the bending wavelength in thin, plate-like structures is usually much smaller than the transducer size so that the capacitive transducer acts as a wavenumber filter, accounting only for those components of the vibration field that results in a net volume displacement. The high-wavenumber components, which result only in local near fields, are "averaged out." The additional advantage of the capacitive transducer is that it does not influence the vibration response of the structure.

Reciprocity can also be used in predicting the sound pressure attributable to the complex vibration pattern of a vibrating body in case where the radiated sound cannot be measured directly (e.g., other correlated vibration sources dominate the sound field). The reciprocity prediction proceeds in two steps. First the vibration pattern of the body is mapped during the operation of the equipment by measuring the vibration velocity $\tilde{v}_i$ at a large number of locations. The phase of the velocity responses is referenced to the velocity measured at a designated reference location. Next the machine is shut off and a point sound source of known volume velocity Q is placed at the receiver location where the sound pressure should be predicted and the sound pressure $\tilde{p}_i$ produced by the point sound source at the various locations along the stationary surface of the body is measured. The phase of the pressure responses is conveniently referenced to the voltage applied to the loudspeaker sound source. The sound pressure at the receiver location, $\tilde{p}_R$, attributable to the periodic vibration of body is predicted as

$$\tilde{p}_R = \sum_{i=1}^{n} \tilde{v}_i\, dA_i \frac{\tilde{p}_i}{Q} \cong \sum_{i=1}^{n} \Delta\tilde{Q}_i \frac{\tilde{p}_i}{Q} \quad \text{N/m}^2 \tag{11.156c}$$

where dA_i is the area and $\Delta\tilde{Q}_i = \tilde{v}_i dA_i$ is the volume velocity of the ith sample of the vibrating surface.

The solid line in Fig. 11.41 represents the directly measured sound pressure $\tilde{p}_R$ at a specific location in a room when a thin plate was excited by a shaker to a

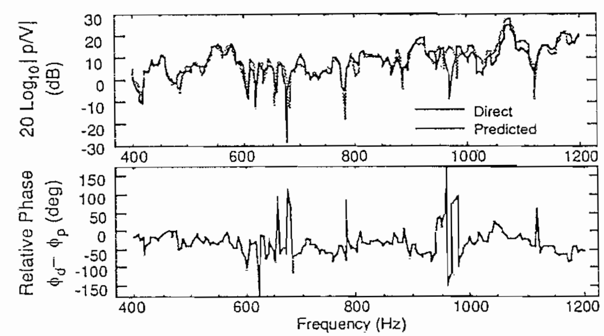

FIGURE 11.41 Sound pressure response at a specific location in a room produced by a thin plate excited by a shaker to complex vibration pattern. Solid line: Directly measured transfer function between sound pressure $\tilde{p}_R$ and excitation force F, phase is referenced to shaker voltage $\tilde{U}$ Dotted line: Transfer function predicted by measuring the magnitude and relative phase of the plate response, $\Delta\tilde{Q}_i = \tilde{v}_i\, dA$ at $i = 81$ position during shaker excitation and the magnitude and phase of the sound pressure $\tilde{p}_i$ at the surface of the stationary plate when a point sound source of volume velocity $\tilde{Q}_R$ is placed at the former receiver position and applying the reciprocity relationship $\tilde{p}_R = \Sigma_{i=1}^{81}\Delta\tilde{Q}_i(\tilde{p}_i/\tilde{Q}_R)$ (after Reference[67]). Top curve, magnitude of pressure; lower curve, phase spectrum of directly measured minus phase spectrum of predicted pressure.

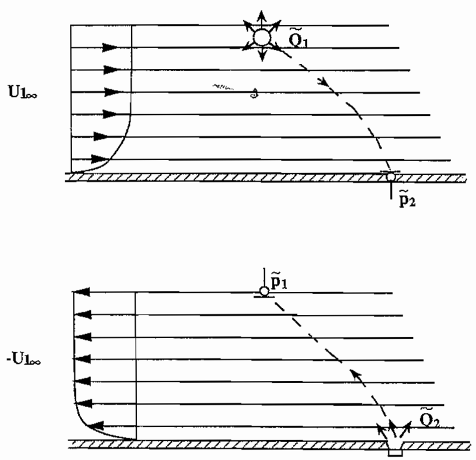
complex vibration pattern. The dotted curve represents the reciprocity prediction according to Eq. (11.156a) utilizing $n = 81$ sampling points on the plate.[67] The experimental results indicate the feasibility of using reciprocity predictions in engineering applications.

Reciprocity in Moving Media

Reciprocity requires that exchanging the function of the source and receiver should not result in any change in the sound propagation path. This is true only if the acoustical medium is at rest. As illustrated in Fig. 11.42, the propagation path between source and receiver remains the same if the exchange of source and receiver positions is accompanied by a reversal of the direction of the uniform mean flow. In this case, or in the case of low-Mach-number potential flow where the shear layer is small compared with the acoustical wavelength, the reciprocity also applies in moving media.[68] Reversal of potential flow is usually easy to accomplish in analytical calculations. However, in many experimental situations where the shear layer is not small compared with the acoustical wavelength, reciprocity does not apply.



$$\left(\frac{\tilde{p}_2}{\tilde{Q}_1}\right)_{U_{1\infty}} = \left(\frac{\tilde{p}_1}{\tilde{Q}_2}\right)_{-U_{1\infty}}$$

FIGURE 11.42 Reciprocity in moving media. Reversal of the function of source and receiver must be accompanied by reversing the flow direction. Streamlines must remain unchanged to assure that the propagation path between source and receiver remains the same.

Fundamental questions regarding reciprocity are dealt with in references 69–71. Analytical applications of reciprocity and superposition for predicting power input structures excited by complex airborne or structure-borne sources is presented in references 66, 72, and 73. Ship acoustics application of reciprocity are treated in references 74 and 75.

11.11 IMPACT NOISE

There are many practical cases where the excitation of a structure can be represented reasonably well by the periodic impact of a mass on its surface. Footfall in dwellings, punch presses, and forge hammers fall into this category. This section deals only with footfall noise in buildings. For the prediction and control of impact noise of machines and equipment, the reader is referred to a series of 10 papers[76–85] that covers all aspects of impact noise of machinery.

Standard Tapping Machine

A standard tapping machine[86] is used to rate the impact noise isolation of floors in dwellings. This machine consists of five hammers equally spaced along a line, the distance between the two end hammers being about 40 cm. The hammers successively impact on the surface of the floor to be tested at a rate of 10 times per second. Each hammer has a mass of 0.5 kg and falls with a velocity equivalent to a free-drop height of 4 cm. The area of the striking surface of the hammer is approximately 7 cm^2; the striking surface is rounded as though it were part of a spherical surface of 50 cm radius. The impact noise isolation capability of a floor is rated by placing the standard tapping machine on the floor to be tested and measuring the one-third-octave-band sound pressure level L'_p averaged in space in the room below.

$$L_n \equiv L_p - 10\log\frac{A_0}{S\overline{\alpha}_{S,\mathrm{ab}}} \quad \text{dB re} 2\times10^{-5}\ \text{N/m}^2 \tag{11.157a}$$

where L_p = one-third-octave-band sound pressure level as measured, dB
$S\overline{\alpha}_{S,\mathrm{ab}}$ = total absorption in receiving room (see Chapter 7), m^2
A_0 = reference value of absorption, =10 m^2

The physical formulation of the problem of impact noise is that of the excitation of a plate by periodic force impulses. Such periodic forces can be presented by a Fourier series consisting of an infinite number of discrete-frequency components, each with amplitude F_n, given by

$$F_n = \frac{2}{T_r}\int_0^{T_r} F(t)\cos\frac{2\pi n}{T_r}t\,dt \quad \text{N} \tag{11.157b}$$

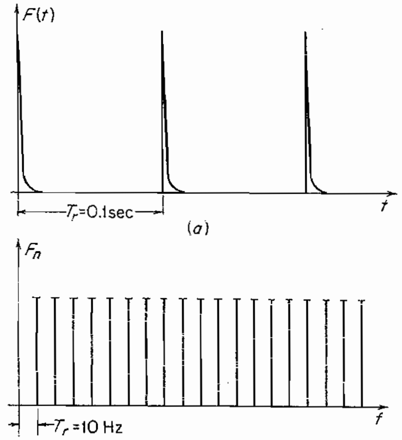


FIGURE 11.43 (*a*) Time function and (*b*) Fourier components of the force that a standard tapping machine exerts on a massive rigid floor.

where $T_r = 1/f_r = 0.1$ is the time interval between hammer strikes and $n = 1, 2, 3, \ldots$. The curve in Fig. 11.43*a* shows the time function of the force $F(t)$, and that in Fig. 11.43*b* shows the amplitude of its Fourier components.

It is an experimental fact that when the hammer strikes a hard concrete slab, the duration of the force impulse is small compared even with the period of the highest frequency of interest in impact testing. For less stiff structures, like wooden floors, this assumption is not valid and the exact shape of $F(t)$ has to be determined and used in Eq. (11.157b). For a thick concrete slab the effective length of the force impulse is short enough so that $\cos[(2\pi n/T_r)t] \approx 1$, and all components have the same amplitude. Because the integral in Eq. (11.157b) is the momentum of a single hammer blow (assuming no rebound) equal to mv_0 (in kg · m/s), the amplitudes of the Fourier components of the force for a repetition frequency f_r are

$$F_n = 2 f_r m v_0 \quad \text{N} \tag{11.158}$$

The velocity of the hammer at the instant of impact is

$$v_0 = \sqrt{2gh} \quad \text{m/s} \tag{11.159}$$

where h = falling height of hammer, m
g = acceleration of gravity (9.8 m/s²)

Let us define a mean-square-force spectrum density S_{f0} that when multiplied by the bandwidth will yield the value of the mean-square force in the same bandwidth,

$$S_{f0} = \tfrac{1}{2} T_r F_n^2 = 4 f_r m^2 g h \quad \text{N}^2/\text{Hz} \tag{11.160}$$

For the standard tapping machine the numerical value of S_{f0} is 4 N²/Hz. Accordingly, the mean-square force in an octave band $\Delta f_{\text{oct}} = f/\sqrt{2}$ is

$$F_{\text{rms}}^2(\text{oct}) = \frac{4}{\sqrt{2}} f \quad \text{N}^2 \tag{11.161}$$

The octave-band sound power level radiated by the impacted slab (which is assumed to be isotropic and homogeneous) into the room below is calculated by inserting Eq. (11.161) into Eq. (11.67a), which yields

$$L_w(\text{oct}) \approx 10 \log_{10} \left(\frac{\rho c \sigma_{\text{rad}}}{5.1 \rho_p^2 c_L \eta_p t^3} \right) + 120 \quad \text{dB re} 10^{-12} \text{ W} \tag{11.162}$$

where ρ = density of air, kg/m³
c = speed of sound in air, m/s
σ_{rad} = radiation factor of slab
ρ_p = density of slab material, kg/m³
c_L = propagation speed of longitudinal waves in slab material, m/s
η_p = composite loss factor of slab
t = thickness of slab, m

Note that the *sound power level is independent of the center frequency of the octave*, that *doubling the slab thickness decreases the level of the noise radiated into the room below by 9 dB*, and that the *sound power level decreases with increasing loss factor*.

Improvement of Impact Noise Isolation by an Elastic Surface Layer

Experience has shown that the impact noise level of even an 8–10-in.-thick dense concrete slab is too high to be acceptable. A further increase of thickness to reduce impact noise is not economical.

Impact noise may be reduced effectively by an elastic surface layer, much softer than the surface of the slab, applied to the structural slab. The resilient layer changes the shape of the force pulse and the amount of mechanical power introduced into the slab by the impacting hammer, as shown in Fig. 11.44.

We would expect, if the elastic layer is linear and nondissipative, that the velocity will be at its maximum v_0 at the instant of impact $t = 0$. It will then decrease to zero and the mass will rebound to nearly the same velocity (it is assumed the hammer is not permitted to bounce a second time) according to the function shown by curve *a* of Fig. 11.44. The force function is shown by curve *b*.

The improvement in impact noise isolation achieved by the addition of the soft surface layer is defined in terms of the logarithmic ratio[87]

$$\Delta L_n = 20 \log \frac{F}{F'} = 20 \log \left(\left| \frac{1 - n f_r / f_0}{\cos[(\pi/2) n (f_r/f_0)]} \right| \right) \quad \text{dB} \tag{11.163}$$

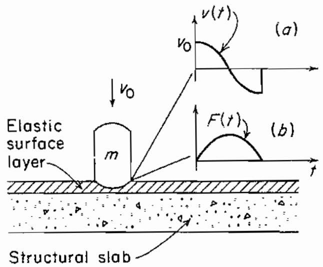

FIGURE 11.44 Velocity and force pulse of a single hammer blow on an elastic surface layer over a rigid slab: (*a*) velocity pulse; (*b*) force pulse.

where

$$n = 1, 2, 3, \ldots \tag{11.164}$$

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{A_h}{m}}\sqrt{\frac{E}{h}} \quad \text{Hz} \tag{11.165}$$

F', F = forces acting on slab with and without resilient surface layer, respectively, N
A_h = striking area of hammer, m^2
m = mass of hammer, kg
E = dynamic Young's modulus of elastic material, N/m
h = thickness of layer, m

The characteristic frequency f_0 of an elastic surface layer for the standard tapping machine is plotted in Fig. 11.45 as a function of E/h.

Equation (11.163), which assumes no damping, is plotted in Fig. 11.46 as a function of the normalized frequency f/f_0. Below $f/f_0 = 1$, the improvement is zero. Above $f/f_0 = 1$ the improvement increases with an asymptotic slope of 40 dB/decade.

Figures 11.45 and 11.46 (use the 40-dB/decade asymptote) permit one to select an elastic surface layer to achieve a specified ΔL_n.

Example 11.6. The required improvement in impact noise isolation should be 20 dB at 300 Hz. Design a resilient covering for the concrete slab.

Solution From Fig. 11.46 we obtain $f/f_0 \approx 3$, which gives $f_0 = 100$ Hz. Entering Fig. 11.45 with this value of f_0 yields $E/h = 2.8 \times 10^8$ N/m^3 (or $E/h \approx$ 1000 psi/in.). Any material having this ratio of Young's modulus to thickness will provide the required improvement. If we wish to select a 0.31-cm- ($\frac{1}{8}$-in.-) thick layer, the dynamic modulus of the material should be 8.7×10^5 N/m^2 (8000 psi). Since the dynamic modulus of most elastic materials is about twice the statically

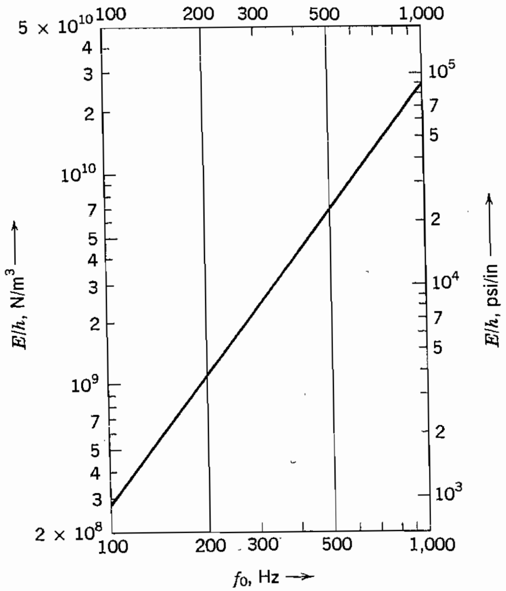

FIGURE 11.45 Chart for the selection of an elastic surface layer, where f_0 = characteristic frequency, E = Young's modulus, and h = thickness of layer.

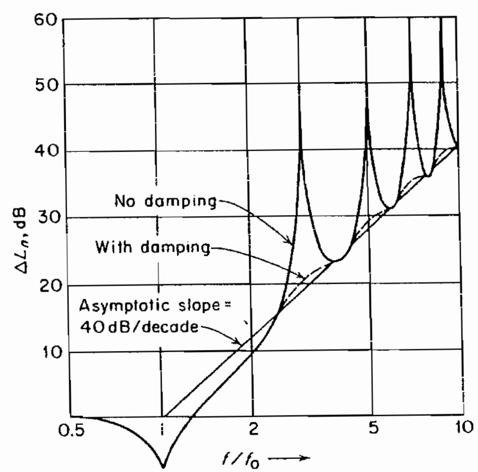

FIGURE 11.46 Improvement in impact noise isolation ΔL_n versus normalized frequency for a resilient surface layer (select f_0 to yield desired improvement).

measured Young's modulus,[88] a material with $E \leq 4.35 \times 10^5$ N/m^2 (4000 psi) should be selected.

Frequently used materials for the elastic surface layer are rubberlike materials, vinyl-cork tile, or carpet. The impact isolation improvement curve (ΔL_n vs. frequency) has been measured and reported[89] for a large variety of elastic surface layer configurations.

The expected normalized impact sound level in the room below (see Fig. 11.1) for a composite floor (with a heavy structural slab) is that of the bare concrete structural floor minus the improvement caused by the elastic surface layer, that is,

$$L_{n,\text{comp}} = L_{n,\text{bare}} - \Delta L_n \tag{11.166}$$

where

$$L_{n,\text{bare}}(\text{oct}) = 116 + 10 \log \left(\frac{\rho c \sigma_{\text{rad}}}{5.1 \rho_p^2 c_L \eta_p t^3} \right) \quad \text{dB re} 2 \times 10^{-5}\ \text{N/m}^2 \tag{11.167}$$

for homogeneous isotropic slabs.

Measured values of impact noise isolation of a large number of floor constructions and improvement of impact noise isolation by various surface layers are presented in reference 89.

Improvement through Floating Floors. It is often more practical to use a floating floor above a structural slab than a soft resilient surface layer. The advantages are that (1) both the impact noise isolation and the airborne sound transmission loss of the composite floor are improved and (2) the walking surface is hard. For analysis, floating floors can be categorized as either (1) locally reacting or (2) resonantly reacting, as defined below.

Locally Reacting Floating Floors. A locally reacting floor is one where the impact force of the hammer on the upper slab (slab 1) is transmitted to the structural slab (slab 2), primarily in the immediate vicinity of the excitation point, and where there is no spatially homogeneous reverberant vibration field on slab 1. In this case the bending waves in the floating slab are highly damped. If the Fourier amplitude of the force acting on plate 1 is given by Eq. (11.158), the reduction in transmitted sound level is[87]

$$\Delta L_n = 20 \log \left[1 + \left(\frac{f}{f_0} \right)^2 \right] \approx 40 \log \frac{f}{f_0} \tag{11.168}$$

where

$$f_0 = \frac{1}{2\pi} \sqrt{\frac{s'}{\rho_{s_1}}} \tag{11.169}$$

and ρ_{s_1} = mass per unit area of floating slab, kg/m^2
s' = dynamic stiffness per unit area of resilient layer between slab 1 and slab 2 including trapped air, N/m^3

Resonantly Reacting Floating Floors. If the floating slab is thick, rigid, and lightly damped, the impact force of the hammers excites a more-or-less spatially homogeneous reverberant bending wave field.

The improvement in impact noise isolation at higher frequencies, where the power dissipated in slab 1 exceeds the power transmitted to slab 2, can be approximated by[87,90]

$$\Delta L_n \approx 10 \log \frac{2.3 \rho_{s_1}^2 \omega^3 \eta_1 c_{L_1} h_1}{n' s^2} \tag{11.170}$$

where h_1 = thickness of floating slab, m
c_{L_1} = propagation speed of longitudinal waves in floating slab, m/s
ρ_{s_1} = mass per unit area of floating slab, kg/m^2
η_1 = loss factor of floating slab
n' = number of resilient mounts per unit area of slab, m^2
s = stiffness of mount, N/m

Equation (11.170) indicates that, in contrast to the locally reacting case where ΔL_n increases at a rate of 40 dB for each decade increase in frequency, the increase is only 30 dB/decade if the loss factor of the floating slab η_1 is frequency independent. Another difference is the marked dependence of ΔL_n on this loss factor. The loss factor is determined both by the energy dissipated in the slab material itself and by the energy dissipated in the resilient mounts.

Figure 11.47 shows the improvement of a floating-floor system under impacting by a standard tapping machine and high-heel shoes, respectively.[91] The negative improvement in the vicinity of the resonance frequency f_0 can be observed.

Impact Noise Isolation versus Sound Transmission Loss

Whether a floor is excited by the hammers of a tapping machine or by an airborne sound field in the source room, it will in both cases radiate sound into the receiving room. There is a close relation between the airborne sound transmission loss R and the normalized impact noise level L_n for a given floor.

In the case of acoustical excitation, the sound power transmitted to the receiver room comprises the contribution of forced waves and of resonance waves. The forced waves usually dominate below the critical frequency of the slab and the resonance waves above. The sound power transmitted by exciting the slab by a standard tapping machine is made up of the contributions of the near-field component and of the reverberant component.

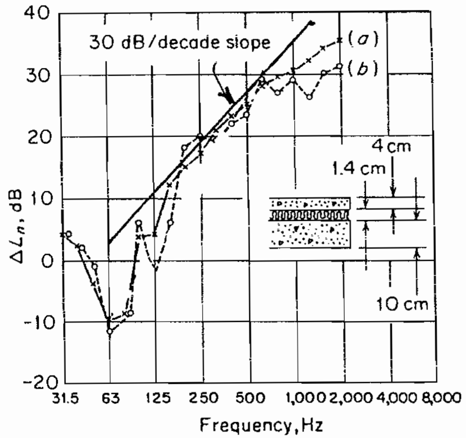

FIGURE 11.47 Improvement in impact noise isolation ΔL_n for a resonantly reacting floating floor for excitation by (*a*) a standard tapping machine and (*b*) high-heeled shoes. Note the negative ΔL_n in the vicinity of the resonance frequency. (After Ref. 91.)

The relation between sound transmission loss R and normalized impact noise level, assuming measurement in octave bands, is[92]

$$L_n + R$$
$$= 84 + 10 \log \left[\frac{S_{f0} f}{\sqrt{2}} \left(\frac{\rho/(2\pi\rho_s^2 c) + \rho c \sigma_{\text{rad}}/(2.3\rho_s^2 c_L \omega \eta_p h)}{\pi \rho c/(\omega^2 \rho_s^2) + \pi\sqrt{12} c^3 \rho \sigma_{\text{rad}}^2/(2\rho_s^2 c_L \omega^3 \eta_p h)} \right) \right] \text{dB} \tag{11.171}$$

where ρ_s = mass per unit area of slab, kg/m^2
c_L = propagation speed of longitudinal waves in slab, m/s
σ_{rad} = radiation factor of slab
h = thickness of slab, m
η_p = composite loss factor of slab
S_{f0} = mean-square force spectrum density as given in Eq. (11.160), N^2/Hz

In the special case of a thick, lightly damped slab,

$$L_n + R = 43 + 30 \log f - 10 \log \sigma_{\text{rad}} - \Delta L_n \tag{11.172}$$

where ΔL_n represents the effect of the surface layer only. For a bare structural slab, by definition, $\Delta L_n = 0$.

Equation (11.172) states that the *sum of the airborne sound transmission loss and the normalized impact noise level is independent of the physical characteristics of the structural slab above the critical frequency of the slab where* $\sigma_{\text{rad}} \approx 1$.

Below the coincidence frequency where the forced waves control the airborne sound transmission loss but the impact noise isolation is still controlled by the resonant vibration of the impacted slab, Eq. (11.171) yields[92]

$$R + L_n = 39.5 + 20 \log f - \Delta L_n - 10 \log \frac{\eta_p}{f_c \sigma_{\text{rad}}} \quad \text{dB} \tag{11.173}$$

where ΔL_n = effect of surface layer only (zero for structural slab), dB
f_c = critical frequency of structural slab, Hz

In this case, the sum $R + L_n$ decibels depends on the physical characteristics of the slab and frequency. Figure 11.48 shows the measured sound transmission loss R and normalized impact sound level L_n as well as their sum for a typical floating floor. The measured and predicted values for the sum are in good agreement,

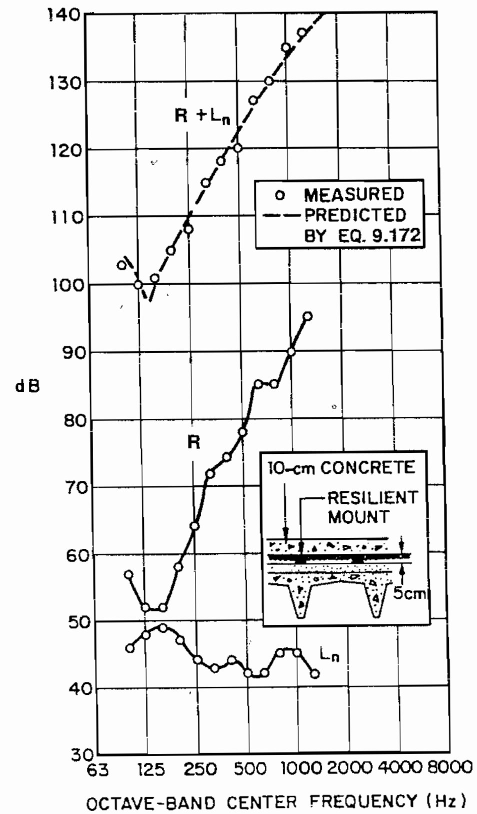

FIGURE 11.48 Measured sound transmission loss R and normalized impact sound level L_n and their sum ($R + L_n$) of a resonantly reacting floating floor assembly. Dotted curve: $R + L_n$ predicted by Eq. (11.172). (After reference 92.)

indicating that the precautionary measures taken to eliminate flanking have been successful.

In checking out the performance of floating floors in the field, it is advisable to measure both R and L_n. The discrepancy between the measured R and that calculated from Eq. (11.173) is a direct indication of flanking. By measuring the acceleration level on the wall surfaces in the source and receiving rooms during acoustical and impact excitation, the flanking paths can be immediately identified.

The measurement and rating of the impact noise isolation of floor assemblies is prescribed in ASTM E492–90 (1996), ASTM E989–89 (1999), and ASTM E1007–97.

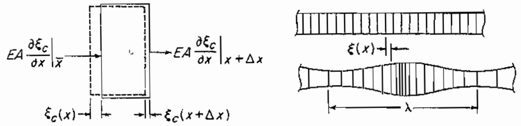
TABLE 11.1 Speeds of Sound in Solids, Deformation of Solids for Different Wave Types, and Formulas for Propagation Speed



Longitudinal Waves Bar

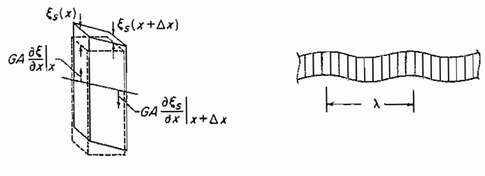
$c_L = \sqrt{E/\rho_M}$

Infinite plate

$c'_L = \sqrt{E/[\rho_M(1-\nu^2)]}$

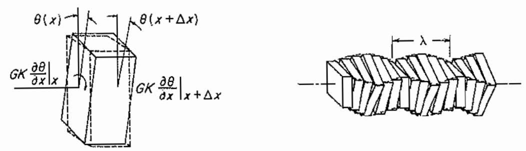
Infinite solid

$$c''_L = \sqrt{\frac{(E/\rho_M)(1-\nu)}{(1+\nu)(1-2\nu)}}$$



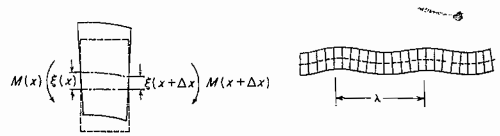
Shear Wave

$c_s = \sqrt{G/\rho_M} \quad G = E/(2+2\nu)$



Torsional Wave Bar

$c_T = \sqrt{GK/\rho_M I}$
$= c_s$ for rods of circular cross section



Bending Wave Plate

$c_B = \sqrt[4]{\omega^2 B/\rho_s}$

Young's modulus E, N/m^2, relates the stress S (force per unit area) to the strain (change in length per unit length). *Poisson's ratio* ν is the ratio of the transverse expansion per unit length of a circular bar to its shortening per unit length, under a compressive stress, dimensionless. It equals about 0.3 for structural materials and nearly 0.5 for rubberlike materials. The *density* of the material is ρ_M, kg/m^3. ρ_s is mass per unit area (kg/m^2) for plates and mass per unit length (kg/m) for bars, rods, or beams. The *shear modulus G* is the ratio of shearing stress to shearing strain, N/m^2. I is the *polar moment* of inertia, m^4. The *torsional stiffness factor K* relates a twist to the shearing strain produced, m^4. The *bending stiffness* per unit width B equals $Eh^3/[12(1-\nu^2)]$ for a homogeneous plate, N·m, where h is the thickness of the bar (or plate) in the direction of bending, m. For rectangular rods $B = Eh^3w/12$, where h is the cross-sectional dimension in the plane of bending and w that perpendicular to it (and width), m.

TABLE 11.2 Key Acoustical Parameters of Solid Materials

Material	Density ρ_M, kg/m^3	Young's Modulus E, N/m^2	Poisson Ratio ν	Speed of Sound c_L, m/s	Product of Surface Density and Critical Frequency $\rho_s f_c$: Hz·kg/m^2	Hz·lb/ft^2	TL at Critical Frequency $R(f_c)$, dB	Internal Damping Factor for Bending at 1000 Hz, η[a]	Acoustical–Mechanical Conversion Efficiency η_{am}, Eq. [a]The range in values of η are based on limited data. The lower values are typical for material alone while the higher values are the maximum observed on panels in place.
[b]The loss factors for structures of these materials are sensitive to construction techniques and edge conditions.
[c]The parameter either is not meaningful or is not available.

TABLE 11.3 Driving Force Point Impedance of Infinite Structures

CHAPTER 12

Enclosures, Cabins, and Wrappings

ISTVÁN L. VÉR

Consultant in Acoustics, Noise, and Vibration Control
Stow, Massachusetts

This chapter deals with the acoustical design of enclosures, cabins, and wrappings. Acoustical enclosures are structures that house a noise source (usually a machine) for protection of the environment from the noise emitted by the source. Cabins are fully enveloping structures specifically designed for protecting a human being from environmental noise. The human being protected by the cabin may be the operator of a noisy machine, supervisor of a manufacturing operation, or attendant of a road toll booth. Wrappings are acoustical structures which closely envelop the casing of machines, valves, and connected piping to provide a high degree of noise reduction at high frequencies, practically no reduction at low frequencies, and modest reduction in the frequency range in-between.

The recently issued international standard ISO 15667:2000E,[1] entitled "Guidelines for Noise Control by Enclosures and Cabins," defines a large number of acoustical performance ratings and specifies the measurement procedure of how to obtain them in the laboratory or in situ. These performance measures, which include single-number and spectral and directivity information, are listed in Table 12.1 for enclosures and in Table 12.2 for cabins. For purposes of easy comparison, these tables retain the somewhat cumbersome nomenclature used in the standard.

The technical content of ISO 15667:2000E is based, to a large extent, on the content of Chapter 13 of the 1992 edition of this book[2] and, consequently, the reader will find much of the information in this chapter. The standard contains excellent suggestions about the collection of input information, planning, and performance verification of acoustical enclosures and cabins.

Annex A provides a large number of sketches depicting (1) details for joining wall panels, (2) mounting the enclosure airtight to the floor, (3) seals around doors and observation windows, (4) vibration isolation of the enclosed machines, (5) pipe and shaft penetrations, (6) ventilation possibilities, and so on. Though the information contained in these sketches is useful, the author cautions the purchaser of acoustical enclosures to contract with an experienced provider of noise control hardware who has similar proven details and the necessary experience to

Sound Pressure Insulation[a] D_P	A-Weighted Sound Pressure Insulation[b] D_{PA}	Apparent Sound Pressure Insulation[c] D'_P
$D_P \equiv \langle L_{p_o}(f)\rangle - \langle L_{p_c}(f)\rangle$	$D_{PA} \equiv L_{PA}(x) - L_{PAC}(x)$	$D'_P \equiv L_{p_o}(f,x) - L_{pc}(f,x)$
$\langle L_{p_o}(f)\rangle$ = space-average sound pressure level in a room with semi diffuse sound field	$L_{PA}(x)$ = A-weighted sound pressure level in room at position x, without cabin	$L_{p_o}(f,x)$ = sound pressure level at frequency f in position x, arbitrary sound field distribution
$\langle L_{p_c}(f)\rangle$ = space-average sound pressure level inside the cabin	$L_{PAC}(x)$ = A-weighted sound pressure level in cabin at the same position x	$L_{pc}(f,x)$ = Sound pressure level at frequency f in position x inside cabin

[a] $\langle L_{p_o}(f)\rangle$ assumed to be semidiffuse field
[b] $L_{PA}(x)$ is the actual A-weighted level in the Room.
[c] L_{po} is produced by an arbitrary sound pressure distribution
Note: According ISO 15667:2000

integrate them into the total design and successfully install them onsite. Giving the construction details included in Annex A to a local sheet metal shop without prior experience in producing noise control hardware may result in a low bid but it is very likely that the end result will be disappointing.

In Annex B the standard provides informative case studies where the non-expert reader can find typical ranges of acoustical performance of functional enclosures and cabins which have operable doors, inlet and discharge openings for ventilation, and so on.

The key difference between enclosures and wrapping is that in the case of enclosures, the sound-absorbing layer is not in contact with the surface of the vibrating equipment, while in the case of wrappings, the porous sound-absorbing layer is in full surface contact with the vibrating body it surrounds. Because the porous sound-absorbing material of wrappings provides a full-surface, structure-borne connection between the vibrating equipment and the exterior layer, it must not only be a good sound absorber but also be highly resilient so as to prevent the transmission of vibration to the outer impervious layer where it can be radiated as sound. Sound-absorbing materials used in enclosures, where there is no contact between the porous material and the vibrating equipment, can have a fairly rigid skeleton. Wrappings are most frequently used to decrease the sound radiation of vibrating surfaces such as ducts and pipes and sometimes also to gain extra sound attenuation of acoustical enclosures. Since fibrous sound-absorbing materials, such as glass fiber and mineral wool, are good heat insulators, properly designed wrappings can provide both substantial acoustical and heat insulation. On the other hand, the heat-insulating properties of the enclosure may be detrimental and require that provision be made for auxiliary cooling of the interior of the enclosure to prevent the buildup of excessively high temperatures. Only the acoustical design aspects of enclosures and wrappings are treated in this chapter.

12.1 ACOUSTICAL ENCLOSURES

Depending on their size (compared with the acoustical and bending wavelength) acoustical enclosures can be termed either small or large. The enclosure is considered small* if both the bending wavelength is large compared with the largest wall panel dimensions and the acoustical wavelength is large compared with the largest interior dimension of the enclosure volume. In small acoustical enclosures, the interior volume has no acoustical resonances. If the largest dimension of the acoustical volume is $L_{\max} \leq \frac{1}{10}\lambda$, the sound pressure is evenly distributed within the volume. The enclosure is considered large if all of its interior dimensions are large compared with the acoustical wavelength and there are a large number of acoustical resonances in the interior volume in the frequency range of interest. Accordingly, even enclosures with large physical dimensions are acoustically small at very low frequencies while enclosures of small physical size are acoustically large at very high frequencies. In almost all acoustical enclosures the

*Small enclosures are also treated in Chapter 6.

enclosure walls already exhibit numerous structural resonances in the frequency range where the first acoustical resonance occurs.

If the enclosure has no mechanical connections to the enclosed equipment, it is termed *free standing*. If there are mechanical connections, then the enclosure is *equipment mounted*. Enclosures that very closely surround the enclosed equipment and the volume of the machine is comparable to the volume of the enclosure are called *close fitting*. Enclosures without acoustically significant openings are referred to as *sealed enclosures*, and those with significant acoustical leaks (intentional or unintentional) as *leaky* acoustical enclosures. Figure 12.1 shows various configurations of sealed acoustical enclosures. This chapter deals with the acoustical design of enclosures. Nonacoustical aspects—such as ventilation, safety, and economy—are treated in a handbook by Miller and Montone (see Bibliography). Construction details and advice for writing purchase specifications are given in a VDI guideline (also see Bibliography).

Insertion Loss as Acoustical Performance Measure

The insertion loss is the most appropriate descriptor for the acoustical performance of enclosures of all types. The operational definition of the insertion loss (IL) of an acoustical enclosure is illustrated in Fig. 12.2. For noise sources that will be positioned indoors, such as machinery in factory spaces, the sound-power-based insertion loss of the enclosure as indicated in Fig. 12.2*a* is the most meaningful. It is defined as

$$\mathrm{IL}_w = 10 \log \left(\frac{W_0}{W_E} \right) = L_{w0} - L_{WE} \quad \mathrm{dB} \tag{12.1}$$

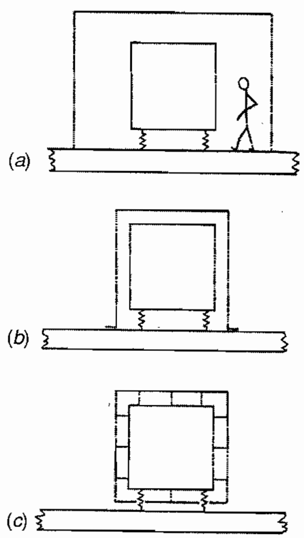

FIGURE 12.1 Enclosure types: (*a*) free standing, large; (*b*) free standing, close fitting; (*c*) equipment mounted, close fitting.

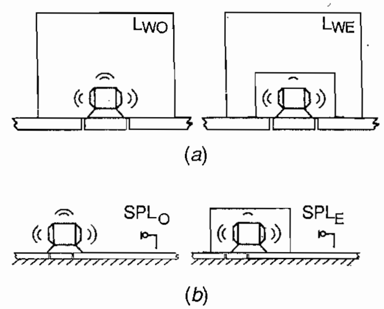

FIGURE 12.2 Operational definition of enclosure insertion loss IL: (*a*) power based; $\mathrm{IL}_w \equiv L_{w0} - L_{WE}$, (*b*) sound pressure based; $\mathrm{IL}_P \equiv \mathrm{SPL}_O - \mathrm{SPL}_E$.

where W_0 is the sound power radiated by the unenclosed source and L_{W0} the corresponding sound power level and W_E is the sound power radiated by the enclosed source and L_{WE} the corresponding sound power level. Both W_0 and W_E are measured in a reverberation room (see Chapter 4) or with the aid of a sound intensity meter.

For enclosures used with equipment deployed outdoors, a less precise but more easily implemented definition of insertion loss, the so-called pressure-based insertion loss, or IL_p, illustrated in Fig. 12.2*b* is most appropriate. It is defined as

$$\mathrm{IL}_p = \mathrm{SPL}_O - \mathrm{SPL}_E \quad \mathrm{dB} \tag{12.2}$$

where SPL_O is the average sound pressure level measured at a number of locations around the source without the enclosure and SPL_E is that measured with the source surrounded by the enclosure. The measurement positions may be chosen on a circle that is centered at the source location. The measurement distance should be at least three times the longest dimension of the enclosure. Equations (12.1) and (12.2) represent definitions readily implemented in the field or laboratory. Using these definitions one can readily determine whether a specific enclosure will or will not meet specific performance requirements stated in the form of a sound-power-level reduction, a sound-pressure-level reduction for a specified distance, or a sound-pressure-level reduction at a specified distance and direction. If the laboratory facilities are available, the sound-pressure-based insertion loss may also be measured in a large hemianechoic chamber.

Note that if the radiation patterns of both the unenclosed and enclosed source is omnidirectional, the two measures yield the same result ($\mathrm{IL}_w = \mathrm{IL}_p$).

Qualitative Description of Acoustical Performance

Figure 12.3 shows the typical shape of a curve of the acoustical insertion loss versus frequency of a free-standing, sealed acoustical enclosure. Region I is the small-enclosure region where neither the interior air volume nor the enclosure

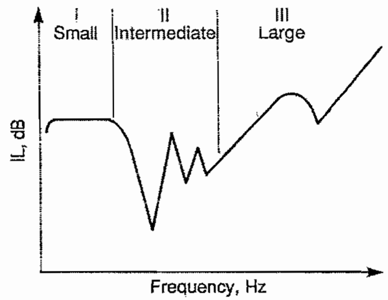

FIGURE 12.3 Typical curve of insertion loss versus frequency of a sealed, free-standing acoustical enclosure. Region I: panel stiffness controlled; damping and interior absorption are ineffective. Region II: resonance controlled; damping and interior absorption are effective. Region III: controlled by sound transmission loss; sound transmission loss and interior absorption are effective; usually limited by leaks.

wall panels exhibit any resonances. In this frequency region the insertion loss is frequency independent and is controlled by the ratio of the volume compliance (inverse of volume stiffness) of the enclosure walls and that of the enclosed air volume.

Region II in Fig. 12.3 is the intermediate region where the insertion loss is controlled by the resonant interaction of the enclosure structure with the enclosed acoustical volume. The region is characterized by a number of alternating maxima and minima in the insertion loss. Typically, the first and most important minima in the insertion loss occurs when the combined volume compliance of the interior air volume and the volume compliance of the wall panels matches the mass compliance of the wall panels. The insertion loss at this resonance frequency usually controls the low-frequency insertion loss of the enclosure and in some instances can become negative, signifying that the equipment with the enclosure may radiate more noise than without the enclosure. Additional minima of the insertion loss occur at acoustical resonances of the enclosure volume. Further minima in insertion loss occur when the frequencies of structural resonances of a wall panel and the frequencies of acoustical resonances of the enclosure volume coincide. It is imperative that enclosures designed for sound sources that radiate noise of predominantly tonal character (such as transformers, gears, reciprocating compressors and engines, etc.) should have no structural or acoustical resonances that correspond to the frequencies of the predominant components of the source noise.

Region III in Fig. 12.3 is the large-enclosure region where both the enclosure wall panels and the interior air volume exhibit a very large number of acoustical resonances. Here, statistical methods of room acoustics can be used to predict the sound field inside the enclosure (see Chapter 7) and the sound transmission through the enclosure walls (see Chapter 11). In this frequency region, the insertion loss is controlled by the interior sound absorption and by the sound

transmission loss (R) of the enclosure wall panels. The dip in the curve of insertion loss versus frequency in region III corresponds to the coincidence frequency of the wall panel (see Chapter 11), which for the most frequently used wall panels (1–2 mm steel or aluminum) falls above the frequency region of interest. The coincidence frequency may fall into the region of interest if the ratio of stiffness of the panel to its mass per unit area is high (e.g., a honeycomb panel).

The prediction of the insertion loss of small and large acoustical enclosures is treated in the following sections. Performance prediction in the intermediate frequency region requires a detailed finite-element analysis of the coupled mechanical acoustical system such as outlined in Chapter 6.

Small Sealed Acoustical Enclosures

For a small, sealed acoustical enclosure, where the sound pressure inside the cavity is evenly distributed, the insertion loss is given by[4–5]

$$\mathrm{IL_{SM}} = 20 \log \left(1 + \frac{C_v}{\sum_{i=1}^{n} C_{wi}}\right) \quad \text{dB} \tag{12.3}$$

where

$$C_v = \frac{V_0}{\rho c^2} \quad \mathrm{m^5/N} \tag{12.4}$$

is the compliance of the gas volume inside the enclosure, V_0 is the volume of the gas in the enclosure volume, ρ is the density of the gas, c is the speed of sound of the gas, and C_{wi} is the *volume compliance* of the ith enclosure wall plate defined as

$$C_{wi} = \frac{\Delta V_{pi}}{p} \quad \mathrm{m^5/N} \tag{12.5}$$

where ΔV_{pi} is the volume displacement of the ith enclosure wall plate in response to the uniform pressure p. It is assumed here that the enclosure is rectangular and is made of n separate, homogeneous, isotropic plates, each with its own volume compliance.

At frequencies below the first mechanical resonance of the isotropic enclosure wall panel, the volume compliance of a homogeneous, isotropic panel C_{pi} is given by[3]

$$C_{wi} = \frac{10^{-3} A_{wi}^3 F(\alpha)}{B_i} \quad \mathrm{m^5/N} \tag{12.6}$$

where A_{wi} is the surface area of the ith wall panel and $F(\alpha)$ is given in Fig. 12.4 as a function of the aspect ratio $\alpha = a/b$ of the panel, where a is the longest and b is the smallest edge dimension of the wall panel. For homogeneous, isotropic wall panels, the bending stiffness per unit length of the panel is

$$B = \frac{Eh^3}{12(1-\nu^2)} \quad \mathrm{N \cdot m} \tag{12.7}$$

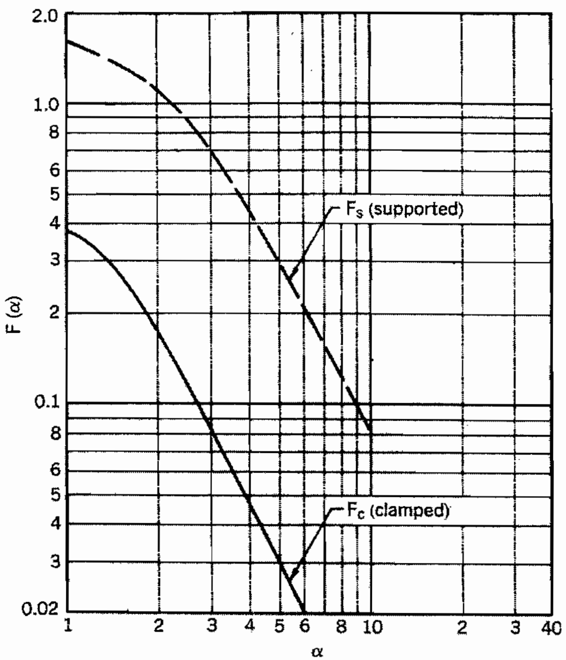

FIGURE 12.4 Plate volume compliance function $F(\alpha)$ plotted versus the aspect ratio $\alpha = a/b$ for homogeneous isotropic panels either with clamped or simply supported edges. (After Ref. 3).

where E is Young's modulus and h is the thickness and ν the Poisson ratio of the wall panel. For a rectangular enclosure combining Eqs. (12.3)–(12.7) yields

$$\mathrm{IL_{SM}} = 20\log\left[1 + \frac{V_0 E h^3}{12\times 10^{-3}(1-\nu^2)\rho c^2}\sum_{i=1}^{6}\frac{1}{A_{wi}^3 F(\alpha_i)}\right]\ \mathrm{dB} \qquad (12.8)$$

For the special case of a cubical enclosure with clamped walls of edge length a Eq. (12.8) yields

$$\mathrm{IL}_s = 20\log\left[1 + 41\left(\frac{h}{a}\right)^3\frac{E}{\rho c^2}\right]\ \mathrm{dB} \qquad (12.9)$$

Equation (12.8) indicates that high insertion loss is achieved if the enclosure has small edge length, high aspect ratio, and large wall thickness, edge conditions are clamped, and the panels are made of a material of high Young's modulus. In short, for an enclosure with high insertion loss at low frequencies, the wall must be made as stiff as possible. According to Eq. (12.9), the low-frequency insertion

loss of a cubical steel enclosure of edge length $a = 300$ mm, $E = 2\times10^{11}$ N/m^2, $\rho = 1.2$ kg/m^3, and $c = 340$ m/s is for two different wall thicknesses h:

	Clamped		Simply Supported	
Wall Thickness h	IL_s	f_0	IL_s	f_0
3 mm	35.5 dB	296 Hz	24 dB	162 Hz
1.5 mm	18.5 dB	148 Hz	9 dB	81 Hz

Here f_0 is the resonance frequency of each of the identical homogeneous isotropic clamped panels. The insertion loss values listed in the table above are valid only at frequencies well below f_0. Note in the table that much higher insertion loss is achieved with a clamped-edge condition than with simply supported edge conditions. In practice, clamped edges are almost impossible to achieve. Consequently, one should use the simply supported edge condition in the initial design to ensure that the designed performance will be achieved.

It is of considerable practical interest to know which material should be used for a small sealed cubical enclosure to yield the highest insertion loss at low frequencies for the same enclosure volume and same total weight. Considering that the total mass M of a cubical enclosure of edge length a is $M = 6\rho_M a^2 h$, Eq. (12.9) can be expressed as

$$\mathrm{IL}_s = 20\log\left[1 + 0.19\frac{M^3}{a^9\rho c^2}\left(\frac{c_L}{\rho_M}\right)^2\right]\ \mathrm{dB} \qquad (12.10)$$

where $c_L = \sqrt{(E/\rho_M)}$ is the speed of longitudinal waves in the bulk enclosure material and ρ_M is the density of the enclosure material. Equation (12.10) indicates that for all materials giving the same enclosure mass M, the material with the highest c_L/ρ_M ratio yields the highest insertion loss. Table 12.3 lists the c_L/ρ_M ratio and the normalized low-frequency insertion loss $\Delta\mathrm{IL}$ for frequently used materials, where $\Delta\mathrm{IL}$ is defined as the low-frequency insertion loss of an enclosure made out of a specific material minus the insertion loss of an enclosure of the same volume and weight built of steel. Table 12.3 indicates that, in regard to low-frequency insertion loss, aluminum and glass are superior to steel and lead is the worst possible choice! Note, however, that this conclusion can be exactly opposite for a large enclosure if the coincidence frequency falls within the frequency range of interest.

Formstiff Small Enclosures. Because the insertion loss of small, sealed enclosures at very low frequencies ($L_{\max} < \frac{1}{10}\lambda$) is controlled by the volume compliance of the enclosure walls, it is desirable to select constructions that provide the highest wall stiffness for the allowable enclosure weight. An enclosure consisting of a round, cylindrical body and two half-spherical end caps yields a very

TABLE 12.3 Difference in Low-Frequency Insertion Loss ΔIL and c_L/ρ_M Ratio for Different Construction Materials[a]

	Lead	Steel	Concrete	Plexiglass	Aluminum	Glass
c_L/ρ_M, m^4/kg·s	0.11	0.65	1.5	1.6	1.9	2.1
ΔIL, dB	−31	0	+14	+15	+19	+20

[a] ΔIL is for a cubical enclosure with identical sides.

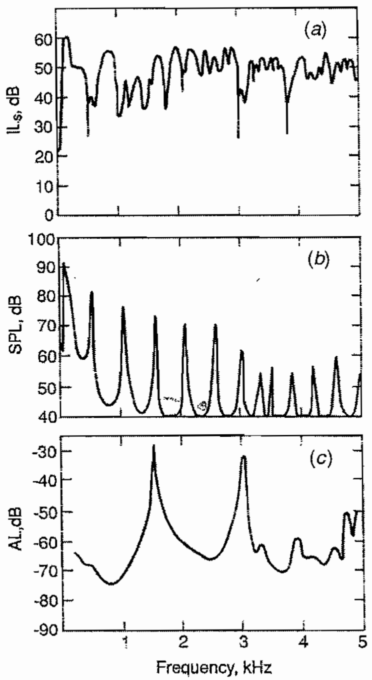

FIGURE 12.5 Acoustical characteristics of a small, sealed, round cylindrical enclosure without interior absorption: (*a*) insertion loss IL; (*b*) resonant acoustical response of interior volume, SPL; (*c*) sound-induced vibration acceleration response of enclosure wall, AL.

stiff construction and much higher insertion loss than a rectangular enclosure of the same volume and weight. Figure 12.5 shows the acoustical characteristics of such a particular small, cylindrical enclosure with no internal sound-absorbing treatment. Curve *A* represents insertion loss versus frequency measured with an external source, indicating that insertion loss at most frequencies exceeds 55 dB. Curve *B* represents the sound pressure levels in the enclosed air volume when excited with an external source, indicating the presence of strong acoustical resonances at 550 Hz and above. Curve *C* represents the sound-induced vibration

acceleration of the cylindrical shell caused by an external sound source. Strong structural resonances are seen at 1.5, 3, and 3.75 kHz. Observing the three curves in Fig. 12.5, it is noted that the frequencies where the insertion loss is minimum coincide either with acoustical resonances of the interior volume or with structural resonances of the enclosure shell. The strong minima of the curve of insertion loss versus frequency in the vicinity of 1.5, 3, and 3.75 kHz are caused by coincidence of the structural resonance of the shell with acoustical resonances of the interior air volume.

Another way to achieve a low wall compliance for a given total weight is to make the enclosure walls out of a composite material consisting of a honeycomb core sandwiched between two lightweight plates. A special form of such high-stiffness, low-weight panel, described by Fuchs, Ackermann, and Frommhold,[6] also provides high sound absorption at low frequencies in addition to the low volume compliance. In this case, the panel on its interior side has two double membranes. The first, thicker membrane, which is rigidly bonded to the honeycomb core, has round openings to make an inward-facing Helmholtz resonator out of each honeycomb cavity. A second, thin, membrane that is covering the first one is free to move over the resonator openings. The presence of this second, thin membrane lowers the resonance frequency of the Helmholtz resonators owing to the mass of the membrane covering the opening and increases the dissipation owing to air pumping. Such Helmholtz plates can be constructed from stainless steel, aluminum, or light-transparent plastic. They are fully sealed and can be hosed down for cleaning. Figure 12.6 shows the curve of insertion loss versus frequency of a cubical enclosure of 1 m edge length. The solid curve was obtained with enclosure walls made of the above-described Helmholtz plates of

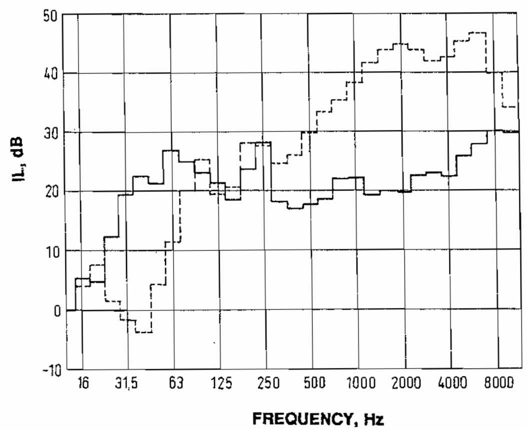

FIGURE 12.6 Measured insertion loss of two 1 × 1 × 1-m enclosures. (After Ref. 6.) Solid curve: Helmholtz plate walls, 10 cm thick, 8.5 kg/m^2, no sound-absorbing treatment. Dashed curve: Woodchip board walls, 1.3 cm thick, 5-cm-thick sounding-absorbing layer, 10 kg/m^2.

10 cm thickness with a mass per unit area of 8.5 kg/m^2 without any additional sound-absorbing lining. The dotted curve was obtained with an enclosure of the same size, made of 1.3-cm-thick wood chip board with 5-cm sound-absorbing lining, yielding a mass per unit area of 10 kg/m^2. The Helmholtz plate enclosure yields superior low-frequency performance and does not require extra sound-absorbing lining. However, the insertion loss of this enclosure at midfrequencies (above 250 Hz) is low because of the low coincidence frequency of the light and stiff panels.

Small Leaky Enclosures. Except for special constructions, such as hermetically sealed compressors, all enclosures are likely to be leaky and provide zero insertion loss as the frequency approaches zero. If an enclosure has a leak in the form of a round opening of radius a_L in a wall of thickness h, the leak represents a compliance $C_L = 1/j\omega Z_L$, where Z_L is the acoustical impedance of the leak given as

$$C_L = \frac{(\pi a_L^2)^2}{-\omega^2 \rho (h + \Delta h)\pi a_L^2 + j\omega R} \quad \text{m}^5/\text{N} \qquad (12.11)$$

where h is the plate thickness, $\Delta h \simeq 1.2 a_L$ represents the end correction, and R is the real part of the impedance of the leak. The sound pressure inside the small, leaky enclosure owing to the operation of a source of volume velocity q_0 is

$$p_{\text{ins}}^{\text{leaky}} = \frac{q_0}{j\omega} \frac{1}{C_L + C_v + \sum_i C_{wi}} \quad \text{N/m}^2 \qquad (12.12)$$

and the insertion loss of the small leaky enclosure is

$$\text{IL}_{\text{leaky}} = \text{IL}_L = 20 \log \frac{C_L + C_v + \sum_i C_{wi}}{C_L + \sum_i C_{wi}} \quad \text{dB} \qquad (12.13)$$

where C_v and C_{wi} are given in Eqs. (12.4) and (12.5), respectively. Since C_L approaches infinity as the frequency approaches zero, the insertion loss of leaky enclosures approaches zero for any form of leak. The insertion loss becomes negative in the vicinity of the Helmholtz resonance frequency of the compliant leaky enclosure given by

$$f_{0L} = \frac{a_L c}{2} \sqrt{\frac{1}{\pi (h + \Delta h)\left(V_0 + \rho c \sum_i C_{wi}\right)}} \quad \text{Hz} \qquad (12.14)$$

As $C_L/\Sigma C_{wi}$ becomes small with increasing frequency, the insertion loss of the small, leaky enclosure, IL_L, approaches that of the sealed enclosure, IL_s. This behavior is illustrated in Fig. 12.7.

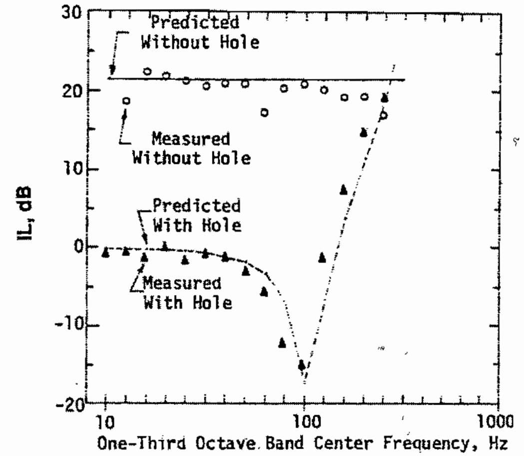

FIGURE 12.7 Measured and predicted sound-pressure-based insertion loss (outside–inside direction) of a 50 × 150 × 300-mm aluminum enclosure of 1.5-mm-thick wall with a single 9.4-mm-diameter hole (after Ref. 5): (——) predicted, sealed; (- - - -) predicted, leaky; (○) measured, sealed; (▲) measured, leaky.

Close-Fitting, Sealed Acoustical Enclosures

A close-fitting acoustical enclosure is one in which a considerable portion of the enclosed volume is occupied by the equipment being quieted. Such enclosures are used in cases where the radiated noise must be reduced using a minimum of added volume. Vehicle engine enclosures, portable compressors, and transportable transformers fall into this category.

Free-standing, close-fitting enclosures, such as shown in Fig. 12.1*b*, have no mechanical connections to the vibrating source and the enclosure walls are excited to vibration only by the airborne path. Conversely, the walls of machine-mounted, close-fitting enclosures, such as depicted in Fig. 12.1*c*, are excited by both airborne and structure-borne paths.

The characteristic property of a close-fitting enclosure is that the air gap (the perpendicular distance between the vibrating surface of the machine and the enclosure wall) is small compared with the acoustical wavelength in most of the frequency range. The walls of the close-fitting enclosures are usually made of thin, flat sheet metal with a layer of sound-absorbing material such as glass fiber or acoustical foam on the interior face. The purpose of the sound-absorbing lining is to damp out the acoustical resonances in the air space.

Free-Standing, Close-Fitting Acoustical Enclosures. Free-standing, close-fitting enclosures, which have no structure-borne connection to the vibrating equipment, always achieve higher insertion loss than a similar machine-mounted enclosure can provide. If the enclosure is perfectly sealed, then its insertion loss depends on (1) thickness, size, and material of the enclosure wall; (2) edge-joining conditions of the wall plates and their loss factors; (3) vibration pattern of the machine surface; (4) average thickness of the air gap between the wall and the machine; and (5) type of sound-absorbing material in the air gap.

Figure 12.8 shows the measured dependence of the power-based insertion loss of a model close-fitting enclosure consisting of 0.6×0.4-m enclosure walls of thickness h and a variable spacing gap of thickness T. To obtain these data, an array of loudspeakers, which represented the vibrating surface of the enclosed machine, was phased to simulate various vibration patterns.[8] Figure 12.8a shows

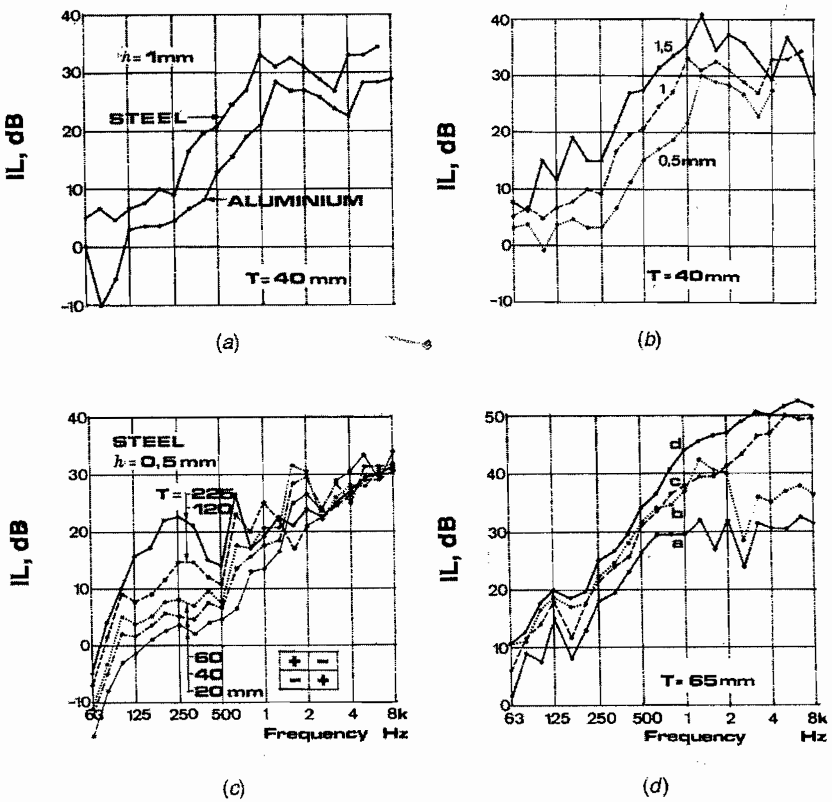

FIGURE 12.8 Effect of key parameters on the power-based insertion loss of a model close-fitting enclosure. Wall panel 0.6×0.4. (After Ref. 8.) (a) Effect of the wall material; 4-cm air gap, in-phase excitation. (b) Effect of wall panel thickness, 4-cm air gap, in-phase excitation. (c) Effect of average air gap thickness; 0.5-mm steel plate, quadrupole excitation. (d) Effect of sound-absorbing material and structural damping; 1-mm steel plate, 6.5-cm air gap, in-phase excitation; a, no damping, no absorption in air space; b, with damping treatment; c, no damping, but absorption in air space; d, with damping and absorption.

the dependence of the measured insertion loss on frequency obtained for 1-mm-thick aluminum and steel wall plates, respectively. Because the steel and aluminum plates have practically the same dynamic behavior, the higher insertion loss of the steel wall panel is attributable to its higher mass. In the frequency range between 300 Hz and 1 kHz, the 9-dB average difference corresponds to the difference in density of the two materials. Figure 12.8b shows the effect of wall thickness. Here again the insertion loss increases with increasing wall thickness. Below 250 Hz, where the insertion loss is controlled by the stiffness of the air and the stiffness and damping of the wall panels, the IL_w changes little with increasing frequency. In the frequency range between 200 Hz and 1 kHz, where the IL_w is controlled by the volume stiffness of the air and by the mass per unit area of the wall, the IL_w increases with a slope of 40 dB/decade. Above 1 kHz, the insertion loss is limited by the acoustical resonances in the air space. Figure 12.8c shows that the insertion loss increases with increasing air gap thickness. Figure 12.8d shows the effect of sound-absorbing material in the air space and damping treatment of the enclosure wall on the achieved insertion loss. The sound-absorbing treatment in the air space prevents the acoustical resonances in the air space and results in a substantial increase of the insertion loss above 1 kHz. Structural damping helps to reduce the deleterious effect of the efficiently radiating plate resonance at 160 Hz. A combination of sound-absorbing treatment and structural damping results in a smooth, steeply increasing insertion loss with increasing frequency and provides a very high degree of acoustical performance.

One-Dimensional Model. According to Bryne, Fischer, and Fuchs,[9] the insertion loss of free-standing, sealed, close-fitting acoustical enclosures can be predicted with reasonable accuracy with the simple one-dimensional model shown in Fig. 12.9. It is assumed that the machine wall (A) vibrates in phase (like a rigid piston) with velocity v_M and that the motion of the machine is not affected by the presence of the enclosure. The vibrating machine is surrounded by a

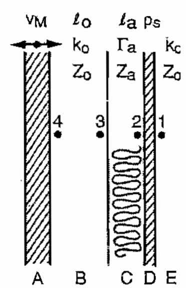

FIGURE 12.9 One-dimensional model for predicting the power-based insertion loss IL of free-standing, sealed close-fitting acoustical enclosures; A machine wall vibrating with velocity v_M; B, air gap thickness l_0; C, sound-absorbing layer thickness l_a; D, impervious enclosure wall of mass per unit area ρ_s; E, free space into which sound is radiated. (After Ref. 9).

flat, limp, impervious enclosure wall (D) which has an internal sound-absorbing lining (C) of thickness l_a and there is an air gap (B) of thickness l_0 between the machine and the sound-absorbing layer. The sound pressure on the outside surface of the enclosure (point 1 in Fig. 12.9) is given by

$$p_1 = p_2\left(1 - \frac{j\omega\rho_s}{Z_0}\right) \quad \text{N/m}^2 \tag{12.15}$$

where $Z_0 = \rho c$ is the characteristic impedance of air. The following equations are used to obtain p_1 as a function of the machine wall vibration velocity v_M:

$$p_3 = 0.5p_2\left[\left(1+\frac{Z_a}{Z_3}\right)e^{-j\Gamma_a l_a} + \left(1-\frac{Z_a}{Z_3}\right)e^{j\Gamma_a l_a}\right] \quad \text{N/m}^2 \tag{12.16}$$

$$p_4 = v_M Z_4 = 0.5p_3\left[\left(1+\frac{Z_0}{Z_4}\right)e^{-jk_0 l_0} + \left(1-\frac{Z_0}{Z_4}\right)e^{jk_0 l_0}\right] \quad \text{N/m}^2 \tag{12.17}$$

$$Z_2 = Z_0 + j\omega\rho_s \quad \text{N}\cdot\text{s/m}^3 \tag{12.18}$$

$$Z_3 = Z_a\frac{(1+Z_a/Z_2)e^{j\Gamma_a l_a} + (1-Z_a/Z_2)e^{-j\Gamma_a l_a}}{(1+Z_a/Z_2)e^{j\Gamma_a l_a} - (1-Z_a/Z_2)e^{-j\Gamma_a l_a}} \quad \text{N}\cdot\text{s/m}^3 \tag{12.19}$$

$$Z_4 = Z_0\frac{(1+Z_0/Z_3)e^{jk_0 l_0} + (1-Z_0/Z_3)e^{-jk_0 l_0}}{(1+Z_0/Z_3)e^{jk_0 l_0} - (1-Z_0/Z_3)e^{-jk_0 l_0}} \quad \text{N}\cdot\text{s/m}^3 \tag{12.20}$$

where $k_0 = 2\pi f/c$ is the wavenumber, ρ the density, and c the speed of sound in air; Z_a is the complex characteristic impedance and Γ_a the complex propagation constant of the porous sound-absorbing material as given in Chapter 8.

The sound power radiated by the unenclosed machine wall is given by

$$W_0 = v_M^2\rho c A \quad \text{W} \tag{12.21a}$$

and when it is enclosed with a free-standing, close-fitting enclosure

$$W_A = \frac{p_1^2}{\rho c}A \quad \text{W} \tag{12.21b}$$

yielding for the insertion loss

$$\text{IL}_F = 10\log\frac{W_0}{W_A} = 20\log\frac{v_M\rho c}{p_1^2} \quad \text{dB} \tag{12.22}$$

In deriving this equation, no account is taken of possible change in surface area or radiation efficiency between the enclosure surface and machine surface.

If the angle of sound incidence on the enclosure wall is known (i.e., a specific oblique angle or random), the power-based insertion loss of free-standing, close-fitting enclosures can be predicted on the basis of the two-dimensional model of sound transmission through layered media presented in Chapter 11.

Machine-Mounted, Close-Fitting Acoustical Enclosure. If the close-fitting enclosure is machine mounted, the rigid or resilient connections between the machine and the enclosure wall give rise to additional sound radiation of the enclosure wall. Assuming that the vibration velocity of the machine v_M is not affected by the connected enclosure, the additional sound power W_M radiated owing to the structural connections is

$$W_M = \sum_{i=1}^{n} F_i^2\left(\frac{\rho}{\rho_s^2 c} + \frac{\rho c\sigma}{2.3\rho_s^2 c_L h\omega\eta}\right) \quad \text{W} \tag{12.23}$$

where

$$F_i^2 = \frac{v_{mi}^2}{|1/2.3\rho_s^2 c_L h + j\omega/s|^2} \quad \text{N}^2 \tag{12.24}$$

In Eq. (12.24), F_i is the force transmitted by the ith attachment point, v_{Mi} is the vibration velocity of the machine at the ith attachment point, n is the number of point attachments between the machine and the homogeneous, isotropic enclosure wall, ρ_s is the mass per unit area of the enclosure wall, h is the wall thickness, c_L is the speed of longitudinal waves in the wall material, η is the loss factor, σ is the radiation efficiency, and s is the dynamic stiffness of the resilient mount connecting the enclosure wall to the machine ($s = \infty$ for rigid point connections). To minimize structure-borne transmission, it is advantageous to select attachment points at those locations on the machine that exhibit the lowest vibration. The insertion loss of the machine-mounted, close-fitting enclosure is

$$\text{IL}_{\text{MM}} = 10\log_{10}\frac{W_0}{W_A + W_M} \quad \text{dB} \tag{12.25}$$

where W_0 and W_A are given in Eqs. (12.21a) and (12.21b).

Figure 12.10 shows a close-fitting enclosure investigated experimentally and analytically by Byrne, Fischer, and Fuchs[9] in three configurations: (1) free standing, (2) rigidly machine mounted, and (3) resiliently machine mounted. Figure 12.11 shows the measured insertion loss obtained for each of the three configurations. The machine-mounted enclosure, which was supported from the machine at four points at each side, yield substantially lower insertion loss at high frequencies than the free-standing enclosure. Elastic mounting yields higher insertion loss than rigid mounting.

As shown by reference 9, the simple one-dimensional analytical model based on Eqs. (12.15)–(12.25) yields predictions that are in good agreement with measured data. The reason for this surprisingly good agreement is that the sound-absorbing treatment effectively prevents sound propagation (and the occurrence of acoustical resonances) in the plane parallel to the enclosure wall and also provides structural damping to the thin enclosure wall. Replacing the effective glass fiber sound-absorbing treatment with a thinner, less effective acoustical foam has resulted in substantial decrease in the insertion loss, indicating the crucial importance of an effective sound-absorbing treatment. Figure 12.12 shows

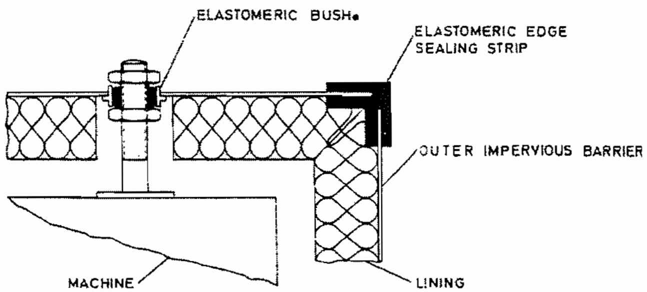

FIGURE 12.10 Machine-mounted, close-fitting enclosure; resilient mounting, resilient panel edge connections. (After Ref. 9).

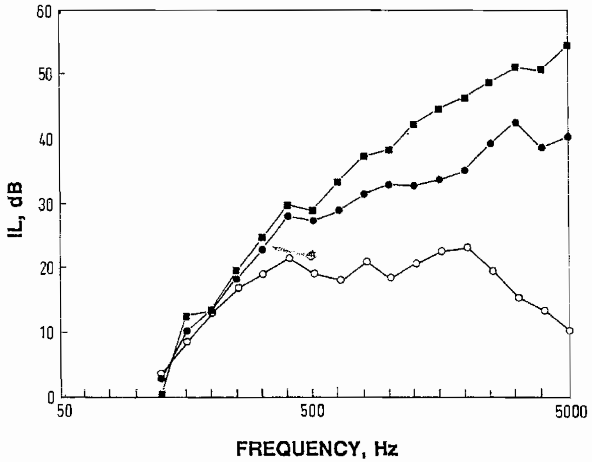

FIGURE 12.11 Insertion loss (IL_s) of a sealed, close-fitting enclosure made of 1-mm steel plates. (After Refs. 7 and 10.) Dimensions: $1 \times 0.6 \times 0.8$ m; machine, enclosure wall distance 50 mm; interior lining 50 mm thick; flow resistivity $R_1 = 2 \times 10^4 \mathrm{N \cdot s/m^4}$. (■) Free standing; (•) machine mounted, resilient mounting (see Fig. 12.10); (O) machine mounted, rigid mounting.

how the specific choice of edge connections of the enclosure plates affected the insertion loss of the machine-mounted, close-fitting enclosure. Elastically sealed edges, such as shown in Fig. 12.10, yield higher insertion loss than rigidly connected (welded) edges. The better performance obtained with elastically sealed edges is due to the reduced coupling between the in-plane motion of one plate (which radiates no sound) with the normal motion of the connected plate (that radiates sound efficiently). The elastic edge seal also increases the loss factor of the enclosure plates, thereby reducing their resonant vibration response.

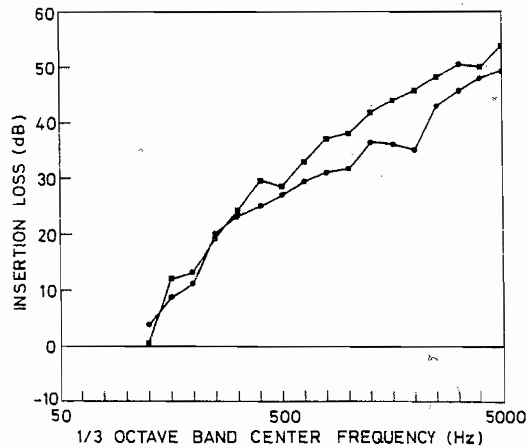

FIGURE 12.12 Effect of plate edge connection on the insertion loss of sealed, resiliently machine-mounted, close-fitting enclosure: (■) elastically sealed edge; (●) welded edge.

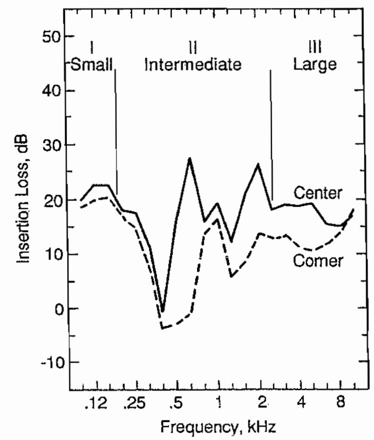

FIGURE 12.13 Effect of microphone position on the sound-pressure-based insertion loss measured in the outside–inside direction of a $50 \times 150 \times 300$-mm (1.6-mm-thick) empty, plane, sealed, unlined aluminum acoustical enclosure. (After Ref. 11.) Solid line: center microphone location. Dashedline: corner microphone location.

Intermediate-Size Enclosures

The intermediate frequency region, designated as region II in Figs. 12.3 and 12.13, is defined as the frequency region where the enclosure walls, the enclosure air volume, or both exhibit resonances; but the resonances do not overlap so that statistical methods are not yet applicable.

Comparison of the solid and dashed curves in Fig. 12.13 show how the insertion loss, measured in the outside–inside direction (such as in a quiet control room in a noisy test facility), depends on the location of the microphone. Below 400 Hz, the sound pressure is uniformly distributed in the enclosure and the microphone in the corner measures the same sound pressure as that placed at the center. The first acoustical resonance occurs at 565 Hz, which results in a very low insertion loss at the enclosure corner in the 500- and 800-Hz center-frequency one-third-octave bands, as illustrated by the dashed curve, but in a high insertion loss in the same bands for the enclosure center location, as depicted by the solid curve. Fluctuations owing to structural resonances can be reduced by application of damping treatment to the panels (see Chapter 14) and those owing to acoustical resonances by internal sound-absorbing lining (see Chapter 8).

Because the insertion loss in this intermediate frequency range fluctuates widely with frequency and position, it is very difficult to make accurate analytical predictions of the insertion loss. Frequently, involved finite-element analysis (see Chapter 6), model-scale or full-scale experiments, or crude approximations must be employed. For crude approximations one connects the low- and high-frequency predictions to cover the intermediate range.

Enclosures without Internal Sound-Absorbing Treatment

There are cases where the danger of bacterial growth or the accumulation of combustible particles precludes the use of porous or fibrous sound-absorbing materials inside of acoustical enclosures. In such cases bare enclosures must be used. Simple analytical models yield zero insertion loss for such enclosures. Consequently, it is also of theoretical interest to treat this extreme case.

Acoustical Performance Prediction of Large, Bare Enclosures. Even if the enclosure is built from homogeneous, isotropic panels without any interior sound-absorbing treatment, the interior sound pressure will not be infinitely high and the insertion loss of the enclosure will not be zero.

The interior sound pressure does not go to infinity because the interior sound field loses power through (1) sound radiation of the walls by the forced bending waves, (2) sound radiation of the walls by the free bending waves, (3) energy dissipation in the panel by the free bending waves, and (4) the inevitable acoustical energy dissipation at the interior surfaces of the impervious enclosure panels owing to the acoustical shear layer and heat conduction losses.

The insertion loss of the enclosure will be finite because of the energy dissipation by processes 3 and 4 above.

The power balance of the interior sound field is given as

$$W_{\text{source}} = W_{\text{rad}}^{\text{forced}} + W_{\text{rad}}^{\text{free}} + W_{d}^{\text{free}} + W_{d}^{\text{shear}} \quad \text{W} \tag{12.26}$$

where W_{source} = sound power of enclosed source
$W_{\text{rad}}^{\text{force}}$ = sound power radiated by forced bending waves

$W_{\text{rad}}^{\text{free}}$ = sound power radiated by free bending waves
W_{d}^{free} = sound power dissipated in plate by free bending waves
W_{d}^{shear} = sound power lost through shear and heat conduction at interior surface of impervious, solid walls

Unless the panel is very heavily damped, the power dissipated by the forced bending waves is small compared with that dissipated by the free bending waves and can neglected.

Inserting into Eq. (12.26) the appropriate relationships from Section 11.8 and for α_{min} from reference 12 yields for the random-incidence sound absorption coefficient of the bare enclosure walls,

$$\overline{\alpha}_{\text{rand}} = \frac{W_{\text{loss}}^{\text{tot}}}{W_{\text{inc}}} = A + B + C + D \tag{12.27}$$

for the space-average mean-square sound pressure in the enclosure,

$$\overline{p}^2 = \frac{4\rho_0 c_0 \, W_{\text{source}}}{S_{\text{tot}}(A + B + C + D)} \quad \text{N}^2/\text{m}^4 \tag{12.28}$$

and for the insertion loss of the bare enclosure,

$$\text{IL}_{\text{bare}} = 10 \log \left(\frac{A + B + D}{A + BC} \right) \quad \text{dB} \tag{12.29}$$

where

$$A = \frac{1}{1 + (1/52)[\omega\rho_s/(\rho_0 c_0)]^2} \qquad B = \frac{2\pi\sqrt{12} c_0^2 \rho_0 c_0 \sigma_{\text{rad}}}{c_L \rho_M h^2 \, \omega^2}$$

$$C = \frac{\rho_0 c_0 \sigma_{\text{rad}}}{\rho_0 c_0 \sigma_{\text{rad}} + \rho_s \omega \eta} \qquad D = \alpha_{\text{min}} = 0.72(10^{-4})\sqrt{\omega}$$

where S_{tot} = total interior surface area of enclosure, m^2 (assuming that all six partitions are made from the same panels)
ρ_s = mass per unit area of plate, $h\rho_M$, kg/m^2
ρ_M = density of plate material, kg/m^3
h = plate thickness, m
ω = radian frequency, $2\pi f$, Hz
ρ_0 = density of air, kg/m^3
c_0 = speed of sound, m/s
σ_{rad} = radiation efficiency of free bending waves on plate (see Chapter 11)
η_c = loss factor of plate (see Chapter 14)

Inspecting Eq. (12.29), note that for $\eta = 0, C = 1$, and $D \approx 0$, Eq. (12.29) yields IL = 0, as it should be. In the vicinity of the coincidence frequency (i.e., in the plateau region of the transmission loss), where $B \gg A$, the insertion loss of the bare enclosure approaches

$$\mathrm{IL} \approx 10 \log\left(\frac{1}{C}\right) = 10 \log\left(\frac{\rho_0 c_0 \sigma_{\mathrm{rad}} + \rho_s \omega \eta}{\rho_0 c_0 \sigma_{\mathrm{rad}}}\right) \simeq 10 \log\left(\frac{\rho_s \omega \eta}{\rho_0 c_0 \sigma_{\mathrm{rad}}}\right) \quad (12.30)$$

Figure 12.14 compares the insertion loss predicted for an unlined, sealed enclosure [using Eq. (12.8) at low frequencies and Eq. (12.27) at high frequencies] with experimental data obtained by reference 11. There is a reasonably good agreement between the predicted and measured values at both low and high frequencies not only for this specific enclosure but also for a large variety of unlined sealed enclosures of different size and wall panel thickness, indicating that the prediction formulas embodied in Eqs. (12.8) and (12.27) yield reasonable estimates for engineering design. Figure 12.14 also indicates that without internal sound-absorbing treatment the insertion loss remains very modest even at high frequencies, highlighting the importance of sound absorption in enclosure design.

Large Acoustical Enclosures with Interior Sound-Absorbing Treatment

Acoustical enclosures are termed large at frequencies where both the enclosure wall panels and the enclosure volume exhibit a large number of resonant modes in a given frequency band and statistical methods for predicting the level of the interior sound field and the vibration response and sound radiation of the enclosure wall panels can be applied. Large acoustical enclosures used in industrial noise control have many paths for transmitting acoustical energy, as illustrated schematically in Fig. 12.15. These paths can be grouped into three basic categories: (1) through the enclosure walls, (2) through openings, and (3) through structure-borne paths. The first group is characterized by the sound excitation of the enclosure wall by the interior sound field, resulting in sound radiation from the exterior wall surfaces. Sound transmission by this path is relatively well understood, and in most cases the sound power transmitted can be predicted with good engineering accuracy (see Chapter 11). The second group is characterized by sound energy escaping through openings in the enclosure wall such as air intake and exhaust ducts, gaps between panels, and gaps around the gasketing at the floor and doors. These are also fairly well understood[13–15] but not so easily controlled. The third group is characterized by radiation of solid surfaces excited to vibration by dynamic forces, such as the enclosure walls when rigidly connected to the enclosed vibrating equipment, shafts and pipes that penetrate the enclosure wall, and the vibration of the uncovered portion of the floor. This path is difficult to predict without detailed information about the motion of the enclosed machine and its dynamic characteristics. Consequently, all possible efforts should be made to prevent any solid connections to the source. To obtain a balanced design, one must control each of these transmission paths and avoid overdesigning any one of them.

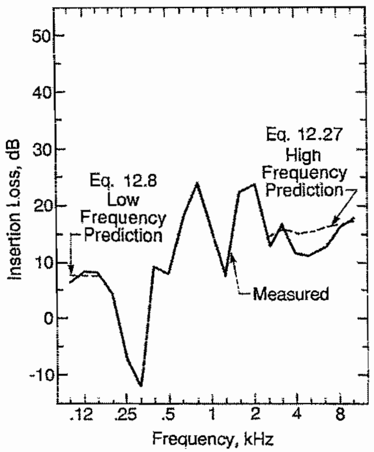

FIGURE 12.14 Comparison of measured and predicted pressure-based IL of a 50 × 150 × 300-mm (0.8-mm-thick) sealed, unlined aluminum enclosure, with source outside. (After Ref. 11).

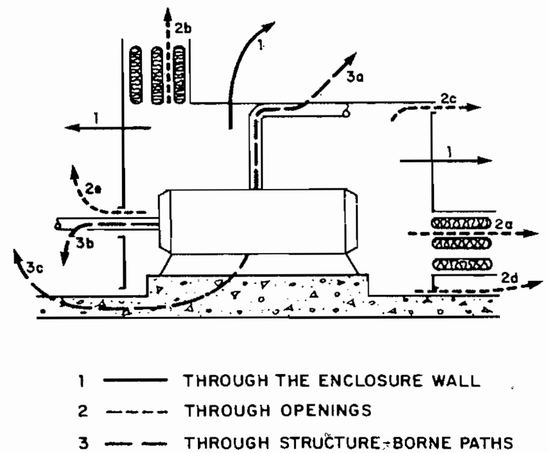

FIGURE 12.15 Paths of noise transmission from a typical acoustical enclosure.

Analytical Model for Predicting Insertion Loss at High Frequencies. A sound source enclosed in a large, acoustically lined enclosure will radiate approximately the same sound power as it would in the absence of the enclosure. To achieve a high power-based insertion loss, a high percentage of this radiated sound power must be dissipated (i.e., converted into heat) within the enclosure proper. This is accomplished by providing walls of high sound transmission loss to contain the sound waves and by covering the interior with sound-absorbing treatment to convert the trapped acoustical energy into heat.

In analyzing the acoustical behavior of an enclosure at high frequencies, the first step is to predict the space–time average mean-square pressure of the diffuse sound field, $\langle p^2 \rangle$, within the enclosure proper. Once the interior sound field is predicted, one can determine the sound power escaping from the enclosure through the various paths. The mean-square value of the diffuse sound pressure in the interior of the enclosure is obtained by balancing (a) the sound power injected into the enclosure from all the noise sources with (b) the power loss through dissipation (in the sound-absorbing lining, in the air, and in the wall structure) and the sound transmission through the walls of the enclosure and through diverse openings. According to reference 4, a sound source of power output W_0 generates in the enclosure a reverberant field with a space–time average mean-square sound pressure $\langle p^2 \rangle$ given by

$$\langle p^2 \rangle = W_0 \frac{4\rho c}{\left\{ \begin{array}{c} S_w \left[\alpha_w + \sum_i (S_{wi}/S_w) 10^{-R_{wi}/10} + D \right] \\ + S_i\alpha_i + \sum_k S_{sk} + mV + \sum_j S_{Gj} 10^{-R_{Gj}/10} \end{array} \right\}} \quad \mathrm{N^2/m^4} \tag{12.31}$$

where

$$D = \left(\frac{4\pi \sqrt{12} \rho c^3 \sigma}{c_L h \rho_s \omega^2} \right) \left(\frac{\rho_s \omega \eta}{\rho_s \omega \eta + 2\rho c \sigma} \right) \tag{12.32}$$

and S_w is the total interior wall surface, S_{wi} is the surface area of the ith wall, α_w is the average energy absorption coefficient of the walls, R_{wi} is the sound transmission loss of the ith wall, ρ_s is the mass per unit area of a typical wall panel, η is the loss factor of a typical wall panel in place, σ is the radiation efficiency of a typical panel, c_L is the propagation speed of longitudinal waves in the plate material, h is the wall panel thickness, $S_i\alpha_i$ is the total absorption in the interior in excess of the wall absorption (i.e., the machine body itself), S_{Gj} is the area of the jth leak or opening, R_{Gj} is the sound transmission loss of the jth leak or opening, S_{sk} is the face area of the kth silencer opening (assumed completely absorbing), m is the attenuation constant for air absorption, and V is the volume of the free interior space. The sound power incident on the unit surface area is given by

$$W_{\text{inc}} = \frac{\langle p^2 \rangle}{4\rho c} = \frac{W_0}{\{\cdots\}} \quad \mathrm{W} \tag{12.33}$$

where $\{\cdots\}$ represents the expression in the denominator in Eq. (12.31) and W_0 is the sound power output of the enclosed machine.

The terms in the denominator of Eq. (12.31) from left to right stand for (1) power dissipation by the wall absorption ($S_w\alpha_w$), (2) power loss through sound radiation of the enclosure walls ($\sum_i S_{wi} \times 10^{-R_{wi}/10}$), (3) power dissipation in the walls through viscous damping effects ($S_w D$), (4) power dissipation by sound-absorbing surfaces in addition to the walls ($S_i\alpha_i$), (5) sound power loss to silencer terminals ($\sum_k S_{sk}$), (6) sound absorption in air (mV), and (7) sound transmission to the exterior through openings and gaps ($\sum_j S_{Gj} \times 10^{-R_{Gj}/10}$).

The relative importance of the various terms may differ widely for different enclosures and even for the same enclosure in the different frequency ranges. For example, for a small airtight enclosure without any sound-absorbing treatment, the power dissipation in the wall panels may be of primary importance, while it is usually negligible for enclosures with proper interior sound-absorbing treatment. Air absorption is important in large enclosures at frequencies above 1000 Hz. The sound power transmitted through the enclosure walls, W_{TW}, that through gaps and openings, W_{TG}, and that through silencers, W_{TS}, are given in Eqs. (12.34)–(12.36), respectively:

$$W_{\text{TW}} = \frac{W_0(\sum_i S_{wi} \times 10^{R_{wi}/10})}{\{\cdots\}} \quad \mathrm{W} \tag{12.34}$$

$$W_{\text{TG}} = \frac{W_0(\sum_j S_{Gj} \times 10^{-R_{Gj}/10})}{\{\cdots\}} \quad \mathrm{W} \tag{12.35}$$

$$W_{\text{TS}} = \frac{W_0(\sum_k S_{sk} \times 10^{-\Delta L_k/10})}{\{\cdots\}} \quad \mathrm{W} \tag{12.36}$$

where ΔL_k is the sound attenuation through the silencer over opening k. The power-based insertion loss of the enclosure in the inside–outside direction is defined as

$$\mathrm{IL} \equiv 10 \log_{10} \frac{W_0}{W_{\text{TW}} + W_{\text{TG}} + W_{\text{TS}} + W_{\text{SB}}} \quad \mathrm{dB} \tag{12.37}$$

which takes the form

$$\mathrm{IL} = 10 \log_{10} \frac{\{\cdots\}}{\sum_i S_{wi} \times 10^{-R_{wi}/10} + \sum_k S_{sk} \times 10^{-\Delta L_k/10}} \times \frac{1}{\sum_j S_{Gj} \times 10^{-R_{Gj}/10} + W_{\text{SB}}(\{\cdots\}/W_0)} \quad \mathrm{dB} \tag{12.38}$$

where W_{SB} is the sound power transmitted through structure-borne paths considered separately according to Eqs. (12.23) and (12.24).

The denominator of Eq. (12.38) reveals that if full advantage is to be taken of the high transmission loss of the enclosure walls, the air paths through gaps, openings, and air intake and exhaust silencers and structure-borne paths must be controlled to a degree that their contribution to the sound radiation is small compared with the sound radiation of the walls. If these paths are well controlled and the dissipation is achieved by the sound-absorbing treatment of the interior wall surfaces and by the absorption in the interior, then for $R_{wi} = R_w$ the insertion loss of the enclosure is well approximated by

$$\mathrm{IL} \cong 10 \log \left(1 + \frac{S_w\alpha_w + S_i\alpha_i}{S_w} \times 10^{R_w/10} \right) \quad \mathrm{dB} \tag{12.39}$$

If we further assume that the second term in Eq. (12.39) is much larger than unity and call the total absorption in the interior of the enclosure $S_w\alpha_w + S_i\alpha_i = A$, Eq. (12.39) simplifies to

$$\mathrm{IL} \cong R_w + 10 \log \frac{A}{S_w} \quad \mathrm{dB} \qquad (12.40)$$

This approximate formula would yield negative insertion loss for very small values of interior absorption. It has been widely promulgated in the acoustical literature without mention of its limited validity. Note that the insertion loss of a large enclosure can approach the sound transmission loss of the enclosure wall panels only if there are no leaks and α_w approaches unity.

Key Parameters Influencing the Insertion Loss of Acoustical Enclosures. The primary paths for the transmission and dissipation of sound in large acoustical enclosures are shown in the block diagram in Fig. 12.16. The key parameter affecting enclosure insertion loss are summarized in Table 12.4. Fisher and Veres[10] and Kurtze and Mueller[16] have carried out systematic experimental investigations on how (1) choice of wall panel parameters, (2) internal sound-absorbing lining, (3) leaks, and (4) vicinity of the enclosed machine to the enclosure walls and its vibration pattern influence the acoustical performance of enclosures. The model–machine sound source employed in reference 10 consisted of 1 × 1.5 × 2-m steel boxes of 1 mm wall thickness and were combined to yield a small (3 × 2 × 1.5-m) and a large (4 × 2 × 1.5-m) model machine. The

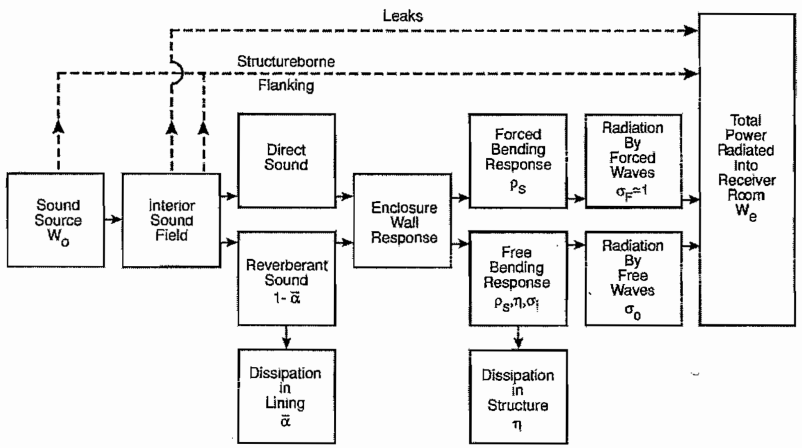

FIGURE 12.16 Block diagram of key components controlling the sound attenuation process in acoustical enclosures: W_0, source sound power output; $\bar{\alpha}$, average sound absorption coefficient; ρ_s, mass per unit area; η, loss factor; σ_i, radiation efficiency of wall panels for radiation for inside direction; σ_0, radiation efficiency of wall panels for radiation for outside direction; σ_F, 1 radiation efficiency of forced waves; W_e, total sound power radiated by the enclosure.

TABLE 12.4 Effect of Key Parameters on Sound Insertion Loss of Large Enclosures

Parameter	Symbol	Effect on Insertion Loss
Absorption coefficient of lining	$\bar{\alpha}$	Increases IL by reducing reverberant buildup
Distance between machine and enclosure wall	d	If d decreases beyond a certain limit, IL decreases at low frequencies (close-fitting enclosure behavior)
Thickness of wall panel	h	Increases IL
Density of wall panel material	ρ_M	Increases IL
Speed of longitudinal waves in panel material	$c_L = \sqrt{E/\rho_M}$	Decreases IL below critical frequency
Loss factor of wall panel	η	Increases IL, especially near and above critical frequency and at first panel resonance
Critical frequency of wall panel	$f_c = c^2/1.8c_L h$	The higher is f_c for a given mass per unit area, the higher is IL
Radiation efficiencies of wall panels	σ_i, σ_0	The higher is the radiation efficiency for inside direction, σ_i, and for outside direction, σ_0, the smaller is IL
Stiffeners	—	Decrease IL by increasing σ
Leaks	—	Limit achievable IL, watch out for door gaskets and penetrations
Structure-borne flanking	—	Limit achievable IL, watch out for solid connections between vibrating machine and enclosure and for floor vibration

walls of the model machines could be excited by either an internal loudspeaker or an internal tapping machine to simulate both sound and structure-borne excitation. The investigated rectangular walk-in enclosure had 4.5 × 2.5 × 2 m inside dimensions and was equipped with an operational personal-access door. The thickness and material of the wall panels as well as the thickness of the interior lining could be varied.

Wall Panel Parameters. Figure 12.17 shows the measured insertion loss versus frequency for three different values of the wall thickness h, indicating that above 1.5 mm, a further increase of the wall thickness brings only slight improvement at low frequencies and a slight deterioration at high frequencies near coincidence. Figure 12.17 also includes, as the dashed line, the field-incidence

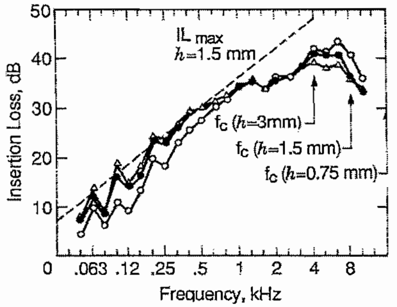

FIGURE 12.17 Curves of power-based insertion loss versus frequency measured (inside–outside direction) for a large walk-in enclosure for various thicknesses of steel plate, h. (After Ref. 10.) Sound-absorbing treatment, 70 mm thick, door sealed; f_c, coincidence frequency; $\mathrm{IL}_{\max} = R_f$ represents the maximum achievable insertion loss. (Δ) $h = 3$ mm; ($\bullet$) $h = 1.5$ mm; ($\circ$) $h = 0.75$ mm.

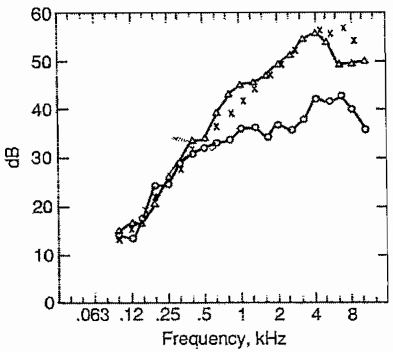

FIGURE 12.18 Comparison of measured enclosure insertion loss IL and panel sound transmission loss R (after Ref. 10): 1.5-mm-thick steel plate, 70-mm-thick sound-absorbing treatment; (Δ) R, measured; ($\times$) R, predicted according to Chapter 11; ($\circ$) IL measured.

sound transmission loss for a 1.5-mm-thick steel plate for comparison, indicating that up to 500 Hz, the insertion loss matches well the field-incidence sound transmission loss of the panel.

Figure 12.18 compares the measured sound transmission loss of a typical 2.1 × 1.2-m wall panel and predicted sound transmission loss of an identical infinite-enclosure panel with the measured insertion loss obtained with an enclosure built with the same panels. The data indicate that the prediction formulas presented in Chapter 11 for infinite panels can be used to predict accurately the sound transmission loss of the finite panels of this specific size and that above 500 Hz the insertion loss is dominated by unintentional small leaks. According to reference 10, the sound-absorbing interior liner provides sufficient structural

damping of the wall panels so that additional damping treatment did not result in improved performance.

Stiffening the wall panels with exterior L-channels, which increase the radiation efficiency, resulted in slight deterioration of the acoustical performance. Using steel and wood chipboard of equal mass per unit area yielded different transmission loss but resulted in practically the same insertion loss because in the frequency range where the chipboard had its coincidence frequency the insertion loss was already controlled by leaks.

As a general rule, wall panels should be selected to have *high enough coincidence frequency* to be above the frequency region of interest and be *large enough that their first structural resonance occurs below the frequency region of interest* but heavy enough to yield a field-incidence mass law sound transmission loss that matches the insertion loss requirements. Steel plates 1.5 mm thick usually fulfill most of these requirements.

Stiff, lightweight panels (such as honeycombs) usually yield a critical frequency as low as 500 Hz and provide a very low sound transmission loss in this frequency region. Consequently, such panels should not be used in enclosure design unless the enclosure is required to provide high insertion loss at only very low frequencies and mid- and high-frequency performance is not required.

Effect of Sound-Absorbing Treatment. The proper choice of sound-absorbing treatment plays a more crucial role than the specific choice of wall material or wall thickness, as shown in Fig. 12.19. The sound-absorbing treatment helps to increase insertion loss by (1) reducing reverberant buildup in the enclosure at mid- and high frequencies, (2) increasing the transmission loss of the enclosure walls at high frequencies, and (3) covering up some of the unintentional leaks between adjacent panels and between panels and frames. Whenever feasible, the thickness of the interior sound-absorbing treatment should be chosen to yield a normal-incidence absorption coefficient $\alpha \geq 0.8$ in the frequency region of interest. As shown in Chapter 8, this can be achieved by a layer thickness $d \geq \frac{1}{10}\lambda$, where λ_L is the acoustical wavelength at the lower end of the frequency region, and by choosing a porous material of normalized flow resistance of $1.5 \leq R_1 d/\rho c < 3$.

Leaks. Leaks reduce the insertion loss of large enclosures just as they reduce it for small enclosures [see Eq. (12.13)]. The reduction in insertion loss due to leaks, $\Delta\mathrm{IL}_L$, is defined as

$$\Delta\mathrm{IL}_L \equiv \mathrm{IL}_s - \mathrm{IL}_L \cong 10\log(1 + \beta \times 10^{R_w/10}) \quad \mathrm{dB} \qquad (12.41)$$

where IL_s and IL_L are the insertion losses of the sealed and leaky enclosures, respectively, R_w is the sound transmission loss of the enclosure wall, and $\beta = (1/S_w)\Sigma_j S_{Gj} \times 10^{-R_{Gj}/10}$ is the leak ratio factor, S_{Gj} is the face area, and R_{Gj} is the sound transmission loss of the jth leak. The sound transmission loss of leaks can be positive or, in the case of longitudinal resonances in wide, rigid-walled gaps, also negative. For preliminary calculations it is customary to assume

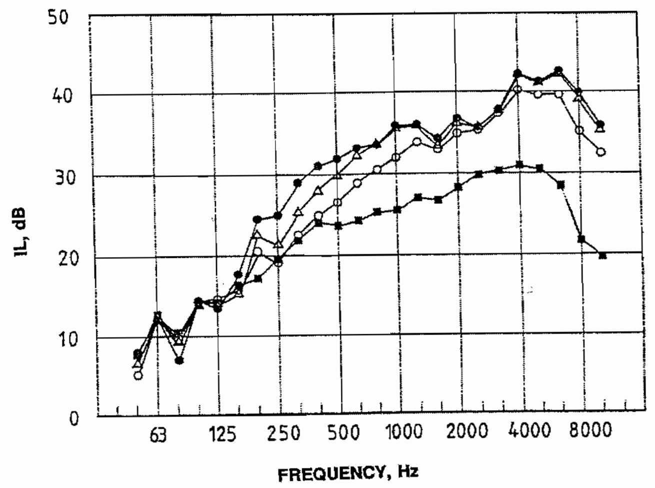

FIGURE 12.19 Measured insertion loss of the enclosure with 1.5-mm-thick steel plates for various thicknesses of the sound-absorbing material (after Ref. 10): (■) 0 mm (no absorption); (○) 20 mm; (△) 40 mm; (•) 70 mm.

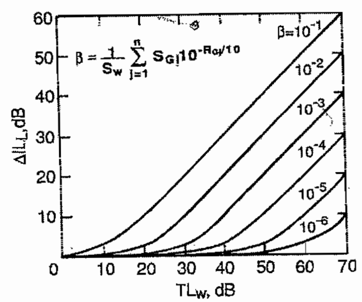

FIGURE 12.20 Decrease of enclosure insertion loss, ΔIL, as a function of the wall sound transmission loss R_w with the leak ratio factor β as parameter; S_w is the wall surface area and R_{Gj} and S_{Gj} are the sound transmission loss and face area of the jth leak, respectively.

$R_{Gj} = 0$. In this case, $\beta = \sum_j S_{Gj}/S_w$ is the ratio of the total face area of the leaks and gaps and the surface area (one side) of the enclosure walls.

Figure 12.20 is a graphical representation of Eq. (12.41) indicating that the higher is the sound transmission loss of the enclosure walls, the higher is the reduction in insertion loss caused by leaks. For example, for an enclosure assembled from wall panels that provide a R_w of 50 dB, the total area of all leaks must be less than 1/1000 percent ($\beta = 10^{-5}$) of the total enclosure surface area if the insertion loss is not to be decreased by more than 3 dB!

Machine Position. Experimental investigations by Fischer and Veres[10] have shown that the insertion loss of an enclosure at low frequencies also depends on the specific position of the enclosed machine within the enclosure. At low frequencies, where the distance between the flat machine wall and the flat enclosure wall panel, d, becomes smaller than one-eighth of the acoustical wavelength ($d < \frac{1}{8}\lambda$), the observed decrease of the insertion loss (from its value obtained when the machine was positioned centrally so that all wall distances were large compared with $\frac{1}{8}\lambda$) was as high as 5 dB. Note that the machine–wall distance d includes the thickness of the internal lining. As a general rule, machines with omnidirectional sound radiation should be positioned centrally. It is especially important to avoid positioning the noisy side of machines very close to enclosure walls, doors, windows, and ventilation openings.

Machine Vibration Pattern. The insertion loss of an enclosure also depends on the specific vibration pattern of the machine, although that dependence appears to not be very strong. Experimental investigations[10] have shown that variation of the insertion loss was about ± 2.5 dB when measured with a loudspeaker inside the model machine and with excitation of the model machine by an ISO tapping machine.

Flanking Transmission through the Floor. The potential insertion loss of an enclosure can be limited severely by flanking if the floor is directly exposed to vibration forces, the internal sound field of the enclosure, or both. Figure 12.21 shows typical enclosure installations ranging from the best to the worst with regard to flanking transmission via the floor. For most equipment it is imperative to provide vibration isolation, a structural break in the floor, or both to reduce the transmission of structure-borne excitation of the floor. Applicable prediction tools and isolation methods are described in Chapters 11 and 13. For the cases depicted in Figs. 12.21*c,d*, where the interior sound field directly impinges on the floor, the sound-induced vibration of the floor sets a limit to the achievable insertion loss of the enclosure. This limit can be estimated roughly from

$$\mathrm{IL}_L \cong R_F + 10 \log \sigma_F \quad \mathrm{dB} \qquad (12.42)$$

where R_F is the sound transmission loss and σ_F is the radiation efficiency of the floor slab.

Relationship between Inside–Outside and Outside–Inside Transmission. Acoustical enclosures are most frequently used to surround a noisy equipment for reducing the noise exposure of a receiver located outside of the enclosure. Less frequently, the enclosure surrounds the receiver (i.e. it is a cabin) to reduce its noise exposure to a sound source located outside of the enclosure. The acoustical performance of the enclosure in the former case is given by its insertion loss in the inside–outside direction, IL_{io}, while the latter is given by its insertion loss in the outside–inside direction, IL_{oi}. All of

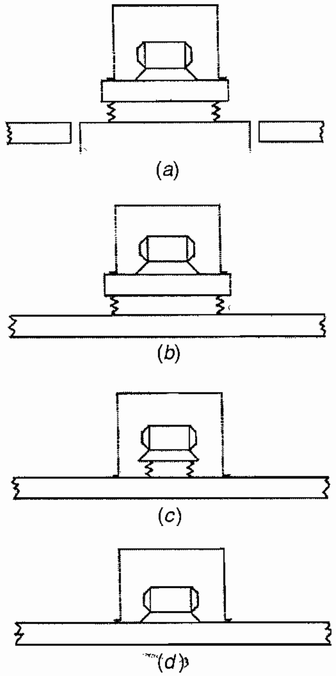

FIGURE 12.21 Rating of enclosure installations with regard to flanking transmission of the floor: (*a*) best; (*b*) good; (*c*) bad; (*d*) worst.

our considerations in this chapter have dealt with sound transmission from the inside to the outside. According to the principle of reciprocity (see Chapter 11), exchanging the position of the source and receiver does not affect the transfer function. Though it is strictly true only for point sound sources and receivers, it also can be applied to extended sound sources and averaged observer positions in an enclosure, yielding $\mathrm{IL}_{io} = \mathrm{IL}_{oi}$.

Example. To demonstrate the use of the previously provided design information, predict the insertion loss of the large, acoustically lined, walk-in enclosure investigated experimentally in reference 10. The enclosure is 4.5 × 2.5 × 2.0 m high and is constructed of 1.5-mm-thick steel plates and has a 70-mm-thick interior sound-absorbing lining. The sound transmission loss of the wall panels, R_w, given in Fig. 12.18 by the triangular data points, and the sound absorption coefficient of the interior panel surfaces, $\overline{\alpha}$, taken from reference 10, as a curve that monotonically increases from 0.16 at 100 Hz and reaches a plateau of 0.9 at 600 Hz. The insertion loss is predicted by Eq. (12.38) using the following values: $S_{wi} = S_w = 39\ \mathrm{m}^2$, $\sum_j S_{Gj} \times 10^{-R_{Gj}/10} = 10^4$, $S_{Gj} = 3.9 \times 10^{-3}$, assuming that leaks account for 1/100 percent of the wall surface area, that there are no silencer openings ($S_s = 0$) and no structure-borne connections ($W_{\mathrm{SB}} = 0$), and

that air absorption (mV), the sound absorbed by the machine ($S_i\alpha_i$), and power lost due to dissipation in the panels ($S_w D$) and due to sound radiation ($10^{-R_w/10}$) are small compared with the power dissipated in the sound-absorbing treatment on the interior wall surfaces.

Then Eq. (12.38) simplifies to

$$\mathrm{IL}_L \cong 10 \log \frac{S_w\overline{\alpha}}{\sum_i S_{wi} \times 10^{-R_{wi}/10} + \sum_j S_{Gj} \times 10^{-R_{Gj}/10}} \quad \mathrm{dB} \qquad (12.43)$$

The curve of insertion loss versus frequency predicted by Eq. (12.43) is represented by the open circles in Fig. 12.22, while the solid curve represents the measured data. The measured sound transmission loss of the wall panels, R_w, is the dashed line and represents the limiting insertion loss that could be achieved only if there would be no leaks and the random-incidence sound absorption coefficient $\overline{\alpha}_w$ would approach unity. Observing Fig. 12.22, note that the assumption of 1/100 percent leaks ($\beta = 10^{-4}$) yielded a prediction that matches reasonably well the measured data, which indicates that even such a very small percentage of leaks, which can be realized only if extreme care is exercised during erecting the enclosure and careful caulking of all leaks detected during the initial performance checkout and careful adjustment of door gaskets, can substantially decrease the potential insertion loss of an enclosure.

Partial Enclosures

When the work process of the machine or safety and maintenance requirements do not allow a full enclosure, a partial enclosure (defined as those with more than 10% open area) is used to reduce radiated noise. When a partial enclosure is far enough from the sound source not to cause an increase in source sound

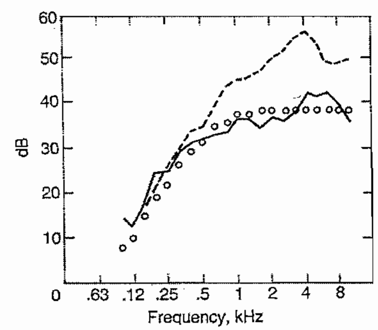

FIGURE 12.22 Typical acoustical performance of a leaky enclosure: (——) IL, measured by Ref. 10; (- - - -) R_w, measured by Ref. 10; (O) IL, predicted by Eq. (12.43) for

$$\beta = \left(\sum_j \left(\frac{S_{Gj}}{S_w} \right) \times 10^{-R_{Gj}/10} \right) = 10^{-4}$$

power by hydrodynamic interactions of the near field of the source with edges of the opening and the walls of the partial enclosure are not rigidly connected to the vibrating machine to serve as a sounding board, a partial enclosure can provide a modest insertion loss of 5 dB or less. According to reference 17, the power-based insertion loss of partial enclosure can be estimated by

$$\mathrm{IL} = 10 \log \left[1 + \alpha \left(\frac{\Omega_{\text{tot}}}{\Omega_{\text{open}}} - 1 \right) \right] \quad \text{dB} \tag{12.44}$$

where Ω_{tot} is the solid angle of sound radiation of the unenclosed source and $\Omega_{\text{open}} = S_{\text{open}}/r$ is the solid angle at which the enclosed source (located at a distance r) "sees" the opening of area S_{open}. Reference 17 contains construction details, curves of measured insertion loss versus frequency, and cost information of 54 different partial enclosures.

12.2 WRAPPINGS

Many machines and pipes need thermal insulation to provide protection of operating personnel or to prevent excessive heat loss. Typically, they need a minimum of 25-mm- (1-in.-) thick glass or ceramic fiber blanket to achieve proper protection. Since many hot equipment, such as turbines, boiler feed pumps, compressor valves, and pipelines, are also sources of intense noise, it is frequently feasible to achieve both heat and acoustical insulation by providing a (preferably) limp, impervious surface layer on top of the porous blanket. The impervious surface layer also provides protection for the porous blanket. Acoustically, the combination of the resilient blanket and the heavy, limp, impervious surface layer provide a spring–mass isolation system. At frequencies where the mass impedance of the surface layer exceeds the combined stiffness impedance of the skeleton of these flexible blankets and the entrapped air, the vibration amplitude of the surface layer becomes smaller than that of the machine surface and wrapping results in an insertion loss that monotonically increases with increasing frequency. The insertion loss of the wrapping is defined the same way as the insertion loss of a close-fitting enclosure and for flat wrappings can be predicted in a manner similar to that of the close-fitting enclosure.

The major difference between wrappings and close-fitting enclosures is that for wrappings the skeleton of the porous layer is in full surface contact with the vibrating surface of the machine, but for the close-fitting enclosures there is no such contact. Consequently, for wrappings the vibrating machine surface transmits a pressure to the impervious surface layer not only through sound propagation in the voids between the fibers but also through the skeleton of the porous material. At low frequencies where the thickness of the porous layer, L, is much smaller than the acoustical wavelength, the porous layer can be represented by a stiffness per unit area, S_{tot}, that according to Mechel[18] can be estimated as

$$S_{\text{tot}} = S_M + S_L \left(1 - \frac{P}{A} \sqrt{\frac{\rho c^2}{L \pi f \gamma R_1 h'}} \right) \quad \text{N/m}^3 \tag{12.45}$$

where S_L is the stiffness of the trapped air,

$$S_L \cong \frac{\rho c^2}{\gamma L h'} \quad \text{N/m}^3 \tag{12.46}$$

γ the adiabatic exponent, h' the porosity, f the frequency, and R_1 the flow resistivity of the material, and S_M is given by

$$S_M = (2\pi f_0)^2 \rho_s \quad \text{N/m}^3 \tag{12.47}$$

In Eq. (12.47) the symbol f_0 represents the measured resonance frequency of a mass–spring system consisting of a small rectangular or square-shaped sample of the porous material covered with a metal plate of mass per unit area ρ_s. The resonance frequency is measured by putting the mass–spring system on top of a shaker table and performing a frequency sweep. The second term in Eq. (12.45) accounts for the air that escapes along the perimeter P of a test sample of surface area A, used in the experiment to determine the resonance frequency f_0 according to Eq. (12.47). Young's modulus of the porous material is then determined as $E = S_{\text{tot}}/L$, the speed of longitudinal waves in the porous layer as $c_L = \sqrt{E/\rho_M}$, where ρ_M is the density of the porous material, and the wavenumber as $k = 2\pi f/c_L$. Characteristics of some frequently used thermal insulation materials reported by Wood and Ungar[19] are given below:

Material	Dynamic Stiffness per Unit Area, S_M (N/m^3)	Density, ρ_M (kg/m^3)
Erco-Mat[a]	1.3×10^7	138
Erco-Mat F[a]	2×10^6	104
Glass fiber[b]	4×10^4	12

[a] Nedled glass fiber insulation.
[b] Low-density Owens Corning Fiberglas blanket.

Considering the porous heat insulating layer as a wave-bearing medium of density ρ and a complex Young's modulus $E' = E(1 + j\eta)$ and characterizing the impervious, limp surface layer by its mass per unit area ρ_s, Wood and Ungar[19] derived the analytical formula

$$\mathrm{IL} = 20 \log \left| \cos(kL) - \frac{\rho_s}{\rho_M L}(kL)\sin(kL) \right| \quad \text{dB} \tag{12.48}$$

where $k = \omega/\sqrt{E(1 + j\eta)/\rho_M}$ is the complex propagation constant of the porous layer, $\eta = 1/Q$ the loss factor, and $\rho_s \omega$ the mass impedance per unit area of the covering layer.

At very low frequencies, where $kL \ll 1$, Eq. (12.48) can be approximated by

$$\mathrm{IL}_L = 20 \log \left[1 - \left(\frac{\omega}{\omega_n} \right)^2 \right] \quad \text{dB} \tag{12.49}$$

where $\omega_n = E/\rho_s L$ is the resonance frequency of a system consisting of a massless spring of stiffness E/L and a mass ρ_s (per unit area). According to Eq. (12.49), the cladding provides no insertion loss for $\omega \ll \omega_n$ and yields a negative insertion loss (amplifies the radiated sound) if $\omega \cong \omega_n$.

For frequencies above the resonance frequency ($\omega \gg \omega_n$) the blanket provides an attenuation that increases monotonically with increasing frequency. Noting that in Eq. (12.48) neither the cosine nor the sine term can exceed unity, an upper bound for the curve of insertion loss versus frequency at high frequencies is obtained by[19]

$$\mathrm{IL}_L \le 20 \log \left[1 + \frac{\rho_s}{\rho_L} (kL)^2 \right] \quad \mathrm{dB} \tag{12.50}$$

Pipe Wrappings

Pipe wrappings consist of a resilient porous layer and an impervious jacket. The impervious jacket is usually sheet metal or loaded plastic. They achieve their acoustical performance in a similar manner as flat wrappings. However, there is an important difference. While flat wrappings do not increase the sound-radiating surface, when a wrapping is applied to a small-diameter pipe, the diameter of the impervious jacket can be substantially larger than that of the bare pipe. This increases both the radiating surface and the radiation efficiency. Accordingly, at low frequencies, below or slightly above the resonance frequency of the pipe wrapping, the insertion loss is negative. Positive insertion loss is usually achieved only above 200 Hz.

According to Michelsen, Fritz, and Sazenhofen,[20] the maximal achievable insertion loss of wrappings can be estimated by the empirical formula

$$\mathrm{IL}_{\max} = \frac{40}{1 + 0.12/D} \log \frac{f}{2.2 f_0} \quad \mathrm{dB} \tag{12.51}$$

where

$$f_0 = 60/\sqrt{\rho_s L} \quad \mathrm{Hz} \tag{12.52}$$

where L is the thickness of the porous resilient layer and D is the pipe diameter, both in meters, and ρ_s is the mass per unit area of the impervious jacket in kilograms per square meter.

Equation (12.51) is valid only if there are no structure-borne connections between the pipe and jacket and for frequencies $f \ge 2 f_0$. Figure 12.23 shows curves of measured insertion loss versus frequency obtained in reference 20 for typical pipe wrapping consisting of a galvanized steel jacket, thickness 0.75–1 mm, and a porous resilient layer with the following parameters:

Thickness L	30, 60, 80, and 100 mm
Density	85–120 kg/m^3
Flow resistivity	3×10^4 N · s/m^4
Dynamic Young's modulus	2×10^5 N/m^2

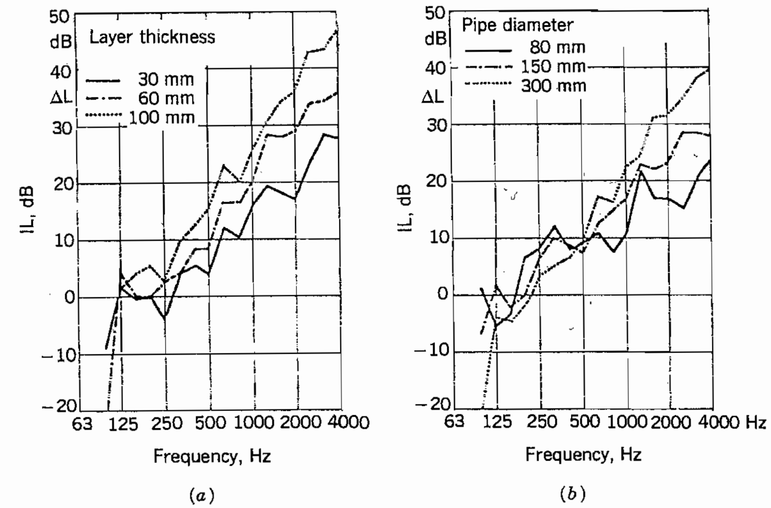

FIGURE 12.23 Curves of measured insertion loss versus frequency of pipe wrappings. (After Ref. 20.) (*a*) Effect of layer thickness. (*b*) Effect of pipe diameter.

Figure 12.23*a* shows the effect of layer thickness L on the insertion loss for a pipe of diameter $D = 300$ mm while Fig. 12.23*b* illustrates the effect of pipe diameter D for a constant layer thickness $L = 60$ mm. The insertion loss above 250 Hz increases with increasing thickness of the porous layer and with increasing diameter of the bare pipe. The standard deviation of the measured insertion loss around that predicted by Eq. (12.52) was 4 dB.

Note that spacers between the pipe and jacket result in insertion loss values that may be substantially lower than those predicted by Eq. (12.50) unless the spacers are less stiff dynamically than the porous layer.

13.1 USES OF ISOLATION

Vibration isolation refers to the use of comparatively resilient elements for the purpose of reducing the vibratory forces or motions that are transmitted from one structure or mechanical component to another. The resilient elements, which may be visualized as springs, are called vibration isolators. Vibration isolation is generally employed (1) to protect a sensitive item of equipment from vibrations of the structure on which it is supported or (2) to reduce the vibrations that are induced in a structure by a machine it supports. Vibration isolation may also be used to reduce the transmission of vibrations to structural components whose attendant sound radiation one wishes to control.

13.2 CLASSICAL MODEL

Mass–Spring–Dashpot System

Many aspects of vibration isolation can be understood from analysis of an ideal, linear, one-dimensional, purely translational mass–spring–dashpot system like that sketched in Fig. 13.1. The isolator is represented by the parallel combination of a massless spring of stiffness k (which produces a restoring force proportional to the displacement) and a massless damper with viscous damping coefficient c (which produces a force proportional to the velocity and opposing it). The rigid mass m, which here is taken to move only vertically and without rotation, corresponds either to an item to be protected (Fig. 13.1a) or to a machine frame on which a vibratory force acts (Fig. 13.1b).

Transmissibility

Although the mass–spring–dashpot diagrams of Figs. 13.1a and b are similar, they describe physically different situations. In Fig. 13.1a, the support S is

CHAPTER 13

Vibration Isolation

ERIC E. UNGAR AND JEFFREY A. ZAPFE

Acentech, Inc.
Cambridge, Massachusetts

13.1 USES OF ISOLATION

Vibration isolation refers to the use of comparatively resilient elements for the purpose of reducing the vibratory forces or motions that are transmitted from one structure or mechanical component to another. The resilient elements, which may be visualized as springs, are called vibration isolators. Vibration isolation is generally employed (1) to protect a sensitive item of equipment from vibrations of the structure on which it is supported or (2) to reduce the vibrations that are induced in a structure by a machine it supports. Vibration isolation may also be used to reduce the transmission of vibrations to structural components whose attendant sound radiation one wishes to control.

13.2 CLASSICAL MODEL

Mass–Spring–Dashpot System

Many aspects of vibration isolation can be understood from analysis of an ideal, linear, one-dimensional, purely translational mass–spring–dashpot system like that sketched in Fig. 13.1. The isolator is represented by the parallel combination of a massless spring of stiffness k (which produces a restoring force proportional to the displacement) and a massless damper with viscous damping coefficient c (which produces a force proportional to the velocity and opposing it). The rigid mass m, which here is taken to move only vertically and without rotation, corresponds either to an item to be protected (Fig. 13.1a) or to a machine frame on which a vibratory force acts (Fig. 13.1b).

Transmissibility

Although the mass–spring–dashpot diagrams of Figs. 13.1a and b are similar, they describe physically different situations. In Fig. 13.1a, the support S is

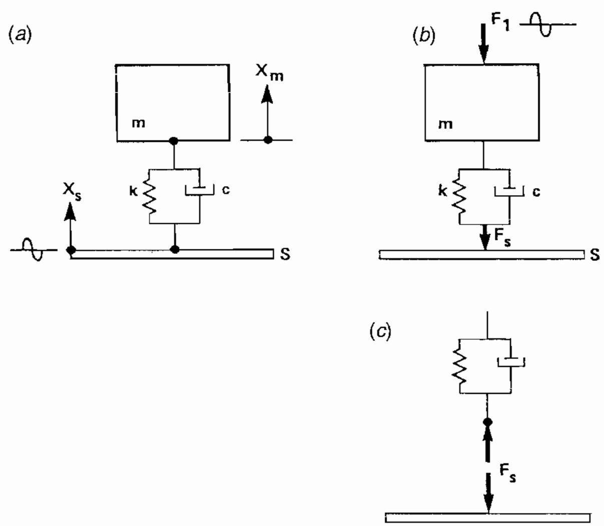

FIGURE 13.1 One-dimensional translational mass–spring–dashpot system: (*a*) excited by support motion; (*b*) excited by force acting on mass; (*c*) force F_s between isolator and support.

assumed to vibrate vertically with a prescribed amplitude X_s at a given frequency; the purpose of the isolator is to keep the displacement amplitude X_m of mass m acceptably small. In Fig. 13.1*b*, a force of a prescribed amplitude F_1 at a given frequency is assumed to act on mass m; the purpose of the isolator is to keep the amplitude F_s of the force that acts on the support within acceptable limits, thereby also keeping the support's resulting motion adequately small.

For the situation represented by Fig. 13.1*a*, the ratio $T = X_m/X_s$ of the amplitude of the mass' displacement to that of the disturbing displacement of the support S is called the (motion) transmissibility. For the situation represented by Fig. 13.1*b*, the ratio $T_F = F_s/F_1$ of the amplitude of the force transmitted to the support S to that of the disturbing force is called the force transmissibility. In many practical instances corresponding to force excitation as represented by Fig. 13.1*b*, the support is so stiff or massive that its displacement may be taken to be zero. It turns out that the force transmissibility T_{F0} obtained with an immobile support (for the case of Fig. 13.1*b*) is given by the same expression as the motion transmissibility (for the case of Fig. 13.1*a*),* namely,[1,2]

$$T = T_{F0} = \sqrt{\frac{1 + (2\zeta r)^2}{(1 - r^2)^2 + (2\zeta r)^2}} \tag{13.1}$$

*This equality holds not only for the simple system of Fig. 13.1, but also for any mathematically linear system.[3] Because of this equality, the literature generally does not differentiate between the two types of transmissibility.

where $r = f/f_n$ is the ratio of the excitation frequency to the natural frequency of the mass–spring system and $\zeta = c/c_c$, which is called the *damping ratio*, is the ratio of the system's viscous damping coefficient c to its critical damping coefficient c_c.

The critical damping coefficient is given by $c_c = 2\sqrt{km} = 4\pi f_n m$. The natural frequency f_n of a spring–mass system obeys[1,2]

$$2\pi f_n = \sqrt{\frac{k}{m}} = \sqrt{\frac{kg}{W}} = \sqrt{\frac{g}{X_{st}}} \tag{13.2}$$

where g denotes the acceleration of gravity, W the weight associated with the mass m, and X_{st} the static deflection of the spring due to this weight. In customary units,

$$f_n(\text{Hz}) \approx \frac{15.76}{\sqrt{X_{st}(\text{mm})}} \approx \frac{3.13}{\sqrt{X_{st}(\text{in.})}} \tag{13.3}$$

The relation $X_{st} = k/W$ and Eq. (13.3) hold only if the spring is mathematically linear—that is, if the slope of the spring's force–deflection curve (which slope corresponds to the stiffness k) is constant. For small-amplitude vibrations about an equilibrium deflection one may take k in the first form of Eq. (13.2) as the slope dF/dx of the spring's force–deflection curve* at the spring's static deflection under an applied load W. However, for some practical isolators, notably those incorporating elastomeric materials, the effective dynamic stiffness may be considerably greater than that obtained from a quasi-static force–deflection curve.[4]

Figure 13.2 shows curves based on Eq. (13.1) for several values of the damping ratio. For small frequency ratios, $r \ll 1$, the transmissibility T is approximately equal to unity; the motion or force is transmitted essentially without attenuation or amplification. For values of r near 1.0, T becomes large (at $r = 1$ or $f = f_n$, $T = 1/2\zeta$); the system responds at resonance, resulting in amplification of the motion or force. All curves pass through unity at $r = \sqrt{2}$.

For $r > \sqrt{2}$, T is less than unity and decreases continually with increasing r. In this high-frequency range, which may be called the *isolation range*, the inertia of the mass plays the dominant role in limiting the mass excursion and thus in limiting the mass' response to support displacement or to forces acting on the mass. Thus, if one desires to achieve good isolation, which corresponds to small transmissibility, one needs to choose an isolator with the smallest possible k (i.e., with the largest practical static deflection X_{st}) in order to obtain the smallest f_n and the greatest value of $r = f/f_n$ for a given excitation frequency.

*Nonlinear spring elements for which $k = dF/dx$ is proportional to the applied load W in a given range are the basis for isolators which have the practical advantage of providing the same natural frequency for all loads in the given range.[4]

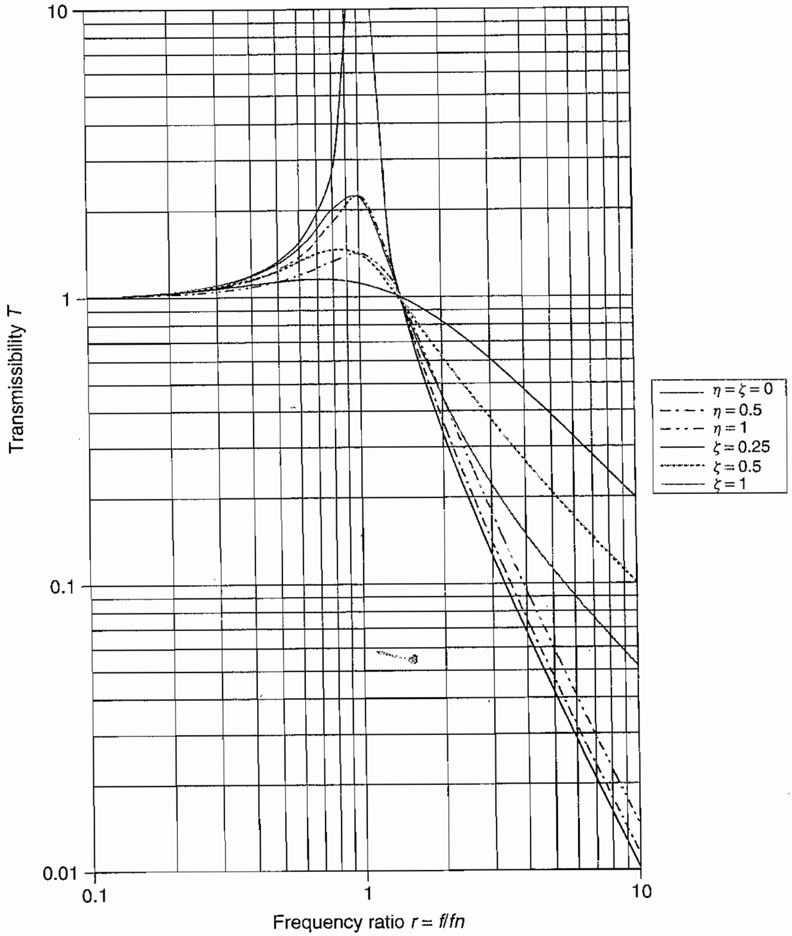

FIGURE 13.2 Transmissibility of mass–spring–damper system of Fig. 13.1 from Eqs. (13.1) and (13.4).

Isolation Efficiency

The performance of an isolation system is sometimes characterized by the isolation efficiency I, which is given by $I = 1 - T$. Whereas the transmissibility indicates the fraction of the disturbing motion or force that is transmitted, the isolation efficiency indicates the fraction by which the transmitted disturbance is less than the excitation. Isolation efficiency is often expressed in percent. For example, if the transmissibility is 0.0085, the isolation efficiency is 0.9915, or 99.15%, indicating that 99.15% of the disturbance does not "get through" the isolator.

Effect of Damping

In the isolation range, that is, for frequency ratios $r > \sqrt{2}$, increased viscous damping results in increased transmissibility, as evident from Fig. 13.2 or Eq. (13.1). Although this fact is mentioned in many texts, it is of little practical consequence for two reasons. First, in practice one rarely encounters systems with damping ratios that are greater than 0.1 unless high damping is designed into a system on purpose—and small values of the damping ratio, and certainly small changes in that damping ratio, have little effect on transmissibility. Second, Eq. (13.1) and Fig. 13.2 pertain only to viscously damped systems, in which a damper produces a retarding force that is proportional to the velocity. Although such systems have been studied most extensively (largely because they are relatively easy to analyze mathematically), the retarding forces in practical systems generally have other parameter dependences.

The effect of damping in practical isolators is generally better represented by *structural damping* than by viscous damping. In structural damping, the retarding force acts to oppose the motion, as in viscous damping, but is proportional to the displacement. For structurally damped systems,[2]

$$T = F_{F0} = \sqrt{\frac{1+\eta^2}{(1-r^2)^2+\eta^2}} \tag{13.4}$$

where η denotes the *loss factor* of the system.*

If a structurally damped system has the same amplification at the natural frequency as a similar viscously damped system, then $\eta = 2\zeta$. The transmissibility of a structurally damped system in the isolation range increases much less rapidly with increasing damping than does that of a system with viscous damping, as evident from Fig. 13.2.

In practical isolation arrangements the damping typically is very small, that is, $\zeta < 0.1$. For such small amounts of damping, the transmissibility in the isolation range differs little from that for zero damping, so that one may approximate the transmissibility in that range by

$$T = T_{F0} = \frac{1}{|r^2-1|} \approx \left(\frac{f_n}{f}\right)^2 \tag{13.5}$$

where the rightmost expression applies for $r^2 = (f/f_n)^2 \gg 1$.

Effects of Inertia Bases

An isolated machine is often mounted on a massive support, generally called an *inertia base*, to increase the isolated mass. If the isolators are not changed as

*The loss factor η in Eq. (13.4) may be taken to vary with frequency as determined from experimental data. See Chapter 14.

the mass is increased, then the natural frequency of the system is reduced, the frequency ratio r corresponding to a given excitation frequency is increased, and the transmissibility is reduced; that is, isolation is improved.

However, practical considerations, such as the load-carrying capacities of isolators, usually dictate that the total isolator stiffness be increased* as the mass is increased, with the static deflection changing little. (In fact, conventional commercial isolators typically are specified in terms of the loads they can carry and the corresponding static deflection.) As evident from Eq. (13.3), the natural frequency remains unchanged if the static deflection remains unchanged, and addition of an inertia base then does not change the transmissibility.

Thus, inertia bases in practice typically do not improve isolation significantly. They are of some benefit, however: With a greater mass supported on stiffer springs, forces that act directly on the isolated mass produce smaller static and vibratory displacements of that mass.

Effect of Machine Speed

In a rotating or reciprocating machine, the dominant excitation forces generally are due to dynamic unbalance and occur at frequencies that correspond to the machine's rotational speed and/or multiples of that speed. Greater speed thus corresponds to increased excitation frequencies and larger values of r—and therefore to reduced transmissibility (or improved isolation). As evident from Eq. (13.1) or (13.5), the transmissibility[3]—the ratio of the transmitted to the excitation force—becomes smaller as the speed (and the excitation frequency) is increased; in the isolation range, the transmissibility is very nearly inversely proportional to the square of the excitation frequency. However, the excitation forces associated with unbalance vary as the square of speed (and frequency) and thus increase with speed about as much as the transmissibility decreases. The net result is that the magnitudes of the forces that are transmitted to the supporting structure are virtually unaffected by speed changes, although speed changes do affect the frequencies at which these forces occur.

Limitations of Classical Model

Although the linear single-degree-of-freedom model provides some useful insights into the behavior of isolation systems, it obviously does not account for many aspects of realistic installations. Clearly, real springs are not massless and may be nonlinear, and real machine frames and supporting structures are not rigid. Resiliently supported masses generally move not only vertically but also horizontally—and they also tend to rock.

In simple classical analyses, furthermore, the magnitude of the exciting force or motion is taken as constant and independent of the resulting response, whereas

*Note that the single spring and dashpot in the schematic diagrams of Fig. 13.1 represent the entire isolation system, which in reality may consist of many isolators. Addition of isolators amounts to an increase in the stiffness of the isolation system.

in actual situations the excitation often depends significantly on the response, as discussed in Section 13.4 under Loading of Sources.

13.3 ISOLATION OF THREE-DIMENSIONAL MASSES

General

Unlike the simple model shown in Fig. 13.1, where the mass can only move vertically without rotation and the system has only one natural frequency, an actual rigid three-dimensional mass has six degrees of freedom; it can translate in three coordinate directions and rotate about three axes. An elastically supported rigid mass thus has six natural frequencies. A nonrigid mass has many additional ones associated with its deformations. Obtaining effective isolation here requires that all of the natural frequencies fall considerably below the excitation frequencies of concern. Descriptions of the natural frequencies and responses of general isolated rigid masses are available[3,5] but are so complex that they provide little practical insight and tend to be used only rarely for design purposes.

Coupling of Vertical Motion and Rocking

Figure 13.3 is a schematic diagram of a mass m supported on two isolators in a plane through its center of gravity, parallel to the plane of the paper (or on two rows of isolators extending in the direction perpendicular to the plane of the paper) with stiffnesses k_1 and k_2 located at distances a_1 and a_2 from the mass' center of gravity. One may visualize easily that a downward force applied at the center of gravity of the mass in general would produce not only a downward displacement of the center of gravity but also a rotation of the mass, the latter due to the moment resulting from the isolator forces. Similarly, purely vertical up-and-down motion of the support S would in general result in rocking of the mass, in addition to its vertical translation. Vertical and rocking motions here are said to be "coupled."

The natural frequency f_v at which pure vertical vibration would occur if the mass would not rock (i.e., the "uncoupled" vertical natural frequency) is given by

$$2\pi f_v = \sqrt{\frac{k_1 + k_2}{m}} \tag{13.6}$$

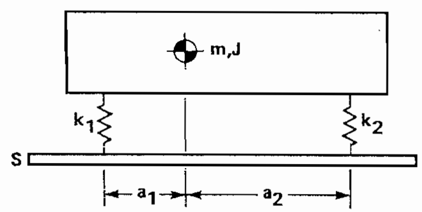

FIGURE 13.3 Mass m with moment of inertia J supported on two isolators.

The natural frequency f_r at which the mass would rock if its center of gravity would not move vertically (i.e., the uncoupled rocking frequency) is given by

$$2\pi f_r = \sqrt{\frac{k_1 a_1^2 + K_2 a_2^2}{J}} \tag{13.7}$$

where J denotes the mass polar moment of inertia about an axis through the mass' center of the gravity and perpendicular to the plane of the paper.

The rocking frequency f_r may be either smaller or larger than f_v. In the general case, the two natural frequencies of the system differ from both of these frequencies and correspond to motions that combine rotation and vertical translation (but without rotation out of the plane of the paper). These "coupled" motion frequencies always lie above and below the foregoing uncoupled motion frequencies; that is, one of the coupled motion frequencies lies below both f_v and f_r and the other lies above both f_v and f_r; coupling in effect increases the spread between the natural frequencies.[6,7]

The presence of coupled motions complicates the isolation problem because one needs to ensure that both of the coupled natural frequencies fall considerably below the excitation frequencies of concern. To eliminate this complication, one may select the locations and stiffnesses of the isolators so that the forces produced by them when the mass moves downward without rotation result in zero net moment about the center of gravity. This situation occurs if the isolators are linear and designed so that they have the same static deflection under the static loads to which they are subject. (Selection of isolators that have the same unloaded height as well as the same static deflection results also in keeping the isolated equipment level.) Then f_v and f_r of Eqs. (13.6) and (13.7) are the system's actual natural frequencies, and vertical forces at the center of gravity or vertical support motions produce no rocking.

Effect of Horizontal Stiffness of Isolators

In the foregoing discussion, horizontal translational motions and the effects of horizontal stiffnesses of the isolators were neglected. However, any real isolator that supports a vertical load also has a finite horizontal stiffness, and in some systems separate horizontally acting isolators may be present. Figure 13.4 is a schematic diagram of a mass on two vertical isolators (or on two rows of such isolators extending perpendicular to the plane of the paper) with stiffnesses k_1 and k_2. The effects of the horizontal stiffnesses of these isolators or of separate horizontally acting isolators are represented by the horizontally acting spring elements with stiffnesses h_1 and h_2, here assumed to act in the same plane at a distance b below the center of gravity of the mass.

The system of Fig. 13.4 has three degrees of freedom and therefore three natural frequencies. If the vertically acting isolators are selected and positioned so that they have the same static deflection, then (as discussed in the foregoing section) there is very little coupling between the vertical translational and the

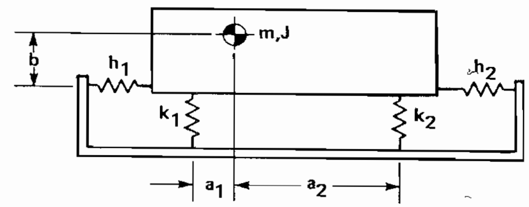

FIGURE 13.4 Mass m with moment of inertia J supported by two vertically and two collinear horizontally acting isolators.

rocking motions, and the natural frequency corresponding to vertical translation is given by Eq. (13.6). The other two natural frequencies, which are associated with combined rotation and horizontal translation, are given by the two values of f_H one may obtain from[6,7]

$$\frac{f_H}{f_v} = (N \pm \sqrt{N^2 - SB})^{1/2} \tag{13.8}$$

where

$$N = \frac{1}{2}\left[S\left(1 + \frac{b^2}{r^2}\right) + B\right] \qquad B = \frac{a_1^2 k_1 + a_2^2 k_2}{r^2(k_1 + k_2)} \qquad S = \frac{h_1 + h_2}{k_1 + k_2} \tag{13.8a}$$

Here, $r^2 = J/m$ represents the square of the radius of gyration of the mass about an axis through its center of gravity.

For a rectangular mass of uniform density, the center of gravity is in the geometric center and the radius of gyration r obeys $r^2 = \frac{1}{12}(H^2 + L^2)$, where H and L represent the lengths of the vertical and horizontal edges of the mass (in the plane of Fig. 13.4).

Nonrigidity of Mass or Support

If the mass of Fig. 13.1a is flexible instead of rigid and has a resonance at a certain frequency, then it will deflect (by deforming) considerably in response to excitation at that frequency, resulting in large transmissibility and thus in poor isolation. An analogous situation occurs if the system of Fig. 13.1b is excited at a resonance frequency of the support.

Figure 13.5 is a schematic diagram representing the vertical translational motion of a machine isolated from a nonrigid support, where the support is represented by a spring–mass system, corresponding, for example, to the static stiffness of a building's floor and to the effective mass that participates in the floor's vibration at its fundamental resonance. Isolator and floor damping have little effect on the off-resonance vibrations and may be neglected for the sake of simplicity. If f_M denotes the natural frequency of the isolated machine on a

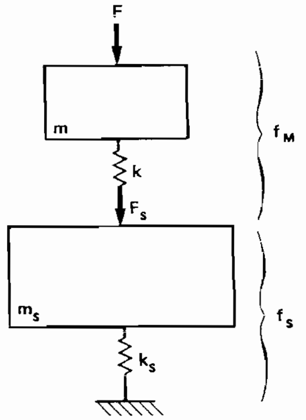

FIGURE 13.5 Schematic representation of isolated machine on nonrigid support structure. Machine is represented by mass m subject to oscillatory force F; isolator is represented by spring k. Support structure is represented by effective mass m_s on spring k_s.

rigid support and f_S represents the natural frequency of the support without the machine in place, so that

$$2\pi f_M = \sqrt{\frac{k}{m}} \qquad 2\pi f_S = \sqrt{\frac{k_s}{m_s}} \tag{13.9}$$

then the force transmissibility, that is, the ratio of the magnitude of the force F_S transmitted to the support to that of the excitation force F, may be written as

$$T_F = \frac{F_S}{F} = \left| \frac{1 - R^2}{(1 - R^2)(1 - R^2G^2) - R^2/M} \right| \tag{13.10}$$

where $R = f/f_S$, $G = f_S/f_M$, and $M = m/m_s$ with f representing the excitation frequency.

Figure 13.6 shows a plot of the transmissibility calculated from Eq. (13.10) for the illustrative case where $M = \frac{1}{2}$, $G = 2$, together with a corresponding plot of the transmissibility that would be obtained with an immobile (infinitely rigid) support. For excitation frequencies that fall between the two resonance frequencies of the system with the nonrigid support, the transmissibility obtained with the nonrigid support is less than that with the rigid support; the reverse is true for excitation frequencies above the upper of the two resonance frequencies. For sufficiently high excitation frequencies, the difference between the two transmissibilities becomes negligible.

The two resonance frequencies f_c of the system with the nonrigid support may be found from

$$\left(\frac{f_c}{f_M}\right)^2 = P \pm \sqrt{P^2 - G^2} \qquad P = \tfrac{1}{2}(1 + G^2 + M) \tag{13.11}$$

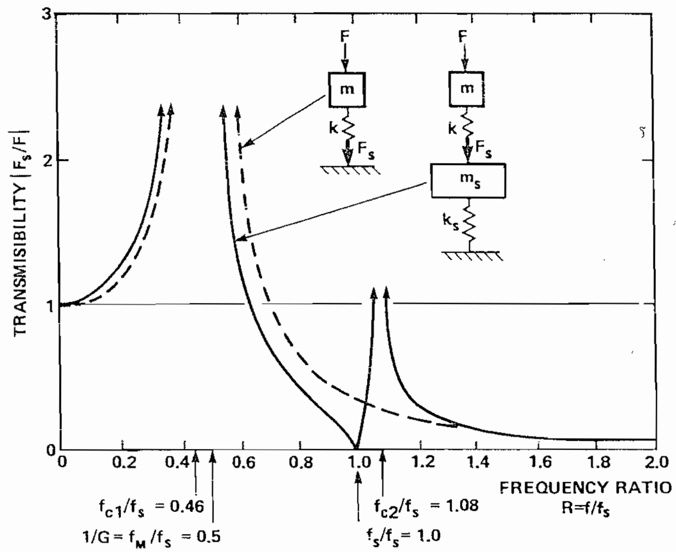

FIGURE 13.6 Comparison of transmissibilities obtained with rigid and nonrigid supports. Curves were obtained from Eqs. (13.1) and (13.10) for zero damping and for mass ratio $M = m/m_s = \frac{1}{2}$ and system frequency ratio $G = f_S/f_M = 2$. Resonance frequencies f_{c1} and f_{c2} of coupled system and f_M and f_S of uncoupled machine and support are indicated on the frequency scale.

with G and M defined as indicated after Eq. (13.10). The higher resonance frequency, obtained with the plus sign in Eq. (13.11), always lies above both f_M and f_S; the lower resonance frequency, obtained with the minus sign, always lies below both f_M and f_S.

13.4 HIGH-FREQUENCY CONSIDERATIONS

Although the relations discussed in the foregoing sections usually suffice for analysis and design in cases where only relatively low frequencies are of concern (i.e., for frequencies that are generally below the resonance frequencies of the machine and support structures themselves), at higher frequencies there occur complications that may need to be taken into account. At high frequencies, the isolated item and the support structure cease to behave as rigid masses, isolators may exhibit internal resonances, and vibration sources tend to be affected by "loading."

Loading of Sources

Loading of a source refers to the reduction of the source's vibratory motion that results from a force that opposes this motion. For example, the vibrations of a sheet metal enclosure tend to be reduced by the opposing forces produced when a hand is placed against it. Similarly, a factory floor that vibrates with a certain amplitude tends to vibrate less when a (nonvibrating) machine is bolted to it as the result of reaction forces produced by the machine.

In the latter example, if the machine is isolated from the floor, it is likely to produce smaller reaction forces on the floor than it would produce if it is bolted rigidly to the floor, and the floor may be expected to vibrate more if the machine is isolated than if it is rigidly fastened to the floor. Since greater floor vibrations then are transmitted to the machine, use of isolation will protect the machine less than anticipated from transmissibility considerations.

To be able to evaluate how much protection of the machine the isolator provides in this case, one needs a quantitative description of the source's response to loading. One may obtain such a description by measuring the motion produced by the source as it acts on several different masses or structures with different dynamic characteristics (impedances), which produce different (known or measurable) reaction forces. For prediction purposes, it often suffices to assume that the source's response to loading at any given frequency is "linear"; that is, the motion amplitude produced by the source decreases in proportion to the amplitude F_0 of the reaction force (which is equal to the amplitude of the force that the source generates). One may describe source motions at a given frequency equally well in terms of acceleration, displacement, or velocity, but use of velocity has become customary. For a linear source one may express the dependence of the source's velocity amplitude V_0 on the force as[8]

$$V_0 = V_{\text{free}} - M_s F_0 \tag{13.12}$$

Here V_{free} represents the velocity amplitude that the source generates if it is free of reaction forces, that is, if it produces zero force. (In general, the parameters V_{free} and M_s for a given source may be different for different frequencies.) The quantity M_s, which indicates how rapidly V_0 decreases with increasing F_0, is known as the *source mobility* and may be found from $M_s = V_{\text{free}}/F_{\text{blocked}}$, where F_{blocked} denotes the force amplitude obtained if the source is "blocked" so that it has zero velocity V_0.

One may readily verify that $M_s = 0$ corresponds to a *velocity source*, that is, to a source whose output velocity amplitude is constant, regardless of the magnitude of its output force F_0. Similarly, infinite M_s corresponds to a *force source*, whose output force F_0 is constant and independent of its output velocity.[8] (For example, a rotating unbalanced mass generates forces that are virtually independent of its support motions and thus acts essentially like a force source. On the other hand, a piston driven by a shaft with a large flywheel moves at essentially the same amplitude regardless of the force acting on it and thus behaves like a velocity source.)

Isolation Effectiveness[3,8]

In the presence of significant source loading, one cannot evaluate the performance of an isolation system on the basis of transmissibility because in the definition

of transmissibility the magnitudes of the disturbances are prescribed and thus, in effect, are taken as constant. A measure of isolation performance that is useful in the presence of loading is the so-called *isolation effectiveness E*. Isolation effectiveness is defined as the ratio of the magnitude of the vibrational velocity of the item to be protected (called the "receiver") that results if the item is rigidly connected to the source to the magnitude of the receiver's velocity that is obtained if the isolator is inserted between the source and the receiver in place of the rigid connection. The definition of isolation effectiveness is analogous to that of insertion loss in airborne acoustics.

If the receiver velocity V_R is proportional to the force F_R that acts on the receiver, so that $V_R = M_R F_R$, where M_R is called receiver mobility,* then the isolation effectiveness may be expressed in terms of a ratio of forces acting on the receiver as well as of a ratio of receiver velocities, namely,

$$E = \frac{V_{Rr}}{V_{Ri}} = \frac{F_{Rr}}{F_{Ri}} \tag{13.13}$$

where the added subscript r refers to the case in which a rigid connection replaces the isolator and the subscript i refers to the situation where the isolator is present.

Whereas small transmissibility T corresponds to good isolation, it is large values of E that imply effective isolation. For this reason, the reciprocal of the effectiveness is sometimes used to characterize the performance of an isolation system. Although this reciprocal differs from the transmissibility T in the general situation where the source is affected by loading, in the special case of sources that are unaffected by loading (i.e., for sources that generate load-independent velocity or force amplitudes), $E = 1/T$.

Effectiveness of Massless Linear Isolator

An isolator may be considered as "massless" if it transmits whatever force is applied to it. (Equal and opposite forces must act on the two sides of a massless isolator if it is not to accelerate infinitely.) A "linear" isolator is one whose deflection is proportional to the applied force. The velocity difference across such an isolator at any frequency then is also proportional to the applied force, and the ratio of the magnitude of this velocity difference to that of the applied force is called the isolator's mobility M_I. Like the reciprocal of isolator stiffness, M_I is large for a soft isolator and zero for a rigid isolator.

For a massless linear isolator, the effectiveness obeys[8,11]

$$E = \left|1 + \frac{M_I}{M_S + M_R}\right| \tag{13.14}$$

*Mobilities of receivers at their attachment points may be estimated analytically for simple configurations (e.g., refs. 9 and 10) or may be measured (as functions of frequency). The velocities and forces usually are expressed in terms of complex numbers, or *phasors*, which indicate both the magnitudes and the relative phases of sinusoidally varying quantities. Mobilities then also are complex quantities in general.

At a resonance of the receiver, the receiver's vibratory velocity V_R resulting from a given force F_R is large, so that the receiver's mobility is large. In view of Eq. (13.14), the effectiveness of an isolator is small in the presence of such a resonance.

Equation (13.14) also indicates that the effectiveness is small if the source mobility M_S is large. For a force source, for which M_S is infinite, the effectiveness is equal to unity, implying that the receiver vibrates just as much with the isolator in place as it does if the isolator is replaced by a rigid connection. This initially somewhat surprising result is correct: After all, the force source generates the same force, regardless of the velocity or displacement it produces, and the isolator transmits all of this force, with a softer isolator merely leading to greater displacement of the source at its output point.

Consequences of Isolator Mass Effects

Isolator mass effects may be neglected—that is, an isolator may be considered as massless—as long as the frequencies under consideration are appreciably lower than the first internal or *standing-wave* resonance frequency of the isolator.* Such standing-wave resonances tend to reduce the isolator's effectiveness severely, as illustrated by Fig. 13.7. This figure shows the calculated transmissibility of a leaf spring modeled as a uniform cantilever beam. The upper left-hand corner of the plot may be recognized as the usual transmissibility curve (similar to Fig. 13.2) in the vicinity of the resonance frequency $f_n = (1/2\pi)\sqrt{k/m}$ obtained for a massless isolator. With increasing excitation frequency the transmissibility does not decrease monotonically, as it would for a massless spring (see curve for $m_{sp} = 0$); instead, there occur secondary peaks associated with standing-wave resonances of the beam. The frequency at which these peaks begin to occur increases as the ratio of the isolated mass m to the mass m_{sp} of the spring increases. Although in the figure only two peaks are shown for each mass ratio, there actually occurs a succession of peaks that become more closely spaced with increasing frequency. The magnitude of these peaks decreases with increasing damping.

To reduce the effects of standing-wave resonances, one thus needs to select an isolator with relatively high damping and a configuration for which the onset of standing-wave resonances occurs at comparatively high frequencies. This implies use of a material with high stiffness-to-weight ratio or, equivalently, with a high longitudinal wave velocity $\sqrt{E/\rho}$ (where E denotes the material's modulus of elasticity and ρ its density), and also use of a configuration with small overall dimensions.

*At lower frequencies, the only effect of the mass of the isolator is to reduce slightly the fundamental resonance frequency of the system. The modified resonance frequency may be calculated from the isolator stiffness and a mass consisting of the isolated mass plus a fraction of the mass of the isolator. If the isolator consists of a uniform spring or pad in compression or shear, the fraction is $\frac{1}{3}$; if the isolator consists of a uniform cantilever beam, the fraction is approximately 0.24.

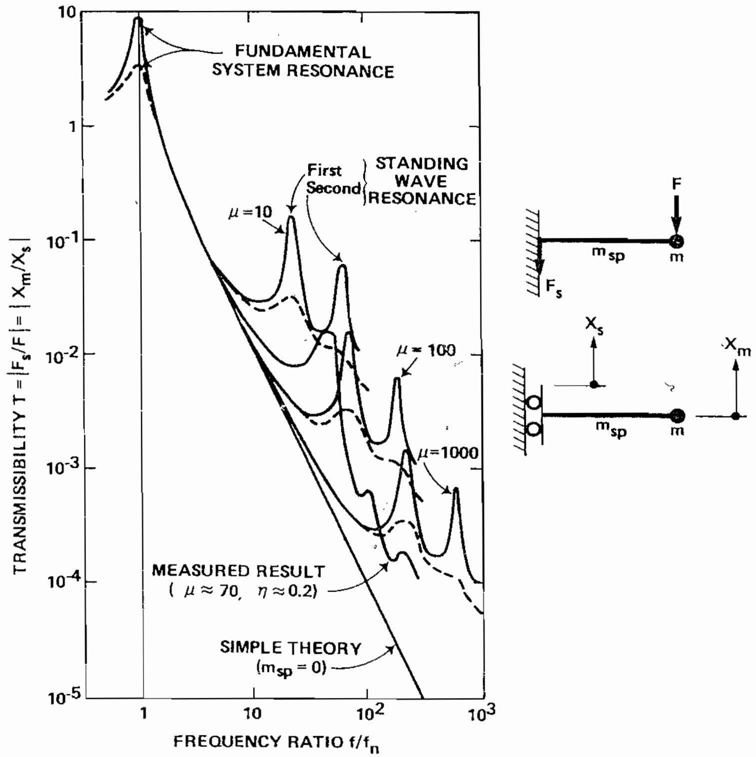

FIGURE 13.7 Effect of isolator mass and damping on transmissibility of uniform cantilever for three values of ratio $\mu = m/m_{sp}$ of isolated mass to mass of cantilever spring. (After Refs. 11 and 12.) Solid calculated lines are for loss factor $\eta = 0.1$; dashed lines for $\eta = 0.6$. (Measured result shown is from Ref. 13.) Frequency is normalized to f_n, the fundamental resonance frequency obtained with a massless spring.

The isolation effectiveness at any specified frequency of a system in which isolator mass effects are not negligible is given by[8]

$$E = \left|\frac{\alpha}{M_S + M_R}\right| \left|1 + \frac{M_S}{M_{Isb}} + \frac{M_R}{M_{Irb}}\left(1 + \frac{M_S}{M_{Isf}}\right)\right| \qquad (13.15)$$
$$\frac{1}{\alpha^2} = \frac{1}{M_{Irb}}\left(\frac{1}{M_{Isb}} - \frac{1}{M_{Isf}}\right)$$

where M_{Isb} denotes the isolator mobility (i.e., the velocity-to-force ratio) measured on the source side of the isolator if the receiver side of the isolator is "blocked" (i.e., prevented from moving), M_{Irb} denotes the mobility measured on the receiver side of the isolator if the source side is blocked, and M_{Isf} denotes the mobility measured on the source side if the receiver side is "free" or unconstrained. One may readily verify that Eq. (13.15) reduces to Eq. (13.14) for massless isolators, for which $M_{Isb} = M_{Irb} = M_I$ and M_{Isf} is infinite.

13.5 TWO-STAGE ISOLATION

A force applied to one side of a massless isolator, as has been mentioned, must be balanced by an equal and opposite force at the other side of the isolator. This is not the case for an isolator that incorporates some mass, because the force applied to one side then is balanced by the sum of the inertia force and the force acting on the other side of the isolator. Thus, unlike for a massless isolator, the force transmitted by an isolator with mass can be less than the applied force.

One may realize such a force reduction benefit, even at low frequencies at which mass effects in isolators themselves are negligible, by adding a lumped mass "inside" an isolator. One may visualize this concept by considering a spring that is cut into two lengths with a rigid block of mass welded in place between the two parts, resulting in an isolator consisting of two lengths of spring with a mass between them. If a mass m is mounted atop this isolator, one obtains a system that may be represented by a diagram like that of Fig. 13.8a. Because this system consists of a cascade of two spring–mass systems, it is said to have two stages of isolation.

Transmissibility

The system of Fig. 13.8a has two natural frequencies f_b that may be found from

$$\left(\frac{f_b}{f_0}\right)^2 = Q \pm \sqrt{Q^2 - B^2} \qquad Q = \frac{1}{2}\left(B^2 + 1 + \frac{k_2}{k_1}\right) \tag{13.16}$$

where

$$B = \frac{f_I}{f_0} \qquad 2\pi f_I = \sqrt{\frac{k_1 + k_2}{m_I}} \qquad 2\pi f_0 = \frac{1}{\sqrt{m(1/k_1 + 1/k_2)}} \tag{13.16a}$$

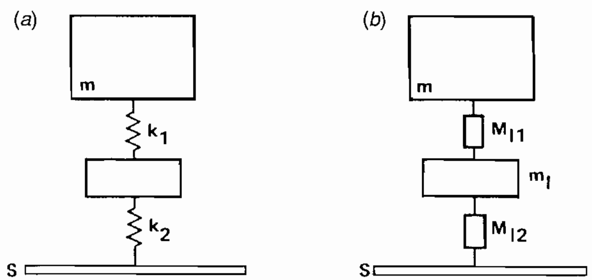

FIGURE 13.8 Two-stage isolation with intermediate mass m_I: (a) springs; (b) general isolation elements.

The frequency f_0 is the natural frequency of the system in the absence of any included mass m_I; that is, it is the natural frequency of a conventional simple single-stage system. The frequency f_I is the natural frequency of mass m_I moving between the two springs, with mass m held completely immobile. The upper frequency f_b, which one obtains if one uses the plus sign before the square root, always is greater than both f_0 and f_I; the lower frequency f_b, corresponding to the minus sign, always falls below both f_0 and f_I.

The transmissibility of a two-stage system like that of Fig. 13.8a obeys

$$\frac{1}{T} = \frac{1}{T_{F0}} = \frac{1}{B^2}\left(\frac{f}{f_0}\right)^4 - \left[1 + \frac{1 + k_2/k_1}{B^2}\right]\left(\frac{f}{f_0}\right)^2 + 1 \approx \left(\frac{f^2}{f_0 f_I}\right)^2 \tag{13.17}$$

where the last approximate expression applies for high frequencies, namely, for excitation frequencies that are much greater than both f_0 and f_I.

Figure 13.9 shows an illustrative plot of the transmissibility of an undamped two-stage system with $B = f_I/f_0 = 5$ and $k_2/k_1 = 1$, together with a plot of the transmissibility of an (undamped) single-stage system. The second natural frequency of the two-stage system (at $f/f_0 \approx 5.1$) is clearly evident, as is the subsequent rapid decrease in that system's transmissibility with increasing frequency. At high frequencies, that is, a little above the aforementioned second natural frequency, the transmissibility of the two-stage system may be seen to be smaller than that of a single-stage system with the same fundamental natural frequency. As evident from Eq. (13.17), the high-frequency transmissibility of a two-stage system varies inversely as the fourth power of the excitation frequency, whereas Eq. (13.5) indicates that the transmissibility of a single-stage system varies inversely as only the second power of the excitation frequency.

The advantage of a two-stage system over a single-stage system is that it results in greatly reduced transmissibility at high frequencies (i.e., above the higher of its two natural frequencies). It has the disadvantage that it introduces an additional transmissibility peak at a low frequency (i.e., at its second natural frequency). Thus, two-stage isolation is beneficial in general only if the aforementioned second natural frequency is somewhat lower than the lowest excitation frequency of concern. Thus, to reap the benefit of a two-stage system, one typically needs a relatively large intermediate mass m_I. Where several items need to be isolated, it often is advantageous to support these on a common massive platform (often called a "subbase" or "raft"), to isolate each item from the platform, and to isolate the platform from the structure that supports it. In this arrangement the platform serves as a relatively large intermediate mass for each of the isolated items, resulting in efficient two-stage isolation performance with comparatively small weight penalty.

Isolation Effectiveness

Although the foregoing results apply strictly only to isolators without damping, they also provide a reasonable approximation to the behavior of lightly damped systems, except near the natural frequencies. To account for high damping or more

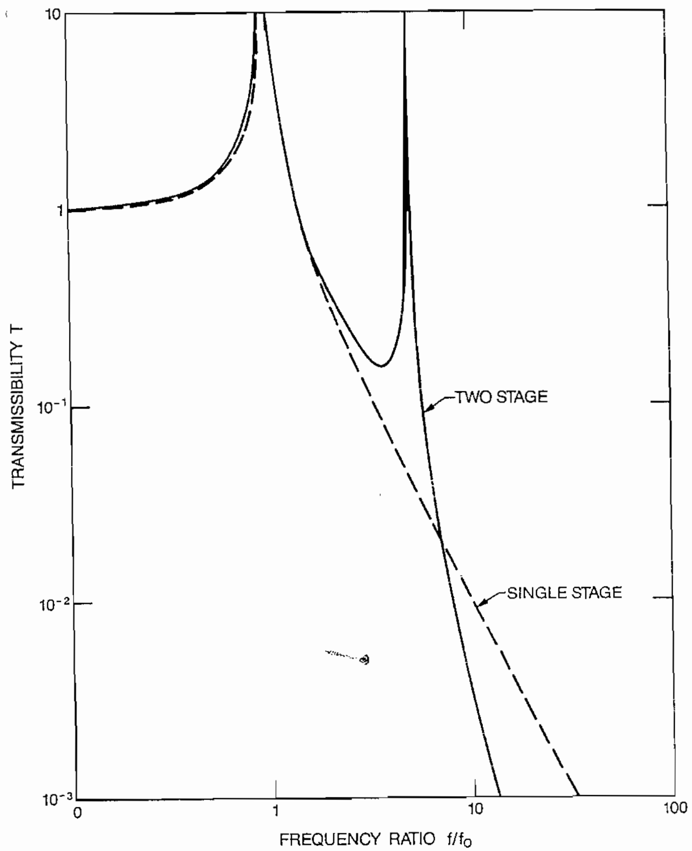

FIGURE 13.9 Transmissibility of two-stage system. Calculated from Eq. (13.17) for $k_2/k_1 = 1$ and $B = f_I/f_0 = 5$.

complicated linear isolator configurations (e.g., where each isolator is modeled by various series and parallel combinations of springs and dampers), it is convenient to represent each isolator by its mobility. A corresponding diagram appears in Fig. 13.8*b*. As has been discussed in Section 13.4, the source mobility M_S is a measure of a vibration source's susceptibility to loading effects, and the isolation effectiveness E is a measure of the isolation performance, which, unlike transmissibility, takes loading effects into account. If one takes S in Fig. 13.8*b* to represent a general linear source and replaces the mass m by a general linear receiver with mobility M_R, one obtains a general linear two-stage system whose effectiveness one may write as[8]

$$E = |E_1 + \Delta E| \qquad E_1 = 1 + \frac{M_I}{M_S + M_R} \tag{13.18}$$

where

$$M_I = M_{I1} + M_{I2} \qquad \Delta E = \frac{(M_{I1} + M_S)(M_{I2} + M_R)}{M_m(M_S + M_R)} \tag{13.18a}$$

One may recognize E_1 as corresponding to the effectiveness of a single-stage system [see Eq. (13.14)], that is, to a two-stage system with zero included mass, with M_I denoting the mobility of the two partial isolators in series. Thus, ΔE represents the effectiveness increase obtained by addition of the included mass m_I, whose mobility is M_m. Note that ΔE is inversely proportional to M_m, indicating that greater included masses generally result in greater effectiveness increases.

Optimization of Isolator Stiffness Distribution

Once one has selected the mobility M_I of the total isolator (or, equivalently, its compliance or stiffness), one needs to consider how to allocate this mobility among the components M_{I1} and M_{I2}. If one lets r_1 denote the fraction of the total mobility on the source side of the included mass, so that $M_{I1} = r_1 M_I$ and $M_{I2} = (1 - r_1)M_I$, it turns out that one may obtain the largest value of ΔE, namely,

$$\Delta E_{\max} = \frac{(M_I + M_s + M_R)^2}{4M_m(M_s + M_R)} \tag{13.19}$$

by making r_1 equal to its optimum value,*

$$r_{\text{opt}} = \frac{1}{2}\left(1 + \frac{M_R - M_S}{M_I}\right) \tag{13.20}$$

In view of Eq. (13.18a), in an efficient isolation system M_{I1} must be considerably greater than M_S, and also M_{I2} must be considerably greater than M_R. For such a system, one finds that $r_{\text{opt}} \approx \frac{1}{2}$ and that $\Delta E_{\max}$ may be approximated by replacing the expression in the parentheses of the numerator of Eq. (13.19) by M_I. Thus, if the total mobility of the isolator is sufficiently great, that is, if the total stiffness of the isolator is sufficiently small, one may generally obtain the greatest improvement $\Delta E_{\max}$ by allocating the same mobility or stiffness to the two isolator components.

It may be shown[8] that placing a given mass "within" the isolator as described above, so as to obtain a two-stage system with two like isolator mobility components, results in greater effectiveness than placement of the mass directly at the receiver as long as $M_I \gg M_R$. This inequality usually is likely to be satisfied in practice, except at resonances of the receiver at which M_R is very large. Similarly, as long as $M_I \gg M_S$, placing the mass within the isolator results in greater

*This result applies strictly only if the various mobilities or mobility ratios are real quantities. It suffices for development of an intuitive understanding, although more complicated expressions apply in the general case where the mobilities are represented by complex quantities.

effectiveness than placement of the mass directly at the source. The foregoing inequality generally is likely to be satisfied in practice, except for sources that behave essentially like force sources and thus have very high mobility.

13.6 PRACTICAL ISOLATORS

A great many different isolators are available commercially in numerous sizes and load capacities, with various attachment means, and with many types of specialized features.[4] Details concerning such isolators typically may be found in suppliers' catalogs.

Most commercial isolators incorporate metallic or elastomeric resilient elements. Metallic elements most often are in the form of coil springs but also occur in the form of flexural configurations such as leaf springs or conical Belleville washers. Coil springs are predominantly used in compression, usually because such tensile springs tend to involve configurations that give rise to stress concentrations and thus have lesser fatigue life. Coil spring isolator assemblies often involve parallel and/or series arrangements of springs in suitable housings, are designed to have the same stiffness in the lateral directions as in the axial direction, and may also incorporate friction devices (such as wire mesh inserts), snubbers to limit excursions due to large disturbances (such as earthquakes), and in-series elastomeric pads for enhanced damping and isolation at high frequencies. Spring systems in housings need to be installed with care to avoid binding between the housing elements and between these elements and the springs.

Some commercial metallic isolators employ pads or woven assemblies of wire mesh to provide both resilience and damping. Others use arrangements of coils or loops of wire rope not only to provide damping but also to serve as springs.

A great many commercially available isolators that employ elastomeric elements have these elements bonded or otherwise attached to support plates or sleeves that incorporate convenient means for fastening to other components. The isolators may be designed so that the elastomeric element is used in shear, torsion, compression, or a combination of these modes. There are also available a variety of elastomeric gaskets, grommets, sleeves, and washers, intended to be used with bolts or similar fasteners to provide both connection and isolation.

Elastomeric pads often are used as isolators by themselves, as are pads of other resilient materials, such as cork, felt, fiberglass, and metal mesh. Such pads often are convenient and relatively inexpensive; their areas can be selected to support the required loads, and their thicknesses can be chosen to provide the desired stiffness.

In the design and selection of pads of solid (in contrast to foamed) elastomeric materials, one needs to take into account that a pad's stiffness depends not only on its thickness and area but also on its shape and constraints. This behavior is due to the incompressibility of elastomeric materials, which essentially prevents a pad from changing its volume as it is compressed and thus in essence does not permit a pad to be compressed if it is confined so that its edges cannot bulge outward. A pad's freedom to compress may be characterized by its shape factor, defined as the ratio of its loaded area to the total area of the edges that are free to bulge; the greater the shape factor, the greater is the pad's effective stiffness. However, a pad's freedom to deform while maintaining constant volume also is affected by how easily the loaded surfaces can slip relative to the adjacent surfaces; the more restricted this slippage, the greater the pad's effective stiffness. Some commercial isolation pads are furnished with top and bottom load-carrying surfaces bonded to metal or other stiff plates to eliminate the stiffness uncertainties due to unpredictable slippage.

To avoid the need for considering the shape factor in pad selection, many commercial isolation pad configurations have a multitude of cutouts (e.g., closely spaced arrays of holes) or ribs, which provide roughly constant amounts of bulging area per unit surface area. If ribbed or corrugated pads or pads with cutouts are used in stacks, plates of a stiff material (e.g., metal sheets) generally are used between pads to distribute the load on the load-bearing surfaces and to avoid having protrusions on one pad extending into openings on the adjacent pad.

So-called pneumatic, or air spring, isolators, which have found considerable use, obtain their resilience primarily from the compressibility of confined volumes of air. They may take the form of air-filled pillows of rubber or plastic, often with cylindrical or annular shapes, or they may consist essentially of piston-in-cylinder arrangements. Air springs can be designed to have small effective stiffnesses while supporting large loads and to have smaller heights than metal springs of equal stiffness. Practical air springs typically can provide fundamental resonance frequencies that may be as low as about 1 Hz. Some air spring configurations are laterally unstable under some load conditions and require the use of lateral restraints; some are available with considerable lateral stability.

Air springs of the piston-and-cylinder type can be provided with leveling controls, which automatically keep the isolated item's static position at a predetermined distance from a reference surface and (by use of several air springs and a suitable control system) at a predetermined inclination. The stiffness of a piston-type air spring is proportional to PA^2/V, where P denotes the air pressure, A the piston face area, and V the cylinder volume. The product $(P - P_0)A$, where P_0 represents the ambient atmospheric pressure, is equal to the static load carried by the spring. Lower stiffnesses may be obtained with a given area at a given air pressure by use of larger effective volumes; for this reason, some commercial air spring isolators are available with auxiliary tanks that communicate with the cylinder volume via piping. In some instances, a flow constriction in this piping is used to provide low-frequency damping. If the pressure in a piston-and-cylinder-type air spring is considerably greater than the atmospheric pressure, the pressure in the spring is nearly proportional to the load it supports. Because the spring's stiffness is proportional to this pressure, the natural frequency one obtains with such an air spring isolation system is essentially independent of the load, making air springs (like other constant-natural-frequency systems[4]) particularly useful for applications in which the loads are variable or uncertain.

Pendulum arrangements often are convenient means for obtaining horizontally acting isolation systems with low natural frequencies. One may calculate the horizontal natural frequency of a pendulum system from Eq. (13.3) if one replaces X_{st} in that equation by the pendulum length. Some commercial isolation systems combine pendulum action for horizontal isolation with spring action for vertical isolation.

Various exotic isolation systems have also been investigated or employed for special applications. These include systems in which the spring action is provided by magnetic or electrostatic levitation or by streams or thin films of gases or liquids.

Active isolation systems (see Chapter 18) have recently received increased attention. Such systems essentially are dynamic control systems in which the vibration of the item to be protected is sensed by an appropriate transducer whose suitably processed output is used to drive an actuator that acts on the item so as to reduce its vibration. Active systems are relatively complex, but they can provide better isolation than passive systems under some conditions, notably, in the presence of low-frequency disturbances, attenuation of which by passive means generally tends to be most difficult.

CHAPTER 14

Structural Damping

ERIC E. UNGAR AND JEFFREY A. ZAPFE

Acentech, Inc.
Cambridge, Massachusetts

14.1 THE EFFECTS OF DAMPING

The dynamic responses and sound transmission characteristics of structures are determined by essentially three parameters: mass, stiffness, and damping. Mass and stiffness are associated with storage of kinetic and strain energy, respectively, whereas damping relates to the dissipation of energy, or, more precisely, to the conversion of the mechanical energy associated with a vibration to a form (usually heat) that is unavailable to the mechanical vibration.

Damping in essence affects only those vibrational motions that are controlled by a balance of energy in a vibrating structure; vibrational motions that depend on a balance of forces are virtually unaffected by damping. For example, consider the response of a classical mass–spring–dashpot system to a steady sinusoidal force. If this force acts at a frequency that is considerably lower than the system's natural frequency, the response is controlled by a quasi-static balance between the applied force and the spring force. If the applied force acts at a frequency that is considerably above the system's natural frequency, the response is controlled by a balance between the applied force and the mass's inertia. In both of these cases, damping has practically no effect on the responses. However, at resonance, where the excitation frequency matches the natural frequency, the spring and inertia effects cancel each other and the applied force supplies some energy to the system during each cycle; as a result, the system's energy (and amplitude) increases until steady state is reached, at which time the energy input per cycle is equal to the energy lost per cycle *due to damping*.

In light of energy considerations like the foregoing, one finds that increased damping results in (1) more rapid decay of unforced vibrations, (2) faster decay of freely propagating structure-borne waves, (3) reduced amplitudes at resonances of structures subject to steady periodic or random excitation with attendant reductions in stresses and increases in fatigue life, (4) reduced response to sound and increased sound transmission loss (reduced sound transmission) above the coincidence frequency (at which the spatial distribution of the disturbing pressure the horizontal natural frequency of a pendulum system from Eq. (13.3) if one replaces X_{st} in that equation by the pendulum length. Some commercial isolation systems combine pendulum action for horizontal isolation with spring action for vertical isolation.

Various exotic isolation systems have also been investigated or employed for special applications. These include systems in which the spring action is provided by magnetic or electrostatic levitation or by streams or thin films of gases or liquids.

Active isolation systems (see Chapter 18) have recently received increased attention. Such systems essentially are dynamic control systems in which the vibration of the item to be protected is sensed by an appropriate transducer whose suitably processed output is used to drive an actuator that acts on the item so as to reduce its vibration. Active systems are relatively complex, but they can provide better isolation than passive systems under some conditions, notably, in the presence of low-frequency disturbances, attenuation of which by passive means generally tends to be most difficult.

14.1 THE EFFECTS OF DAMPING

The dynamic responses and sound transmission characteristics of structures are determined by essentially three parameters: mass, stiffness, and damping. Mass and stiffness are associated with storage of kinetic and strain energy, respectively, whereas damping relates to the dissipation of energy, or, more precisely, to the conversion of the mechanical energy associated with a vibration to a form (usually heat) that is unavailable to the mechanical vibration.

Damping in essence affects only those vibrational motions that are controlled by a balance of energy in a vibrating structure; vibrational motions that depend on a balance of forces are virtually unaffected by damping. For example, consider the response of a classical mass–spring–dashpot system to a steady sinusoidal force. If this force acts at a frequency that is considerably lower than the system's natural frequency, the response is controlled by a quasi-static balance between the applied force and the spring force. If the applied force acts at a frequency that is considerably above the system's natural frequency, the response is controlled by a balance between the applied force and the mass's inertia. In both of these cases, damping has practically no effect on the responses. However, at resonance, where the excitation frequency matches the natural frequency, the spring and inertia effects cancel each other and the applied force supplies some energy to the system during each cycle; as a result, the system's energy (and amplitude) increases until steady state is reached, at which time the energy input per cycle is equal to the energy lost per cycle *due to damping*.

In light of energy considerations like the foregoing, one finds that increased damping results in (1) more rapid decay of unforced vibrations, (2) faster decay of freely propagating structure-borne waves, (3) reduced amplitudes at resonances of structures subject to steady periodic or random excitation with attendant reductions in stresses and increases in fatigue life, (4) reduced response to sound and increased sound transmission loss (reduced sound transmission) above the coincidence frequency (at which the spatial distribution of the disturbing pressure matches that of the structural displacement), (5) reduced rate of buildup of vibrations at resonances, and (6) reduced amplitudes of "self-excited" vibrations, in which the vibrating structure accepts energy from an external source (e.g., wind) as the result of its vibratory motion.

14.2 MEASURES AND MEASUREMENT OF DAMPING

Most measures of damping are based on the dynamic responses of simple systems with idealized damping behaviors. Damping measurements typically involve observation of some characteristics of these responses.

Decay of Unforced Vibrations with Viscous Damping

Many aspects of the behaviors of vibrating systems can be understood in terms of the simple ideal linear mass–spring–dashpot system shown in Fig. 14.1. If this system is displaced by an amount x from its equilibrium position, the massless spring produces a force of magnitude kx tending to restore the mass m toward its equilibrium position, and the massless dashpot produces a retarding force of magnitude $c\dot{x}$. Here k and c are constants of proportionality; k is known as the spring constant and c as the *viscous damping coefficient.*

If this system is displaced from its equilibrium position by an amount X_0 and then released, the resulting displacement varies with time t as[1]

$$x = X_0 e^{-\zeta\omega_n t} \cos(\omega_d t + \phi) \tag{14.1}$$

provided that $\zeta < 1$. Here ϕ represents a phase angle, which depends on the velocity with which the mass is released, and ω_n and ω_d represent the undamped and damped radian natural frequencies of the system. These obey

$$\omega_n = \sqrt{\frac{k}{m}} = 2\pi f_n \qquad \omega_d = \omega_n\sqrt{1-\zeta^2} \tag{14.2}$$

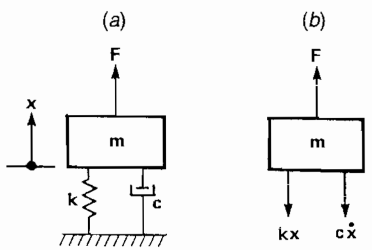

FIGURE 14.1 System with single degree of freedom: (*a*) schematic representation of mass–spring–dashpot system or of a vibrational mode of a structure; (*b*) free-body diagram of mass. Spring produces restoring force kx; dashpot produces retarding force $c\dot{x}$.

with f_n representing the cyclic (undamped) natural frequency. The constant ζ is called the *damping ratio* or *fraction of critical damping*; it is defined as

$$\zeta = \frac{c}{c_c} \qquad c_c = 2\sqrt{km} = 2m\omega_n \tag{14.3}$$

where c_c is known as the *critical damping coefficient*. For the small values of ζ one usually encounters in practice, ω_d is sufficiently close to ω_n so that one rarely needs to distinguish between the damped and the undamped natural frequencies. Furthermore, the foregoing expression for ω_d applies only for viscous damping; other relations hold for other damping models.

The right-hand side of Eq. (14.1) represents a cosine function with an amplitude $X_0 e^{-\zeta\omega_n t}$ that decreases as time t increases (see Fig. 14.2); its rate of decrease is $\zeta\omega_n$ and thus is proportional to ζ. However, Eq. (14.1) does not apply for values of ζ that equal or exceed unity (or for values of c that equal or exceed c_c). For such large values of ζ or c one obtains a nonoscillatory decay represented by pure exponential expressions instead of the decaying oscillation represented by Eq. (14.1). The critical damping coefficient c_c constitutes the boundary between oscillatory and nonoscillatory decays.

The *logarithmic decrement* δ is a convenient, time-honored representation of how rapidly a free oscillation decays. It is defined by[1]

$$\delta = \frac{1}{N}\ln\frac{X_i}{X_{i+N}} \tag{14.4}$$

where X_i represents the value of x at any selected peak and X_{i+N} represents the value at the peak at N cycles from the aforementioned one. It follows from Eq. (14.1) that $\delta = 2\pi\zeta$.

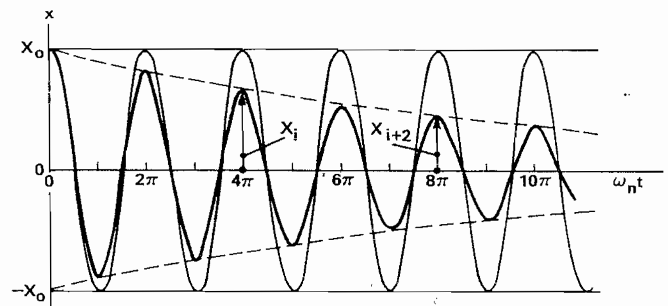

FIGURE 14.2 Time variation of displacement of mass–spring–dashpot system released with zero velocity from initial displacement X_0. *Light curve*: Undamped system ($c = \zeta = 0$); amplitude remains constant at X_0. *Heavy curve*: Damped system ($0 < c < c_c$; $0 < \zeta < 1$); amplitude decreases according to $x = X_0 e^{-\zeta\omega_n t}$, which is represented by upper dashed curve. Lower dashed curve corresponds to $x = -X_0 e^{-\zeta\omega_n t}$. Amplitudes X_i and X_{i+2} illustrate values that may be used to calculate logarithmic decrement from Eq. (14.4) for $N = 2$.

The utility of logarithmic measures of oscillatory quantities has long been recognized in acoustics, and definitions analogous to acoustical levels have come into use in the field of vibrations, particularly in regard to measurement. For example, one may define the displacement level L_x, in decibels, corresponding to an oscillatory displacement $x(t)$ in analogy to sound pressure level, as

$$L_x = 10 \log_{10} \frac{x^2(t)}{x_{\text{ref}}^2} \tag{14.5}$$

where x_{ref} denotes a (constant) reference value of displacement. One may then define a decay rate Δ, in decibels per second, and find that for a viscously damped system[2]

$$\Delta = -\frac{dL_x}{dt} = 8.69\zeta\omega_n = 54.6\zeta f_n \tag{14.6}$$

Also in analogy to acoustics, one may define the reverberation time T_{60} as the time it takes for the displacement level to decrease by 60 dB; thus,

$$T_{60} = \frac{60}{\Delta} = \frac{1.10}{\zeta f_n} \tag{14.7}$$

Because velocity and acceleration levels may be defined in full analogy to the definition of displacement level in Eq. (14.5), the decay rate and reverberation time expressions of Eqs. (14.6) and (14.7) also apply to these other vibration levels.

If any extended structure that is not too highly damped vibrates in the absence of external forces at one of its natural frequencies, all points on that structure move either in phase or in opposite phase with each other, and the structure is said to vibrate in one of its modes. In addition to the modal natural frequency, there corresponds to each mode a modal mass, a modal stiffness, and a modal damping value. With the aid of these parameters the behavior of a modal vibration may be described in terms of that of an equivalent simple mass–spring–dashpot system.[1,3,4] Thus, all of the foregoing discussion concerning this simple system also applies to structural modes.

Of course, extended structures also can exhibit wave motions at a given frequency in which all points are not in or out of phase with each other. Such motions, which can be described in terms of freely propagating waves, also decrease due to damping. For flexural waves on a beam or for nonspreading (straight-crested) flexural waves on a plate, the *spatial decay rate* Δ_λ, defined as the reduction in vibration level per wavelength, obeys[2] $\Delta_\lambda = 27.2\zeta$ in decibels per wavelength.

Steady Forced Vibrations

If the system of Fig. 14.1 is subject to a sinusoidal force $F(t) = F \cos \omega t$, then its equation of motion may be written as

$$m\ddot{x} + c\dot{x} + kx = F(t) = F \cos \omega t \tag{14.8}$$

One may find its steady-state solution by substituting $x(t) = X\cos(\omega t - \phi)$ and solving for X and ϕ. Alternatively, one may obtain this solution by taking $x(t) = \text{Re}\lfloor \overline{X} e^{j\omega t} \rfloor$, where $j = \sqrt{-1}$ and the complex amplitude or *phasor* $\overline{X} = Xe^{-j\phi}$ indicates both the amplitude and the phase of the vibration.* In terms of phasors (and omitting the writing of "Re"), the equation of motion may be written as

$$(-m\omega^2 + j\omega c + k)\overline{X} = (\overline{k} - m\omega^2)\overline{X} = F \tag{14.9}$$

In the foregoing there has been introduced the complex stiffness

$$\overline{k} = k + j\omega c = k + k_i = k\left(1 + \frac{jk_i}{k}\right) \tag{14.10}$$

which includes information about the system's damping as well as about it stiffness. By means of either solution approach one may determine that

$$\frac{X}{F/k} = \frac{X}{X_{\text{st}}} = \frac{1}{\sqrt{(1-r^2)^2 + (2r\zeta)^2}} \qquad \tan\phi = \frac{2r\zeta}{1-r^2} \tag{14.11}$$

where $r \equiv \omega/\omega_n$.

The deflection $X_{\text{st}} = F/k$, which was introduced in order to obtain a nondimensional expression, is the quasi-static or zero-frequency deflection that the system would experience due to a statically applied force of magnitude F. The ratio X/X_{st}, which indicates by what factor the amplitude under dynamic excitation exceeds the quasi-static deflection, is called the *amplification*.

The foregoing response expressions (and related ones that involve velocity V or acceleration A instead of displacement) depend on damping; thus, damping data may be extracted from corresponding measurements. Two widely used measures of damping may be derived readily from the amplification expressions of Eq. (14.11), a plot of which is shown in Fig. 14.3. One is the *amplification at resonance*, conventionally represented by the letter Q and often simply called "the Q" of the system.[2] This corresponds to the value of X/X_{st} that results if the excitation frequency ω is equal to the natural frequency ω_n and is related to the viscous damping ratio by $Q = 1/2\zeta$. The second commonly used measure is the *relative bandwidth* $b = \Delta\omega/\omega_n \approx 1/Q$, where $\Delta\omega$ represents the difference between the two frequencies† (one below and one above ω_n; see Fig. 14.3) at which the amplification is equal to $Q/\sqrt{2}$.

In view of Eq. (14.11), the phase lag ϕ also provides a measure of damping. It is particularly convenient to use phase information in "Nyquist plots," that is, in plots of the real and imaginary parts of responses at a number of frequencies, as illustrated in Fig. 14.4. These plots are circles or nearly circles, with a diameter that is equal to Q if the plots are appropriately nondimensionalized.[5,6]

*Note that $e^{jz} = \cos z + j \sin z$ for any real number z. The amplitude X is equal to the absolute value of the phasor; that is, $X = |\overline{X}|$.

†These frequencies often are called the *half-power points* because at these the energy stored in the system (and that dissipated by it), which is proportional to the square of the amplitude [see Eq. (14.6)], is half of the maximum value.

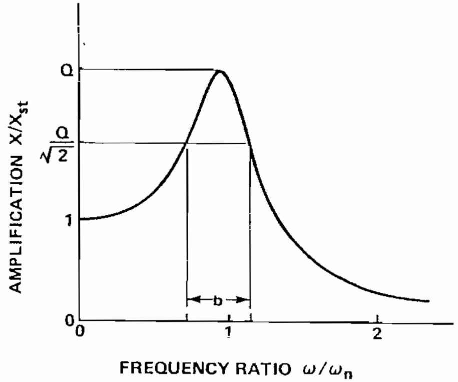

FIGURE 14.3 Steady-state response of mass–spring–dashpot system to sinusoidal force. See Eq. (14.11): Q = value of amplification X/X_{st} at resonance. Relative bandwidth $b = \Delta\omega/\omega_n$ is determined from "half-power points," that is from frequencies at which response amplitude is $1/\sqrt{2}$ times the maximum.

If the system of Fig. 14.1 (or a structural mode modeled by it) is subject to a broadband force (or broadband modal force) rather than a single-frequency sinusoidal force, then the mean-square displacement $\overline{x}^2$ of the mass is given by[7]

$$\frac{\overline{x}^2}{\pi S_F(\omega)\omega_n/k^2} = \frac{1}{2\zeta} \tag{14.12}$$

where $S_F(\omega)$ denotes the spectral density of the force in terms of radian frequency (i.e., the value of excitation force squared per unit radian frequency interval). Note that the spectral density in cyclic frequency obeys $S_F(f) = 2\pi S_F(\omega)$. The foregoing equation is exact for excitations with spectral densities that are constant for all frequencies. It is a good approximation for excitations with spectral densities that vary only slowly in the vicinity of the system's natural frequency ω_n; the spectral density value to be used in the equation then is that corresponding to ω_n.

Energy; Complex Stiffness

All of the measures of damping discussed so far are based on the motions of simple systems. However, since damping pertains to the dissipation of energy, damping measures that relate to energy are more basic and more general.

The *damping capacity* ψ is defined as the ratio of the energy that is dissipated per cycle to the total energy present in the vibrating system. The *loss factor* η is defined similarly as the ratio of the energy that is dissipated per radian to the total energy. If D denotes the energy dissipated per cycle and W the total energy in the system, then

$$\eta = \frac{\psi}{2\pi} = \frac{D}{2\pi W} \tag{14.13}$$

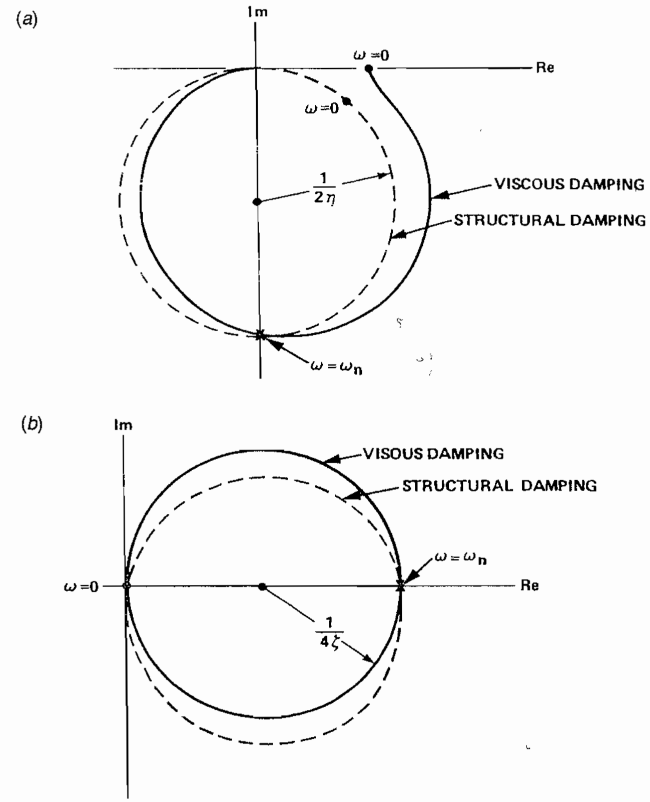

FIGURE 14.4 Nyquist plots of nondimensional responses of viscously and structurally damped mass–spring–damper systems. (*a*) Real and imaginary parts of amplification X/X_{st}. (*b*) Real and imaginary parts of mobility $Vk/F\omega_n = Vc_c/2F$. Amplification plot for structural damping and mobility plot for viscous damping are exact circles; others are approximate circles that become more nearly circular with decreased damping. Diameter is exactly or approximately equal to Q. Figure plots correspond to $\zeta = 0.2$, $\eta = 0.4$.

These expressions apply for any damping mechanism. However, it is interesting to relate them to the special case of a viscously damped mass–spring–dashpot system like that of Fig. 14.1. In this system the energy dissipated corresponds to the work that is done on the dashpot, and one may readily determine that the energy dissipated per cycle in a steady vibration at radian frequency ω and displacement amplitude X obeys $D = \pi\omega c X^2$. The total energy W stored by the system consists of the kinetic energy W_{kin} of the mass and the potential (or strain) energy W_{pot} in the spring. If the energy dissipated is small compared to the total energy stored, then W is approximately equal to the energy stored in the spring when the kinetic energy is zero—that is, when the spring is displaced to the full extent of its amplitude—and $W = W_{kin} + W_{pot} \approx kX^2/2$.

Thus, one finds by use of Eqs. (14.3) and (14.13) that for a viscously damped system

$$\eta \approx \frac{\omega c}{k} = \frac{2\zeta\omega}{\omega_n} = 2r\zeta \tag{14.14}$$

From Eq. (14.10) one finds that

$$\overline{k} = k(1 + j\eta) \qquad k_i/k = \eta \tag{14.15}$$

Equation (14.14) indicates that for the particular case of a viscously damped system the loss factor is proportional to the frequency. In cases where the loss factor exhibits some other frequency dependence, Eqs. (14.13) and (14.15) still apply—and Eq. (14.11) holds if $2r\zeta$ is replaced by η. These equations then permit one not only to consider the case of *structural damping*, which is characterized by a constant loss factor, but also to take into account experimentally determined frequency variations of the loss factor.

Interrelation of Measures of Damping

The following relations apply at all frequencies:

$$\eta = \frac{\psi}{2\pi} = \frac{k}{k_i} = |\tan\phi|_{r=0} \tag{14.16a}$$

but the relations of Eq. (14.16b) are exact only at resonance:

$$\eta = \frac{1}{Q} = 2\zeta \qquad \text{and} \qquad \eta \approx b \text{ for small damping} \tag{14.16b}$$

For systems with viscous damping,

$$2\zeta = \frac{\delta}{\pi} = \frac{2.20}{f_n T_{60}} = \frac{\Delta}{27.3 f_n} = \frac{\Delta_\lambda}{13.6} \tag{14.16c}$$

For systems with small damping, one may take $\eta \approx 2\zeta$, consider that the system behaves approximately like a viscously damped one, and use the relations of Eq. (14.16c).

Measurement of Damping

Most approaches to measurement of the damping of structures are based on the previously discussed responses of simple systems, which, as has been mentioned, also correspond to those of structural modes. However, unlike mass–spring–dashpot systems, structures have a multiplicity of modes and corresponding natural frequencies. Therefore, many of the approaches applicable to simple systems can be applied only to structural modes whose responses can be separated adequately from those of all others because of differences in their natural frequencies or mode shapes.

Measurement of logarithmic decrement δ typically is applicable only to the fundamental modes of structures for which a clear record of the amplitude-versus-time trace can be obtained. If more than one mode is present, their decaying responses are superposed and the record becomes difficult to interpret.

The counting of peaks that is required for determination of the logarithmic decrement from Eq. (14.4) is not needed if one focuses on the decaying signal's envelope. For purposes of evaluating this envelope it is particularly convenient to use a display of the logarithm of the rectified amplitude versus time. Rectification is needed because the logarithm of negative numbers is undefined. In such a logarithmic display the envelope becomes a straight line whose slope is proportional to $\zeta\omega_n$ and thus to the decay rate. Not only does measurement of the slope enable one to evaluate the damping, but also observation of deviations of the envelope from a straight line permit one to judge whether the structure's damping is indeed viscous and amplitude-independent and whether a superposition of responses with different decay rates is present.

Determination of decay rates is useful also in frequency bands in which a multitude of modes are excited. A typical measurement here involves excitation of a structure by a broadband force in a given frequency band, cutting off the excitation, then observing the envelope of the logarithm of the rectified signal obtained by passing the output of a transducer (usually an accelerometer) through a bandpass filter* tuned to the excitation band. The center frequency of this passband may be taken to represent ω_n for all modes in the band. Some judgment in interpreting the resulting envelopes and averaging of results from repeated measurements is generally required because different modes in the band may exhibit somewhat different decays.

A conceptually straightforward approach to measuring the damping of a structure involves the application of Eq. (14.13) to observed values of the energy dissipation and total vibrational energy W present in a structure in the steady state.[8] The structure is excited via an impedance head or a similar transducer arrangement that measures the force and motion at the excitation point. The instantaneous force and velocity values are multiplied and the product is time averaged to yield the average energy input per unit time, which is equal to the energy dissipated per unit time under steady-state conditions. For a given excitation frequency f, the energy D dissipated per cycle is equal to $1/f$ times the energy dissipated per unit time.

The energy W stored in the structure may be determined from its kinetic energy, which may be calculated from information on its mass distribution and from velocity values measured by a suitable array of accelerometers or other motion transducers. This measurement approach requires particular care in instrumentation selection and calibration, but it has a significant advantage: Because it involves direct measurement of the dissipated energy, it does not rely on any

*The filter's response must be fast enough so that it can follow the decaying signal; otherwise one observes the decay of the filter response instead of that of the structural vibration. Filters with wider passbands need to be used to observe the more rapid decays associated with greater damping.

particular model of dissipation. It also permits one, for example, to investigate how the loss factor varies with amplitude.

Force-and-motion transducer combinations may also be employed for the direct measurement of complex impedance or mobility (or of other force–motion ratios), from which damping information may be extracted, typically on the basis of Nyquist plots. Much corresponding specialized *modal testing* or *modal parameter extraction* instrumentation and software has recently become available.

Simple steady sinusoidal response measurements may also be made to measure Q and the half-power point bandwidth b directly on the basis of their definitions. These measurements require particular care to ensure that the near-resonance response of the mode of interest is not affected significantly by the responses of other modes with resonance frequencies near that of the mode of interest.

14.3 DAMPING MODELS

Analytical Models

Most of the foregoing discussion has dealt with "viscous" damping, where energy dissipation results from a force that is proportional to the velocity of a vibrating system and that acts opposite to the velocity. This viscous model of damping action has been used most widely because it results in relatively simple linear differential equations of system motion and because it yields a reasonable approximation to the action of some real systems, particularly at small amplitudes.

Among the many other models that have received considerable attention, most also involve a motion-opposing force that is a function of velocity. In *dry friction* or *Coulomb* damping, the force is constant in magnitude (but changes its algebraic sign when the velocity does). In *square law* and *power law* damping the force magnitude is proportional to the square or to some other power of velocity. Of course, modern numerical methods also permit one readily to analyze models involving other velocity dependences, such as one might obtain from corresponding experiments.

Whereas in viscous damping the retarding force is proportional to the velocity, in *structural damping* the retarding force is proportional to the displacement. As has been mentioned, structural damping is characterized by a constant loss factor η and the dimensionless response relation for a system with structural damping is given by Eq. (14.11) with $2r\zeta$ replaced by η. Because of the difference in the retarding forces, a structurally damped system behaves differently from a viscously damped one, except near the natural frequency. The structural damping model is often extended to loss factors that vary with frequency as determined from experimental data. With the appropriate frequency dependence of the loss factors, the structural damping model can be made to represent the sinusoidal response of viscously damped systems—and, indeed, of any system whose loss factor is independent of amplitude.*

*Caution is required if one wants to undertake transformations from the frequency to the time domain. Not all conceivable frequency variations of the loss factor lead to physically realizable results; e.g., some imply system motions that begin before application of a force.[9]

Applicability of Models

If one desires to determine the precise response of a system to a prescribed excitation, one generally needs to have a complete description of all forces, including the damping forces; that is, one needs a damping model that corresponds to the actual system. This is true, for example, if one wants to study the "wave shape" of the motion of a screeching brake or a chattering tool or if one needs to determine the response of a system to a transient, such as a shock.

In many practical instances, however, the details of the system's motion are of no interest and only the amplitudes are of concern. As has been mentioned, under steady resonant or free decay conditions (and in a few other situations), the amplitudes are established essentially by the energy in the system. For such conditions, the details of the damping model are unimportant as long as the model gives the correct energy dissipation per cycle. It is for this reason that measures of damping that involve only energy considerations have found wide acceptance.*

14.4 DAMPING MECHANISMS AND MAGNITUDES

Since damping involves the conversion of energy associated with a vibration to other forms that are unavailable to the vibration, there are as many damping mechanisms as there are ways to remove energy from a vibrating system. These include mechanisms that convert mechanical energy into heat, as well as others that transport energy away from the vibrating system of concern.

Energy Dissipation and Conversion

Material damping, mechanical hysteresis, and internal friction refer to the conversion of mechanical energy into heat that occurs within materials due to deformations that are imposed on them. This conversion may result from a variety of effects on the molecular, crystal lattice, or metal grain level, including magnetic, thermal, metallurgical, and atomic phenomena.[10] Figure 14.5 indicates the ranges of the loss factors reported for some common materials.

Damping of a vibrating structure may also result from friction associated with relative motion between the structure and solids or fluids that are in contact with it. Also, an electrically conductive structure moving in a magnetic field is subject to damping due to eddy currents that result from the motion and that are converted into heat.

A granular material, such as sand, placed in contact with a vibrating structure tends to produce damping by two different mechanisms. At small amplitudes, damping results predominantly from interaction of asperities on adjacent grains and the attendant energy loss due to mechanical hysteresis. At large amplitudes,

*Equivalent viscous damping, defined as viscous damping that results in the same energy dissipation as the damping actually present in the system, is often used in analyses. This damping model obviously should not be used where details of the system motion are of concern.

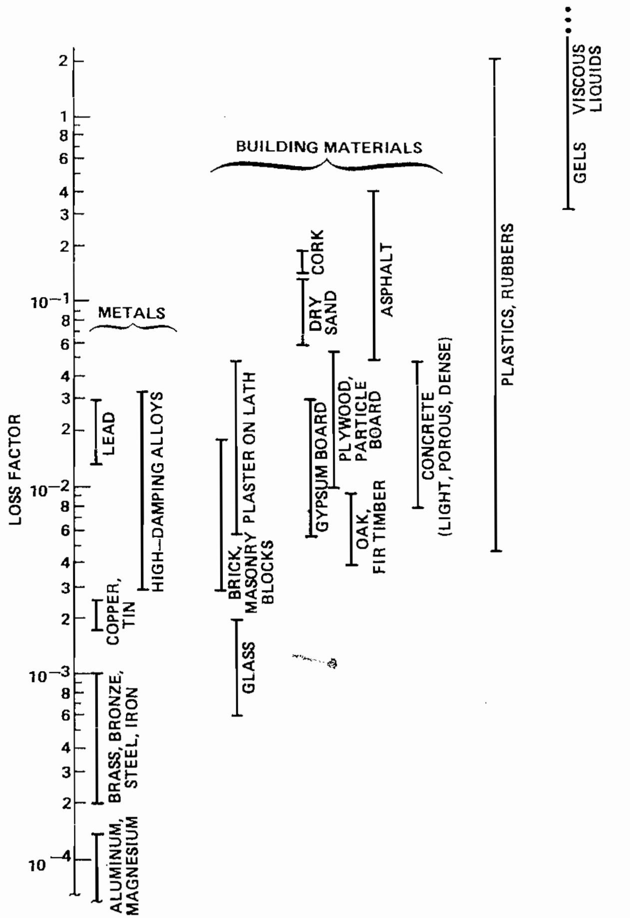

FIGURE 14.5 Typical ranges of material loss factors at small strains, near room temperature, at audio frequencies. The loss factors of metals tend to increase with strain amplitude, particularly near the yield point, but the loss factors of plastics and rubbers tend to be relatively independent of strain amplitude up to strains of the order of unity. The loss factors of some materials, particularly those that can flow or creep, tend to vary markedly with temperature and frequency.

damping results predominantly from impacts between the structure and the grains or between grains; these impacts produce high-frequency vibrations of the structure and of the granular material, and the energy that goes into these vibrations (which eventually is converted to heat) is no longer available to the structural vibrations of concern.[11] Impact dampers, in which a small element is made to rattle against a vibrating structure, similarly rely on conversion of the energy of the vibrating structure to higher frequency vibrations.

Damping due to Boundaries and Reinforcements

For panels or other structural components that may be considered as uniform plates, one may estimate the loss factor η_b associated with energy loss at the panel boundaries, due to both energy transport to adjacent panels and dissipation at its boundaries, from information on the boundary absorption coefficients.[12] For a panel of area A vibrating at a frequency at which the flexural wavelength λ on the panel is considerably shorter than a panel edge, this loss factor is given by

$$\eta_b = \frac{\lambda}{\pi^2 A} \sum \gamma_i L_i \tag{14.17}$$

where γ_i denotes the absorption coefficient of the ith boundary increment whose length is L_i and where the summation extends over all boundary increments.

At frequency f the flexural wavelength on a homogeneous plate of thickness h of a material with longitudinal wave speed c_L and Poisson's ratio ν is given by $\lambda = \sqrt{(\pi/\sqrt{3})hc_L/f(1-\nu^2)}$.

The absorption coefficient γ of a boundary element is defined as the fraction of the panel bending-wave energy impinging on the boundary element that is not returned to the panel. Although the absorption coefficient values associated with a given boundary element rarely can be predicted well analytically, they can often be determined experimentally. For example, one might add a boundary element of length L_0 to a panel, measure the resulting loss factor increase $\Delta\eta$ at various frequencies, and calculate the absorption coefficient values γ_0 of this boundary element from $\gamma_0 = (\Delta\eta)\pi^2 A/\lambda L_0$, which follows from Eq. (14.17). Both Eq. (14.17) and the expression for γ_0 are based on the assumption that the absorption coefficient of a boundary element is independent of its length, an assumption that generally holds true if the wavelength λ is considerably smaller than the element length.

Equation (14.17) also permits one to account for the damping effects of linear discontinuities, such as seams or attached reinforcing beams, on panels, provided one knows the corresponding absorption coefficients. Since plate waves can impinge on both sides of a discontinuity located within the panel area, for such a discontinuity location one needs to use in Eq. (14.17) twice the actual discontinuity length.

The energy that beams or reinforcements attached to a panel can dissipate, and thus the damping they can produce, depends markedly on the fastening method used. Metal beams attached to metal panels or seams in such panels generally produce little damping if they are continuously welded or joined by means of a rigid adhesive. However, they can contribute significant damping if they are fastened by a flexible, dissipative adhesive or if they are fastened at only a number of points, for example, by rivets, bolts, or spot welds. At high frequencies, at which the flexural wavelength on the panel is smaller than the distance between fastening points, damping results predominantly not from interface friction but from an "air-pumping" effect produced as adjacent surfaces (at locations between the connection points) move away from and toward each other. Energy loss here is due to the viscosity of the air or other fluid present between the surfaces.[13–15]

The high-frequency absorption coefficient corresponding to a beam that is fastened to a panel at a multitude of points may be estimated from the experimental results summarized in Fig. 14.6, which shows how the beam's reduced absorption coefficient γ_r varies with reduced frequency f_r or with the ratio d/λ of fastener spacing to plate flexural wavelength. These reduced quantities, definitions of which are given in the figure, account for the absorption coefficients' dependence on beam width w, plate thickness h, fastener spacing d, and longitudinal wave speed c_L in the plate material by relating these to reference values of these parameters (indicated by the subscript 0). It should be noted that Fig. 14.6 pertains to panels immersed in air at atmospheric pressure; lesser absorption coefficient values apply for panels at reduced pressure and higher values for panels at greater pressures. A theory is available[13] to account for the effects of atmospheric pressure changes and for other gases or liquids present between the contacting surfaces.

Damping due to Energy Transport

Structural Transmission. Energy that is transported away from a vibrating structure constitutes energy lost from that structure and thus contributes damping. Energy transport may occur to neighboring structural elements or to fluids in contact with the vibrating structure.

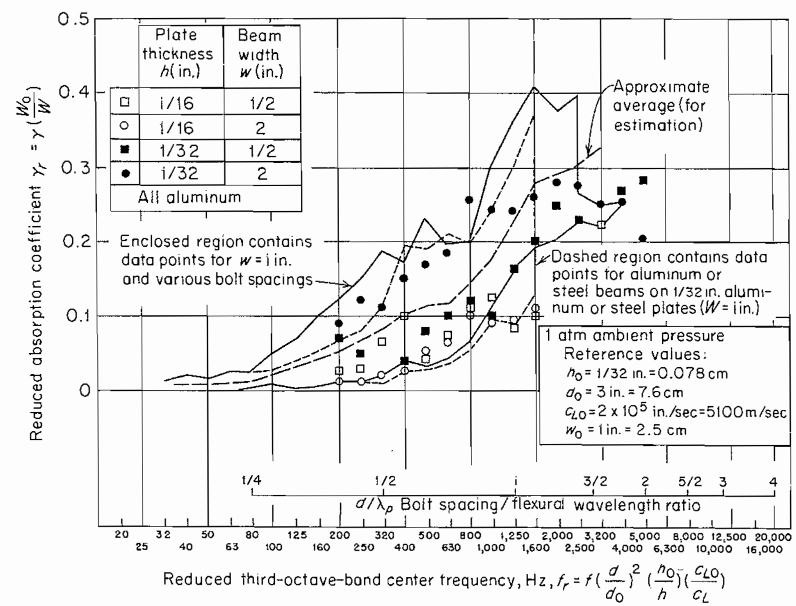

FIGURE 14.6 Summary of reduced absorption coefficient data for beams fastened to plates by rows of rivets, bolts, or spot welds.[15]

For example, a panel that is part of a multipanel array (such as an aircraft fuselage) is damped not only due to energy dissipation within the panel but also due to energy transport to adjacent panels. Energy transport makes it very difficult in practice to measure the dissipative damping of a structural component that is connected to others. Energy transported via the supports of test samples also tends to contaminate laboratory measurements of dissipative damping, potentially introducing large errors in measurements on samples with small inherent damping.

If a structural element is attached to a vibrating structure at a given point, then the energy D that is transported to the attached structure per cycle at frequency f is given by

$$D = \frac{V_S^2 \operatorname{Re}[Z_A]}{2f}\left|1 + \frac{Z_A}{Z_S}\right|^{-2} \tag{14.18}$$

Here V_S denotes the amplitude of the velocity of the vibrating structure at the attachment point before the added structure is attached; Z_A denotes the driving-point impedance of the attached structure, and Z_S denotes the impedance of the vibrating structure at the attachment point (with both impedances measured in the direction of V_S). The loss factor contribution due to an attached structure then may be found by use of Eq. (14.13).

A *waveguide absorber* is a damping device that is intended to conduct energy away from its attachment point and to dissipate that energy. Such an absorber consists essentially of a structural element along which waves can travel and which includes means for dissipating the energy transported by these waves. For example, a long slender beam (which may be straight or coiled in some fashion) that is made of a highly damped plastic or coated with a high-damping material may serve as a waveguide absorber at frequencies considerably above its fundamental resonance. To be effective, a waveguide absorber must support waves in the frequency range of interest, it must be attached at a point where the vibrating structure moves with considerable amplitude, and its impedance must be such that it does not excessively reduce the vibrating structure's motion at the attachment point.[16]

A *tuned damper*, often also called a *dynamic absorber* or *neutralizer*, may be visualized as a mass–spring–damper system whose spring base is attached to a point on a vibrating structure. In the region near its natural frequency a tuned damper tends to impede the motion of the attachment point and to dissipate considerable energy; outside this frequency region, the damping effect of such a damper typically is small. Any system, such as a beam or plate, which exhibits a resonance at the frequency of concern, can act as a tuned damper at that frequency. Considerable damping of a plate over a relatively wide frequency range can be obtained by distributing a number of small tuned dampers with slightly different natural frequencies over the plate surface.[17]

Sound Radiation. Sound radiated by a vibrating structure transports energy from the structure and thus contributes damping. For a homogeneous panel of thickness h and material density ρ_p, one may calculate the panel's loss factor η_R at frequency f due to sound radiation from one side of the panel from its radiation efficiency σ by use of the relation[14]

$$\eta_R = \frac{\rho}{\rho_p}\frac{c}{2\pi f h}\sigma \tag{14.19}$$

where ρ and c denote the density of the ambient medium and the speed of sound in it, respectively. If the panel can radiate from both of its sides, η_R is twice as great as indicated by Eq. (14.19). The magnitude of the radiation efficiency σ depends on the vibratory velocity distribution on the panel, as well as on frequency, and thus generally is different for different excitation distributions.

For a plate that has little inherent damping and that is excited at a single point, the radiation efficiency σ obeys[18]

$$\sigma = \begin{cases} (Uc/\pi^2 A f_c)\sqrt{f/f_c} & \text{for } f \ll f_c \\ 0.45\sqrt{U f_c/c} & \text{for } f = f_c \\ 1.0 & \text{for } f \gg f_c \end{cases} \tag{14.20}$$

where A denotes the panel's surface area (one side), U its circumference, and f_c the coincidence frequency. This frequency, which is defined as that at which the plate flexural wavelength is equal to the acoustical wavelength in the ambient medium, is given by $f_c \approx c^2/1.8hc_L$, where c_L represents the longitudinal wave speed in the plate material. More detailed information on radiation efficiency is provided in Chapter 11. Equation (14.20) may be used for the general estimation of radiation efficiency values for plates that are not too highly damped. This equation also provides a reasonable estimate of the radiation efficiency of rib-stiffened plates if twice the total rib length is included in the circumference U.

14.5 VISCOELASTIC DAMPING TREATMENTS

Viscoelastic Materials and Material Combinations

Materials that have both damping (energy dissipation) and structural (strain energy storage) capability are called "viscoelastic." Although virtually all materials fall into this category, the term is generally applied only to materials, such as plastics and elastomers, that have relatively high ratios of energy dissipation to energy storage capability.

Structural materials with high strength-to-weight ratios typically have little inherent damping, as is evident from Fig. 14.5, whereas plastics and rubbers that are highly damped tend to have relatively low strength. This circumstance has led to the consideration of combinations of high-strength materials and high-damping viscoelastic materials for applications where both strength and damping are required. Additions of viscoelastic materials to structural elements have come to be known as viscoelastic damping treatments.

If a composite structure is deflected, it stores energy via a variety of deformations (such as shear, tension and compression, flexure) in each structural element. If η_i denotes the loss factor corresponding to the ith element deformation and W_i represents the energy stored in that deformation, then the loss factor η of the entire structure obeys[19]

$$\eta = \sum \eta_i \frac{W_i}{W_T} \tag{14.21}$$

where $W_T = \sum W_i$ denotes the total energy stored in the structure. The foregoing expression indicates that the loss factor η of the composite structure is equal to a weighted average of the loss factors corresponding to all of the element deformations, with the energy storages serving as the weighting factors. This expression also leads to an important conclusion: An element deformation can make a significant contribution to the total loss factor only if (1) the loss factor associated with it is significant *and* (2) the energy storage associated with it is a significant fraction of the total energy storage.*

Mechanical Properties of Viscoelastic Materials

Because viscoelastic materials have both energy storage and energy dissipation capability, it is convenient to describe their behavior in terms of elastic and shear moduli that are complex quantities, in analogy to the definition of the complex stiffness introduced in Eq. (14.10). The complex Young's modulus $\overline{E}$ of a material, defined as the ratio of the stress phasor to the strain phasor, may be written as[10] $\overline{E} = E_R + jE_I = E_R(1 + j\eta_E)$, where the real part E_R is called the storage modulus, the imaginary part E_I is called the loss modulus, and the loss factor η_E associated with Young's modulus is equal to E_I/E_R. A completely analogous definition applies to the complex shear modulus.†

For plastics and elastomers, the viscoelastic materials of greatest practical interest, the real and imaginary moduli as well as the loss factors vary considerably with frequency and temperature. However, these parameters usually vary relatively little with strain amplitude, preload, and aging.[10] The loss factor associated with the shear modulus typically is equal to that associated with the Young's modulus for all practical purposes, so that one generally need not distinguish between the two. Also, since most of the viscoelastic materials of practical interest are virtually incompressible, the shear modulus value is nearly equal to one-third of the corresponding Young's modulus value. One may also note that often $\eta_E^2 \ll 1$, so that $|\overline{E}| \approx E_R$.

*Equation (14.21) applies precisely only for cases where all energy storage elements are deflected in phase, so that they reach their maximum energy storages at the same instant.

†An advantage of the complex modulus representation is the ease with which it enables one to incorporate damping in an analysis. One merely needs to replace the real moduli in the undamped formulation of a problem by the corresponding complex moduli—or, equivalently, to replace the real stiffnesses by the corresponding complex stiffnesses—to obtain a formulation of the problem that includes damping. This approach applies for lumped-parameter dynamic systems as well as for continuous systems and can take account of different values of damping in different elements and materials.

Figure 14.7 shows how the (real) shear modulus and loss factor of a typical viscoelastic material vary with frequency and temperature. At low frequencies and/or high temperatures, the material is soft and mobile enough for the strain to follow an applied stress without appreciable phase shift so that the damping is small; the material is said to be in its "rubbery" state. At high frequencies and/or low temperatures, the material is stiff and immobile, may tend to be brittle, is relatively undamped, and behaves somewhat like glass; it is said to be in its "glassy" state. At intermediate frequencies and temperatures, the modulus takes on intermediate values and the loss factor is highest; the material is said to be in its "transition" state.

This material behavior may be explained on the basis of the interactions of the long-chain molecules that constitute polymeric materials. At low temperatures, the molecules are relatively inactive; they remain "locked together," resulting in high stiffness, and because they move little relative to each other, there is little intermolecular "friction" to produce damping. At high temperatures, the molecules become active; they move easily relative to each other, resulting in low stiffness, and because they interact little, there is again little energy dissipation due to intermolecular friction. At intermediate temperatures, where the molecules have intermediate relative motion and interaction, the stiffness also takes on an intermediate value and the loss factor is greatest. A similar discussion applies to the effect of frequency on the material properties, with the inertia of the molecules leading to their decreasing mobility and interaction with increasing frequency.

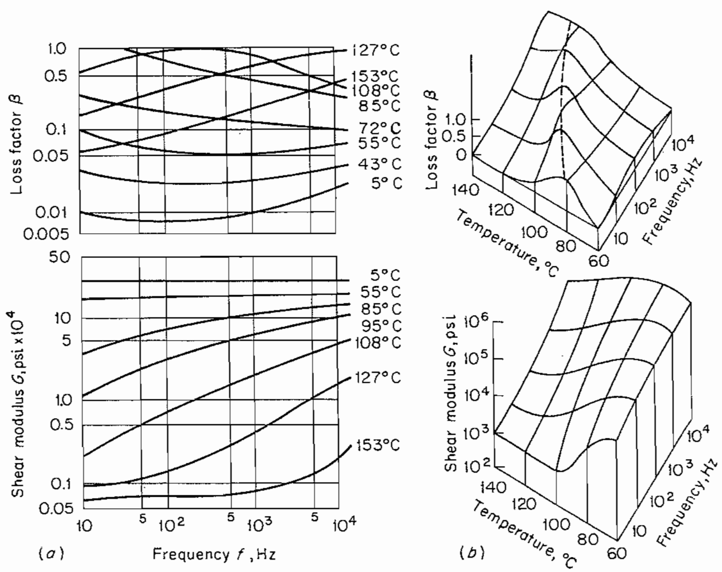

FIGURE 14.7 Dependence of shear modulus and loss factor of a polyester plastic on frequency and temperature[20]: (*a*) functions of frequency at constant temperature; (*b*) isometric plots on temperature–frequency plane. Note logarithmic frequency axes.

The observation that there exists a *temperature–frequency equivalence*, namely that an appropriate temperature decrease produces the same effect as a given frequency increase, has led to the development of convenient plots in which data for the frequency and temperature variations of each material modulus collapse onto single curves.[10,21] This collapse is achieved by plotting the data against a reduced frequency $f_R = f\alpha(T)$, where $\alpha(T)$ is an appropriately selected function of temperature T. In presentations of data in this form the function $\alpha(T)$ may be given analytically, in a separate plot or, as has recently been standardized[22,23], in the form of a nomogram that is superposed on the reduced data plot. Figure 14.8 is an illustration of such a plot and nomogram; its use is explained in the figure's legend.

Data on the properties of damping materials are available from knowledgeable suppliers of these materials. Compilations of data appear in references 10, 21, and 24. Key information on some of these materials appears in Table 14.1 in a form that is useful for preliminary material comparison and selection for specific applications in keeping with the concepts discussed in the later portions of this chapter. For each listed material the table shows the greatest loss factor value η_{max} exhibited by the material and the temperatures at which this value is obtained at three frequencies. The table also lists three values of the modulus of elasticity: E_{max}, the greatest value of Young's modulus, applies at low temperatures (i.e.,

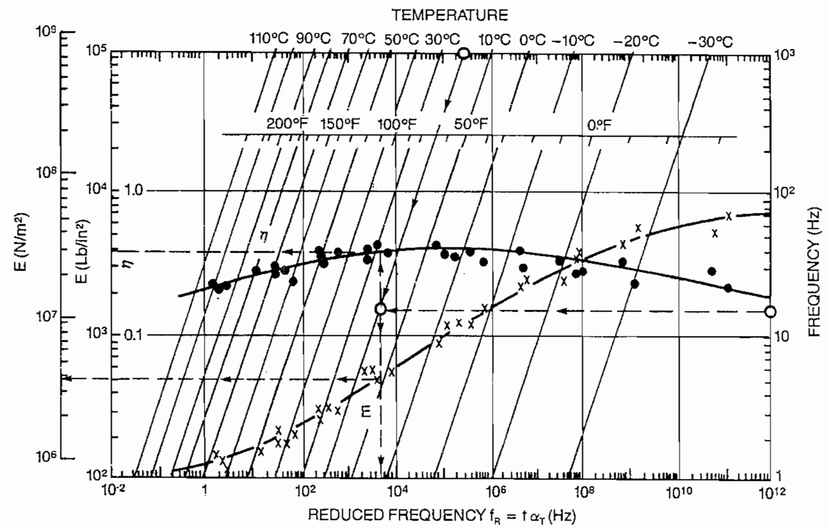

FIGURE 14.8 Reduced frequency plot of elastic modulus E and loss factor η of "Sylgard 188" silicone potting compound. (After Ref. 25) Points indicate measured data to which curves were fitted. Nomograph superposed on data plot facilitates determination of reduced frequency f_R corresponding to frequency f and temperature T. Use of nomogram is illustrated by dashed lines: For $f = 15$ Hz and $T = 20°C$, one finds $f_R = 5 \times 10^3$ Hz and $E = 3.8 \times 10^6$ N/m², $\eta = 0.36$.

[c] Numbers shown correspond to storage (real) values of Young's modulus, except that $E_{I,max}$ represents the maximum values of the loss (imaginary) modulus. E_{max} applies for low temperatures and/or high frequencies. E_{min} applies for high temperatures and/or low frequencies. E_{trans} and $E_{I,max}$ applies in the range of η_{max}. Divide by 3 to obtain the corresponding shear modulus values.
To convert to N/m², multiply tabulated values by 7×10^3. The number following e represents the power of 10 by which the number preceding e is to be multiplied; e.g., 1.2e3 represents 1.2×10^3

temperatures considerably below those corresponding to η_{max}); E_{min}, the smallest value of E, applies at high temperatures; the transition value E_{trans} applies in the η_{max} range; and $E_{I,max} \approx \eta_{max} E_{trans}$, the maximum value of the loss modulus, applies in the transition range.

It is important to keep in mind that the mechanical properties of polymeric materials, including plastics and elastomers, tend to be more variable than those of metals and other classical structural materials. Some of this variability results from a polymer's molecular structure and molecular weight distribution, which depend not only on the material's chemical composition but also on its processing. Additional variability results from the various types and amounts of plasticizers and fillers that are added to most commercial materials for a number of practical

purposes. Thus, it is quite common for nominally identical polymeric materials to exhibit considerably different mechanical behaviors. It may also occur that even material samples from the same production run have considerably different loss factors and moduli at frequencies and temperatures at which they are intended to be used, pointing toward the need for careful quality control and performance verification for critical applications.

Structures with Viscoelastic Layers

One may calculate the loss factor of a structure vibrating in a given mode by use of Eq. (14.21) if one knows the energies W_i stored in the various deformations of all of the component elements. Indeed, modern finite-element analysis methods[26–28] proceed by calculating the modal deflections, applying these to evaluate all the energy storage components, and then using Eq. (14.21) to find the loss factor.

Analytical results have been developed for flexure of uniform beam and plate structures under conditions that are often approximated in practice. These results, which are extremely useful for design guidance and for development of an understanding of the important parameters, apply to structures whose deflection distributions are sinusoidal.*

Two-Component Beams

In flexure of a uniform beam with an insert or added layer of viscoelastic material, as illustrated by Fig. 14.9, the energy storage (and dissipation) associated with shear and torsional deformations may generally be neglected. If contact between the components is maintained without slippage at all surfaces and if the loss factor of the basic structural (nonviscoelastic) component is negligible, then the

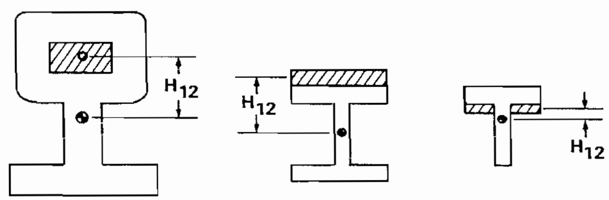

FIGURE 14.9 End views of beams with viscoelastic inserts or added layers. Structural material is unshaded, viscoelastic material is shown shaded; H_{12} represents distance between neutral axis of structural component and that of viscoelastic component. Beam deflection is vertical, with wave propagation along the beam length, perpendicular to the plane of the paper.

*The deflection distribution of any beam (or plate) vibrating in one of its natural modes is at least approximately sinusoidal (in one dimension for beams and in two dimensions for plates) at locations that are one wavelength or more from the boundaries, regardless of the boundary conditions. Therefore, the assumption of a sinusoidal deflection distribution is valid for a larger fraction of the structure as the frequency increases.

loss factor η of the composite beam is related to the loss factor β of the material of the viscoelastic component by[29,30]

$$\frac{\eta}{\beta} = \left[1 + \frac{k^2(1+\beta^2) + (r_1/H_{12})^2\alpha}{k[1 + (r_2/H_{12})^2\alpha]}\right]^{-1} \tag{14.22}$$

where $\alpha = (1+k)^2 + (\beta k)^2$ and H_{12} denotes the distance between the neutral axes of the two components. With subscript 1 referring to the structural (undamped) component and subscript 2 referring to the viscoelastic component, $k = K_2/K_1$, where $K_i = E_i A_i$ denotes the extensional stiffness of component i, expressed in terms of its Young's modulus (real part) E_i and cross-sectional area A_i. Furthermore, $r_i = \sqrt{I_i/A_i}$ represents the radius of gyration of A_i, where I_i denotes the centroidal moment of inertia of A_i.

For the often-encountered case where the structural component's extensional stiffness is much greater than that of the viscoelastic component, $k \ll 1$ and Eq. (14.22) reduces to

$$\eta \approx \frac{\beta E_2 I_T}{E_1 I_1 + E_2 I_T} \approx \frac{\beta E_2}{E_1}\frac{I_T}{I_1} \tag{14.23a}$$

where $I_T = I_2 + H_{12}^2 A_2 = A_2(r_2^2 + H_{12}^2)$ denotes the moment of inertia of A_2 about the neutral axis of A_1.

The last expression in Eq. (14.23a) applies for $E_2 I_T \ll E_1 I_1$, which is generally true in practical structures where the area and elastic modulus of the viscoelastic component are small compared to those of the structural component. In this case the composite structure's neutral axis coincides very nearly with that of the structural component and the dominant energy storage is associated with flexure of the structural component (whose flexural stiffness is $E_1 I_1$). The dominant energy dissipation is associated with extension and compression of the viscoelastic component, with the average extension (equal to the extension at the viscoelastic component's neutral axis) resulting from the flexural curvature and the distance H_{12} between the neutral axes of the viscoelastic and the structural components.* The flexural curvature is greatest at the antinodes of the vibrating structure; most of the damping action thus occurs at these locations, with little damping resulting from the material near the nodes.

The second form of Eq. (14.23a) contains two ratios; the first involves only material properties and the second only geometric parameters. It indicates that the most important dynamic mechanical property of the viscoelastic material is its extensional loss modulus $E_I = \beta E_2$. In keeping with the conclusions based on the general energy expression [Eq. (14.21)], good damping of the composite structure can be obtained only from a viscoelastic material that has not only a high loss factor but also a considerable energy storage capability.

*A "spacer," a layer that is stiff in shear and soft in extension (e.g., like honeycomb), inserted between the structural and the viscoelastic component can increase H_{12} and thus the damping obtained with a given amount of viscoelastic material.[30]

Plates with Viscoelastic Coatings

A strip of a plate (see insert of Fig. 14.10) may be considered as a special case of a two-component beam, where the two components have rectangular cross sections. Thus Eqs. (14.22) and (14.23a) apply, with $r_i = H_i/\sqrt{12}$ and $H_{12} = \frac{1}{2}(H_1 + H_2)$, where H_i denotes the component thickness. The energy storage and dissipation considerations that were discussed in the foregoing section, as well as the foregoing remarks concerning the dominant damping material properties, apply here also.

Figure 14.10 is a plot based on Eq. (14.22) for $\beta^2 \ll 1$. It shows that for small relative thicknesses $h_2 = H_2/H_1$, the loss factor ratio η/β is proportional to the viscoelastic layer thickness, whereas for very large relative thicknesses the loss factor ratio approaches unity; that is, the loss factor of the coated plate approaches that of the viscoelastic coating, as one would expect.* As also is evident from

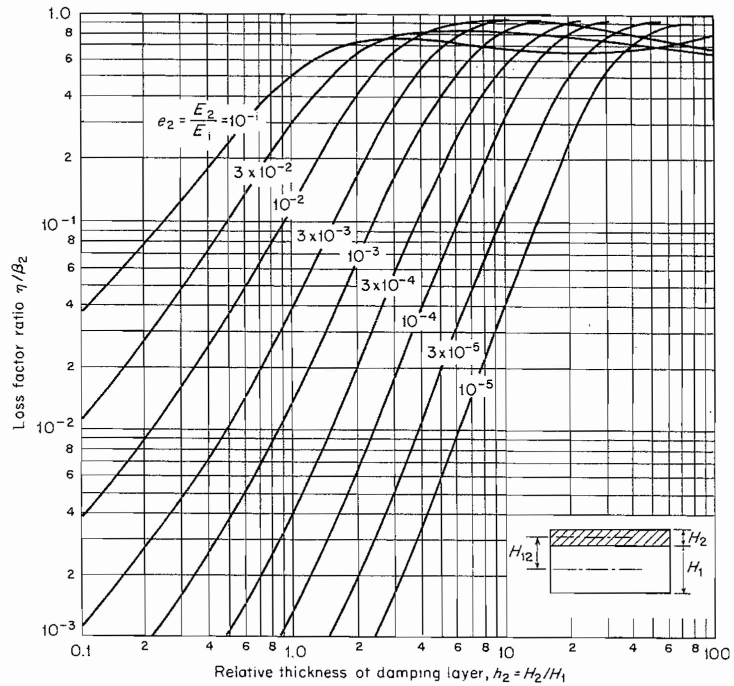

FIGURE 14.10 Dependence of loss factor η of plate strip with added viscoelastic layer on relative thickness and relative modulus of layer.[30] Curves apply for loss factors β of viscoelastic material that are small compared to unity.

*For very thick viscoelastic coatings, deformations in the thickness direction (which are not considered in this simplified analysis) also may play a significant role, particularly at frequencies at which standing-wave resonances may occur in the viscoelastic material.[31]

the figure, at small relative thicknesses the loss factor ratio is proportional to the modulus ratio $e_2 = E_2/E_1$. For small relative thicknesses, that is, in the regions where the curves of Fig. 14.10 are nearly straight, the loss factor of a coated plate may be estimated from[30]

$$\eta \approx \frac{\beta E_2}{E_1} h_2 \ (3 + 6h_2 + 4h_2^2) \tag{14.23b}$$

where $h_2 = H_2/H_1$.

If two viscoelastic layers are applied to a plate, one layer on each side, then the loss factor of the coated plate may be taken as the sum of the loss factors contributed by the individual layers, with each contribution calculated as if the other layer were absent, provided that each viscoelastic layer has low relative extensional rigidity, that is, that $E_2 H_2 \ll E_1 H_1$. If this inequality is not satisfied, a more complex analysis is required.

Three-Component Beams with Viscoelastic Interlayers

Figure 14.11 illustrates uniform beams consisting of two structural (nonviscoelastic) components interconnected via a relatively thin viscoelastic component. Such three-component beams may be preferable to two-component beams for practical reasons because the viscoelastic material is exposed only at its edges; however, such beams can also be designed to have higher damping than two-component beams of similar weight.*

In flexure of a three-component beam with a viscoelastic layer whose extensional and flexural stiffnesses are small compared to those of the structural components, the dominant energy dissipation is associated with shear in the viscoelastic component and the most significant energy storage occurs in connection with extension/compression and flexure of the two structural components. The shear in the viscoelastic component is greatest at the vibrating structure's nodes. Thus, most of the energy dissipation occurs in the viscoelastic material near

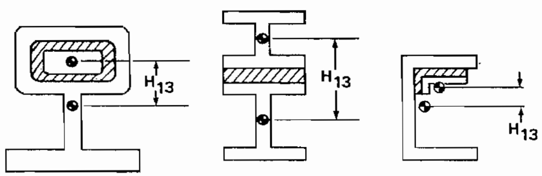

FIGURE 14.11 End views of composite beams made up of two structural components (unshaded) joined via a viscoelastic component (shaded); H_{13} is distance between neutral axes of structural components. Beam deflection is vertical, with wave propagation along the beam length, perpendicular to the plane of the paper.

*It should be noted that design changes to obtain increased damping generally also result in mass and stiffness changes, which tend to affect a structure's vibratory response and should be considered in the design process.[17,32,33]

the nodes, with relatively little resulting in that near the antinodes. For efficient damping, it is important that the shearing action in the viscoelastic material not be restrained (particularly at and near nodes) by structural interconnections, such as bolts.

The loss factor η corresponding to a spatially sinusoidal deflection shape of such a three-component beam is related to the loss factor β of the viscoelastic material by[29,30]

$$\eta = \frac{\beta Y X}{1 + (2 + Y)X + (1 + Y)(1 + \beta^2)X^2} \tag{14.24}$$

where

$$X = \frac{G_2 b}{p^2 H_2} S \qquad \frac{1}{Y} = \frac{E_1 I_1 + E_3 I_3}{H_{13}^2} S \qquad S = \frac{1}{E_1 A_1} + \frac{1}{E_3 A_3} \tag{14.25}$$

Here subscripts 1 and 3 refer to the structural components and 2 to the viscoelastic component; E_i, A_i, and I_i represent, respectively, the Young's modulus, cross-sectional area, and moment of inertia of component i; H_{13} denotes the distance between the neutral axes of the two structural components; and G_2 represents the shear modulus (real part) of the viscoelastic material, H_2 the average thickness of the viscoelastic layer, and b its length as measured on a cross section through the beam. The wavenumber p of the spatially sinusoidal beam deflection obeys

$$\frac{1}{p^2} = \left(\frac{\lambda}{2\pi}\right)^2 = \frac{1}{\omega}\sqrt{\frac{B}{\mu}} \tag{14.26}$$

where λ represents the bending wavelength and B denotes the flexural rigidity and μ the mass per unit length of the composite beam.

The *structural parameter* Y of three-component structures depends only on the geometry and Young's moduli of the two structural components, whereas the *shear parameter* X depends also on the properties of the viscoelastic layer and on the wavelength of the beam deflection. The shear parameter X is proportional to the square of the ratio of the beam flexural wavelength to the *decay distance*,[34] that is, the distance within which a local shear disturbance decays by a factor of e, where $e \approx 2.72$ denotes the base of natural logarithms; thus, X also is a measure of how well the viscoelastic layer couples the flexural motions of the two structural components.

The (complex) flexural rigidity of a three-component beam is given by

$$\overline{B} = (E_1 I_1 + E_3 I_3)\left(1 + \frac{X^* Y}{1 + X^*}\right) \qquad X^* = X(1 - j\beta) \tag{14.27}$$

Its magnitude is $B = |\overline{B}|$. Thus, for small X, the flexural rigidity B of the composite beam is equal to the sum of the flexural rigidities of the structural components, that is, to the total flexural rigidity that the two components exhibit if they are not interconnected. For $X \gg 1$, however B approaches $1 + Y$ times the foregoing value, which is equal to the flexural rigidity of a beam with rigidly interconnected structural components 1 and 3.

For a given value of β and Y, the loss factor η of the composite beam takes on its greatest value,

$$\eta_{\max} = \frac{\beta Y}{2 + Y + 2/X_{\text{opt}}} \tag{14.28}$$

at the optimum value of X, which is given by

$$X_{\text{opt}} = [(1 + Y)(1 + \beta^2)]^{-1/2} \tag{14.29}$$

With the aid of these definitions, one may rewrite Eq. (14.24) in terms of the ratio $R = X/X_{\text{opt}}$ in the following form, which provides a convenient view of the damping behavior of three-component beams:

$$\frac{\eta}{\eta_{\max}} = \frac{2(1 + N)R}{1 + 2NR + R^2} \qquad N = (1 + \tfrac{1}{2}Y)X_{\text{opt}} \tag{14.30}$$

Figure 14.12, which is based on Eqs. (14.28) and (14.29), shows how $\eta_{\max}/\beta$ increases monotonically with Y, indicating the importance of selecting a configuration with a large value of Y in the design of highly damped composite structures.* Figure 14.13 gives approximate values of Y for some often encountered

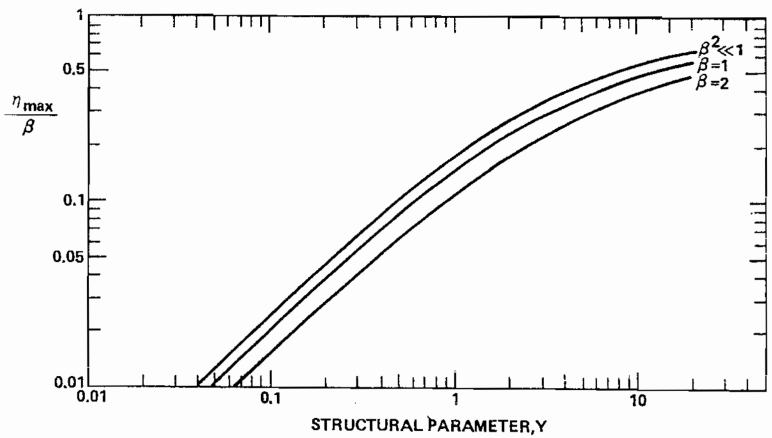

FIGURE 14.12 Dependence of maximum loss factor $\eta_{\max}$ of three-component beams or plates on structural parameter Y and loss factor β of viscoelastic material.

*A shear-stiff, extensionally soft "spacer" (e.g., honeycomb) inserted between the viscoelastic and one or both structural components can serve to increase H_{13} and, therefore, the value of Y. See Eq. (14.25). For a given deflection of the composite structure, a spacer increases the damping by increasing the shear strain—and thus the energy storage and dissipation—in the viscoelastic component.[30,34]

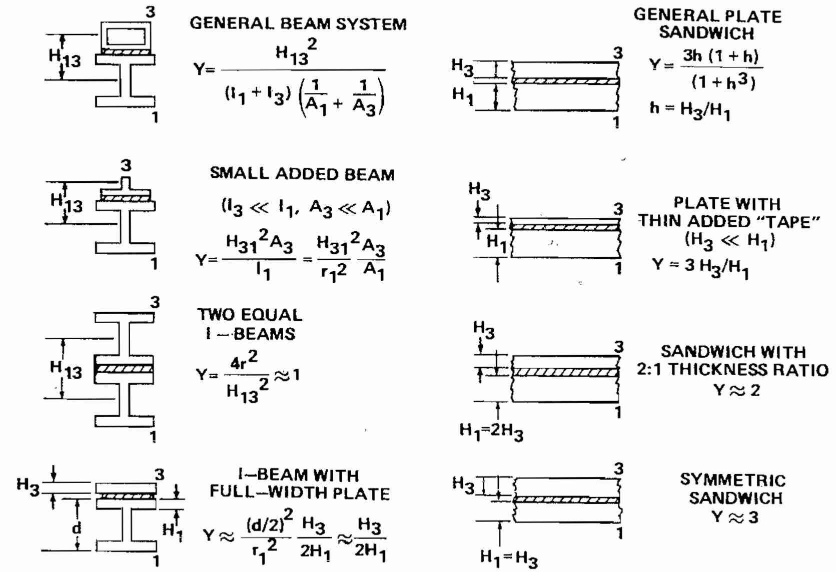

FIGURE 14.13 Values of structural parameter Y for three-component beam and plate configurations with thin viscoelastic components and with structural components of the same material; viscoelastic component is shown cross-hatched. I, moment of inertia; A, cross-sectional area; r, radius of gyration; H_{13}, distance between neutral axes.

configurations. Figure 14.14 shows how $\eta/\eta_{\max}$ varies with X/X_{opt}, indicating the importance of making the operating value of X of a given design match X_{opt} as closely as possible in order to obtain a loss factor that approaches $\eta_{\max}$.

If one knows the wavenumber $p = 2\pi/\lambda$ and the frequency associated with a given beam vibration, one may calculate the loss factor η of a composite beam simply by substituting the beam parameters and the material properties at any frequency (and temperature) of interest into Eqs. (14.24) and (14.25) or (14.28)–(14.30). The latter set of equations is particularly useful for judging how far from the optimum a given configuration may be operating.

If one knows only the frequency and not the wavenumber p corresponding to a beam vibration, one needs to use Eq. (14.26) to determine p. Substitution of B as calculated from Eq. (14.27) into Eq. (14.26), followed by substitution of the result into the first of Eqs. (14.25), leads to a cubic equation in X. Although one may solve this numerically, it is often more convenient to determine X by use of an iteration procedure like that indicated in Fig. 14.15.

In contrast to the previously discussed two-component beam, the loss factor η of a three-component beam does not depend primarily on the loss modulus (i.e., on the product of the loss factor β and storage modulus E_2 or G_2) of the viscoelastic material. The loss factor of a three-component beam depends on β and G_2 separately, and the separate dependences must be taken into account in

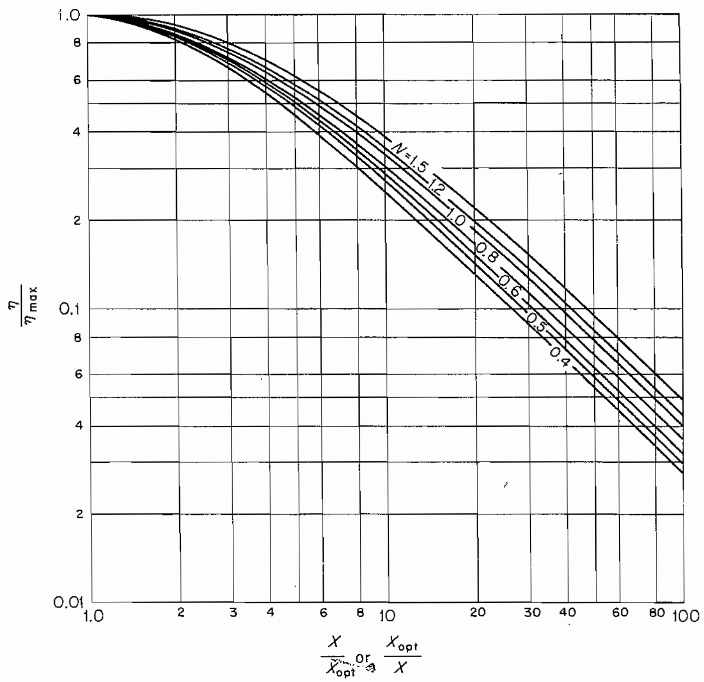

FIGURE 14.14 Dependence of loss factor η of three-component beam or plate on shear parameter X [from Eq. (14.30)].

the design of such a beam. Design of a highly damped three-component beam structure requires (1) choice of a configuration with a large structural parameter Y, (2) selection of a damping material with a large loss factor β in the frequency and temperature range of interest, and (3) adjustment of the damping material thickness H_2 and length b so as to make X [as calculated from Eq. (14.25) for the value of G_2 applicable to the frequency and temperature of concern] approximately equal to X_{opt} [given by Eq. (14.29)]. The resulting design then will have a loss factor approximately equal to η_{max} as given by Eq. (14.28).

The expected performance of any design should be checked for the frequency and temperature ranges of interest by means of the procedure described in the previous paragraph. Note that a given design may be expected to perform optimally—that is, to have X under operating conditions approximately equal to X_{opt}—only in a limited range of frequencies and temperatures, with reduced performance outside this range.

Plates with Viscoelastic Interlayers

A strip of a plate consisting of a viscoelastic layer between two structural layers may be considered as a special case of a three-component beam. In a plate strip,

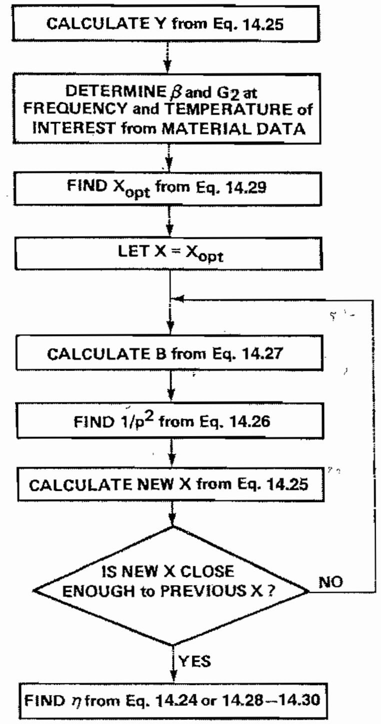

FIGURE 14.15 Iteration procedure for determination of loss factor of three-component beams or plates for which wavelength is not known initially.

all components have rectangular cross sections of the same width; Eqs. (14.25) accordingly become

$$X = \frac{G_2}{p^2 H_2} S \qquad \frac{1}{Y} = \frac{E_1 H_1^3 + E_3 H_3^3}{12 H_{31}^2} S \qquad S = \frac{1}{E_1 H_1} + \frac{1}{E_3 H_3} \tag{14.31}$$

If, furthermore, $E_1 I_1 + E_3 I_3$ in Eq. (14.27) is replaced by $\frac{1}{12}(E_1 H_1^3 + E_3 H_3^3)$ and if μ in Eq. (14.26) is interpreted as the mass per unit surface area of the plate, then all of the foregoing discussion pertaining to beams also applies to plates.

15.1 INTRODUCTION

The sound produced by unsteady gas flows and by interactions of gas flows with solid objects is called *aerodynamic sound*. The same flows often excite structural modes of vibration in surfaces bounding the flow and are then said to generate *structure-borne sound*. Unwanted flow-generated sound, noise, is a common by-product of most industrial processes. It also accompanies the operation of ships, automobiles, aircraft, rockets, and so on, and can adversely affect structural stability and be an important source of fatigue.

A practical understanding of the sources of aerodynamic sound is necessary over the whole range of mean-flow Mach numbers, from the very lowest (0.01 or less) associated with flows in air conditioning systems and underwater applications to the high supersonic range occurring in jet engines and high-pressure valves. In subsonic flows, the sound may be attributed to three basic aerodynamic source types: monopole, dipole, and quadrupole.[1]

These fundamental source types are discussed in this chapter, together with a survey of noise mechanisms associated with turbulent jets, spoilers and airfoils, boundary layers and separated flow over wall cavities, combustion, and valves.

15.2 AEROACOUSTICAL SOURCE TYPES

Aerodynamic Monopole

Monopole radiation is produced by the unsteady introduction of mass or heat into a fluid. Typical examples are pulse jets (where high-speed air is periodically ejected through a nozzle), turbulent flow over a small aperture in a large wall (where the flow induces pulsating motion in the aperture), unsteady combustion processes, and heat release from boundaries or from a pulsed laser beam.

The radiation from a monopole source in an otherwise stationary fluid is equivalent to that produced by a pulsating sphere (Fig. 15.1*a*). Both the amplitude and phase of the acoustical pressure are spherically symmetric. When the monopole sound is generated by unsteady flow velocities, the dimensional relation between the radiated sound power and the flow parameters is

$$W_{\text{monopole}} \propto \frac{\rho L^2 U^4}{c} = \rho L^2 U^3 M \tag{15.1}$$

where W_{monopole} = radiated sound power, W
ρ = mean speed of gas, kg/m^3
c = speed of sound in gas, m/s
U = flow velocity in source region, m/s
L = length scale of flow in source region, m
M = Mach number, $= U/c$, dimensionless

Aerodynamic Dipole

Dipole sources arise when unsteady flow interacts with surfaces or bodies, when the dipole strength is equal to the force on the body, or when there are significant variations of mean fluid density in the flow. This source type is found in compressors where turbulence impinges on stators, rotor blades, and other control surfaces. Similarly, the unsteady shedding of vorticity from solid objects,

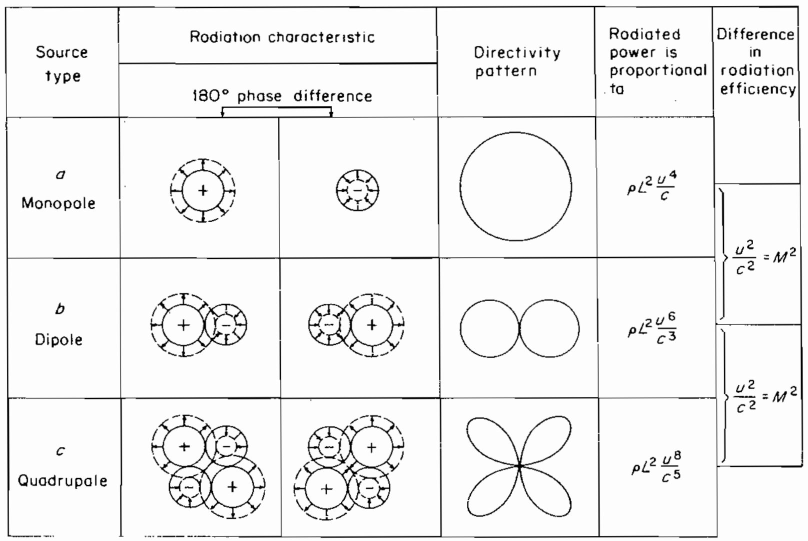

FIGURE 15.1 Aeroacoustical source types and their dimensional properties in fluid of uniform mean density. See also Fig. 1.2.

such as telegraph wires, struts, and airfoils, generates "singing" tones that are also attributable to dipole sources. Other examples include the noise generated by hot jets exhausting into a cooler ambient medium and by the acceleration of temperature (or "entropy") inhomogeneities in a mean pressure gradient, as in a duct contraction.

The dipole is equivalent to a pair of equal monopole sources of opposite phase separated by a distance that is much smaller than the wavelength of the sound. Destructive interference between the radiations from the monopoles reduces the efficiency with which sound is generated by the dipole relative to a monopole and produces a double-lobed, figure-eight radiation field shape proportional to the cosine of the angle measured from the dipole axis (Fig. 15.1*b*). In fluid of uniform mean density, the dimensional dependence of the aerodynamic dipole sound power is

$$W_{\text{dipole}} \propto \frac{\rho L^2 U^6}{c^3} = \rho L^2 U^3 M^3 \tag{15.2}$$

This differs by a factor M^2 from the power output of the monopole. In subsonic flow ($M < 1$) the dipole is a less efficient source of sound.

If the specific entropy or temperature of the flow in the source region is not uniform (e.g., in the shear layer of a hot jet exhausting into a cooler ambient atmosphere), the density must also be variable. The relatively strong pressure fluctuations in the turbulent flow are then scattered by the density variations and produce sound of the dipole type. The dipole strength is proportional to the difference between the actual acceleration of the density inhomogeneity in the turbulent pressure field and that which it would have experienced had the density been uniform.[2] The dimensional dependence of the corresponding sound power is

$$W_{\text{entropy}} \propto \frac{\rho L^2 (\delta T/T)^2 U^6}{c^3} = \rho L^2 \left(\frac{\delta T}{T}\right)^2 U^3 M^3 \tag{15.3}$$

where $(\delta T/T)^2$ is the mean-square fractional temperature fluctuation.

Aerodynamic Quadrupole

Quadrupole radiation is produced by the Reynolds stresses in a turbulent gas in the absence of obstacles. These arise from the convection of fluid momentum by the unsteady flow. The Reynolds stress forces must occur in opposing pairs, since the net momentum of the fluid is constant. Force pairs of this type are called quadrupoles and are equivalent to equal and opposite dipole sources (see Fig. 15.1*c*).

Aerodynamic quadrupoles and entropy dipoles are the dominant source types in high-speed, subsonic, turbulent air jets. The quadrupole strength is larger where both the turbulence and mean velocity gradients are high, for example, in the turbulent mixing layer of a jet.

The dimensional dependence of the radiated quadrupole sound power is

$$W_{\text{quadrupole}} \propto \frac{\rho L^2 U^8}{c^5} = \rho L^2 U^3 M^5 \tag{15.4}$$

This differs from the dipole power by a factor M^2. At subsonic speeds ($M < 1$), the quadrupole radiation efficiency is lower than that of the dipole because of the double cancellation illustrated in Fig. 15.1c.

The monopole, dipole, and quadrupole sources decrease in their respective radiation efficiencies for subsonic flows, but the dependencies of their radiated sound powers on flow velocity show the opposite trend, that is, the total radiated sound power varies as the fourth, sixth, and eighth powers of the flow speed U for monopole, dipole, and quadrupole sources, respectively. Thus, if the flow velocity is high enough, the radiation from the quadrupole sources may be the dominant source of sound even though the efficiency with which the sound is produced is small. This is usually the case for a jet engine at high subsonic exhaust velocities, although other internal sources caused by unsteady combustion or rough burning (predominantly monopole) or compressor noise (predominantly dipole) can also make a significant contribution to the total noise.

The value of the constant of proportionality for each type of source depends on both the sound-generating mechanism and the flow configuration. Thus, the constant for a singing wire differs from that of an edge tone, although both arise from unsteady surface forces (dipole sources). However, the proportionality relations (15.1)–(15.4) can be used to estimate the influence on radiated sound power of changes in one or more of the source parameters. A twofold increase in the exhaust velocity U of a jet (quadrupole-type source) causes the sound power level to increase by 24 dB (eighth power of flow velocity), whereas a doubling of the exhaust nozzle area A (proportional to L^2) increases the sound power level by only 3 dB. Because the thrust of a jet engine is proportional to AU^2, the increase in radiated sound will be smaller if a doubling of the thrust is achieved by increasing the nozzle area by a factor of 2 rather than the exhaust velocity by a factor of 1.4.

Aerodynamic Sources of Fractional Order

The efficiency with which sound is produced by aerodynamic dipole sources on surfaces whose dimensions greatly exceed the acoustical wavelength frequently differs from those implied by Eqs. (15.2) and (15.3). For example, the net dipole strength associated with turbulent flow over a smooth, plane wall is zero: The radiation is the same as that generated by the quadrupole sources in the flow when the wall is regarded as a plane reflector of sound. Similarly, the net strength of the dipoles induced by turbulence near the edge of a large wedge-shaped body varies with angle ν—being equivalent to that of a quadrupole when $\nu = 180°$ (i.e., for a plane wall) and to a *fractional* multipole order $\frac{3}{2}$ when $\nu = 0$ (knife edge). The latter case is important in estimating the leading and trailing edge noise of an airfoil, where at high enough frequency the sound power is proportional to $\rho L U^3 M^2$.

Influence of Source Motion

The directional characteristics of the radiation from acoustical sources are changed if the source moves relative to the fluid. Both the frequency and intensity of the sound are increased ahead of the source and decreased to its rear. It is usual to refer the observer to a coordinate system based on the source location at the time of emission of the received sound.

For a monopole source of strength $q(t)$ kilograms per second (equal to the product of the volume velocity and the fluid density) moving at constant speed U in the direction illustrated in Fig. 15.2, the acoustical pressure p in the far field is

$$p_{\text{monopole}} = \pm \left[\frac{dq/dt}{4\pi r(1 - M_{fr})^2}\right] \tag{15.5}$$

where the square brackets denote evaluation at the time of emission of the sound, (r, Φ) are coordinates defining the observer position relative to the source at the time of emission of the sound, and the plus and minus sign is taken according as $M_{fr} < 1$ or $M_{fr} > 1$, where

$$M_{fr} = \left(\frac{U}{c}\right) \cos \Phi \quad \text{(dimensionless)}$$

The frequency of the received sound is $f/(1 - M_{fr})$, where f, per second, is the frequency in a frame fixed relative to the source. The term $1/(1 - M_{fr})$ is called the *Doppler factor*. Its effect is to modify both the frequency and the amplitude of the acoustic field.

For a uniformly translating dipole of strength $f_i(t)$ (newtons), which is equivalent to an applied force in the i direction, and for a quadrupole $T_{ij}(t)$ (newtons-meters), specified by directions i, j (and equivalent to a force pair applied to the fluid), the respective acoustical pressure fields become

$$p_{\text{dipole}} = \pm \left[\frac{df_r/dt}{4\pi c r(1 - M_{fr})^2}\right] \qquad p_{\text{quadrupole}} = \left[\frac{d^2 T_{rr}/dt^2}{4\pi c^2 r|1 - M_{fr}|^3}\right] \tag{15.6}$$

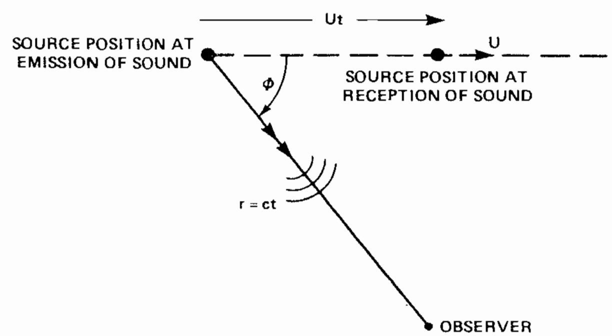

FIGURE 15.2 Coordinates defining the observer position at the time of emission of the received sound from a moving source.

where f_r, T_{rr} denote the components of the dipole and quadrupole source strengths in the observer direction at the time of emission of the sound and the plus and minus sign is taken according as $M_{fr} < 1$ or $M_{fr} > 1$.

These expressions are valid for ideal, point sources moving at constant velocity. The influence of source motion on real, aerodynamic sources is often much more complicated. For example, a pulsating sphere is a monopole source when at rest. In uniform translational motion, however, the radiation is amplified by a Doppler exponent of $\frac{7}{2}$ instead of the 2 of Eq. (15.5). This is because the monopole is augmented due to the motion by a dipole whose strength is proportional to the convection Mach number M_f. The interaction of the volume pulsations with the mean flow over the sphere produces a net fluctuating force on the fluid.

15.3 NOISE OF GAS JETS

The sound generated by high-speed jets is usually associated with several different sources acting simultaneously. *Jet mixing noise*, caused by the turbulent mixing of the jet with the ambient medium, and for imperfectly expanded supersonic jets *shock-associated noise*, produced by the convection of turbulence through shock cells in the jet, are the principal components of the radiation. The properties of sound sources in real jets differ considerably from those of the idealized models described in Section 15.2. Sources located within the "jet pipe" can also make a significant contribution to the noise. In the case of a gas turbine engine, the additional radiation includes combustion noise as well as tonal and broadband sound produced by interactions involving fans, compressors, and turbine systems. The following discussion is based on experimental data obtained and validated by several independent investigators and collated for prediction purposes by the Society of Automotive Engineers.[3] Formulas are given for predicting the *free-field* radiation from a jet in an ideal acoustical medium. In many applications it will be necessary to modify these predictions to account for atmospheric attenuation and interference caused by reflections from surfaces.

Jet Mixing Noise

Mixing noise is the most fundamental source of sound produced by a jet. The simplest free jet is an air stream issuing from a large reservoir through a circular convergent nozzle (Fig. 15.3). The gas accelerates from near-zero velocity in the reservoir to a peak velocity in the narrowest cross section of the nozzle. Sonic flow occurs at the nozzle exit when the pressure ratio p_0/p_s exceeds 1.89, where p_0 is the steady reservoir pressure and p_s is the ambient pressure downstream of the nozzle. An increase above this critical pressure ratio leads to the appearance of a shock cell structure downstream of the nozzle and "choking" of the flow unless the convergent part of the nozzle is followed by a divergent section in which the pressure decreases smoothly to p_s.

For the idealized, shock-free jet, no interaction is assumed between the gas flow and the solid boundaries. The noise is produced entirely by turbulent mixing

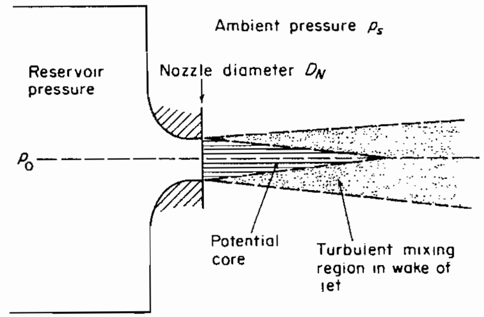

FIGURE 15.3 Subsonic turbulence-free jet.

in the shear layer. The sources extend over a considerable distance downstream of the nozzle. The high-frequency components of noise are generated predominantly close to the nozzle, where eddy sizes are small. Lower frequencies are radiated from sources further downstream where eddy sizes are much larger. The sources may be regarded as quadrupoles, whose strength and directivity are modified by the influences of nonuniform fluid density (temperature) and convection by the flow.

The total radiated sound power W in watts of the mixing noise may be expressed in terms of the mechanical stream power of the jet, equal to

$$W_{\text{mech stream}} = \tfrac{1}{2} m U^2 \qquad (15.7)$$

where m = mass flow of gas, kg/s
U = fully expanded mean jet velocity, m/s

The dependence of $W/\frac{1}{2}mU^2$ on jet Mach number $M = U/c$ and density ratio ρ_j/ρ_s, where c is the ambient sound speed and ρ_j, ρ_s are respectively the densities (in kilograms per cubic meter) of the fully expanded jet and the ambient atmosphere, is illustrated in Fig. 15.4. For $M < 1.05$ the sound power increases as ρ_j/ρ_s decreases (i.e., as the jet temperature increases) and decreases at higher Mach numbers. When $M < 1$, W may be estimated from

$$\frac{W}{W_{\text{mech stream}}} = \frac{4 \times 10^{-5} (\rho_j/\rho_s)^{(w-1)} M^{4.5}}{(1 - M_c^2)^2} \qquad M < 1 \qquad (15.8)$$

where $M_c = 0.62U/c$ and w is the jet density exponent given by[4]

$$w = \frac{3M^{3.5}}{0.6 + M^{3.5}} - 1 \qquad (15.9)$$

Equation (15.9) is applicable for M greater than about 0.35, including the supersonic region and is also used in the formulas given below.

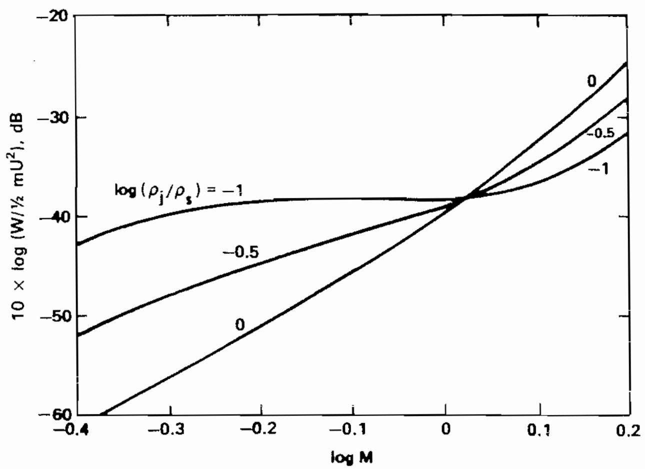

FIGURE 15.4 Ten times the logarithm of the ratio of acoustical power of jet mixing noise to mechanical stream power as a function of the fully expanded jet Mach number $M = U/c$ for different values of ρ_j/ρ_s.

The overall sound pressure level (OASPL) at any point in space is defined as

$$\text{OASPL} = 20 \times \log_{10} \frac{p_{\text{rms}}}{20\ \mu\text{Pa}} \qquad \text{dB} \tag{15.10}$$

where p_{rms} is the rms sound pressure in pascals (newtons per square meter) (see Chapter 2). Source convection and refraction in the shear layers causes the sound field to be directive, the maximum noise being radiated in directions inclined at angles θ to the jet axis between about 30° and 45°.

Typical field directivities at a fixed observer distance for an air jet at three different jet Mach numbers $M = U/c$ are shown in Fig. 15.5. The curves give the variation of OASPL(θ) − OASPL(90°), the sound pressure level relative to its value at $\theta = 90°$, and are approximated by the formula

$$\text{OASPL}(\theta) = \text{OASPL}(90°) - 30 \times \log\left[1 - \frac{M_c \cos\theta}{(1 + M_c^5)^{1/5}}\right]$$
$$- 1.67 \times \log\left[1 + \frac{1}{10^{(40.56-\theta')} + 4 \times 10^{-6}}\right] \tag{15.11}$$

where $M_c = 0.62U/c$
$\theta' = 0.26(180 - \theta)M^{0.1}$, degrees

The final term on the right of (15.11) is negligible unless $\theta < 180° - 150°/M^{0.1}$, that is, except in directions close to the jet axis.

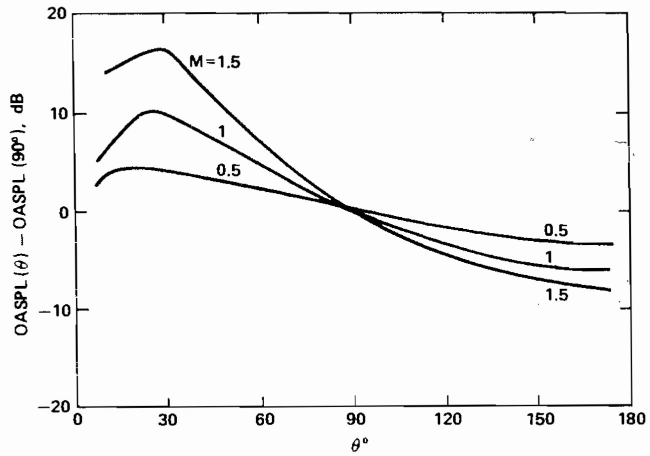

FIGURE 15.5 Directivity of jet mixing noise.

At $\theta = 90°$ the overall sound pressure level of jet mixing noise can be calculated from the formula

$$\text{OASPL} = 139.5 + 10 \times \log \frac{A}{R^2} + 10 \times \log\left[\left(\frac{p_s}{p_{\text{ISA}}}\right)^2 \left(\frac{\rho_j}{\rho_s}\right)^w\right]$$
$$+ 10 \times \log\left(\frac{M^{7.5}}{1 - 0.1M^{2.5} + 0.015M^{4.5}}\right) \tag{15.12}$$

where A = fully expanded jet area, $= \frac{1}{4}\pi D_N^2$ for a subsonic jet, m²
D_N = nozzle exit diameter, m
R = distance from center of nozzle exit, m
p_{ISA} = international standard atmospheric pressure at sea level, = 10.13 μPa

The dependence of OASPL(90°) − $10 \times \log(A/R^2)$ on jet Mach number M and density ratio ρ_j/ρ_s is illustrated in Fig. 15.6.

The sound-pressure-level (SPL) frequency spectrum of jet mixing noise is broadband and peaks at a frequency $f = f_p$ that is a function of the radiation direction θ, jet Mach number M, and temperature ratio T_j/T_s, where T_j (in kelvin) is the fully expanded jet temperature and T_s (kelvin) is the ambient gas temperature. The spectrum has a broad peak that occurs in the range $0.3 < S < 1$, where

$$S = \frac{f_p D_N}{U} \tag{15.13}$$

is the *Strouhal number* (dimensionless), tabulated in Table 15.1 for $\theta \geq 50°$ and for different values of T_j/T_s. For practical purposes the difference $\Delta =$

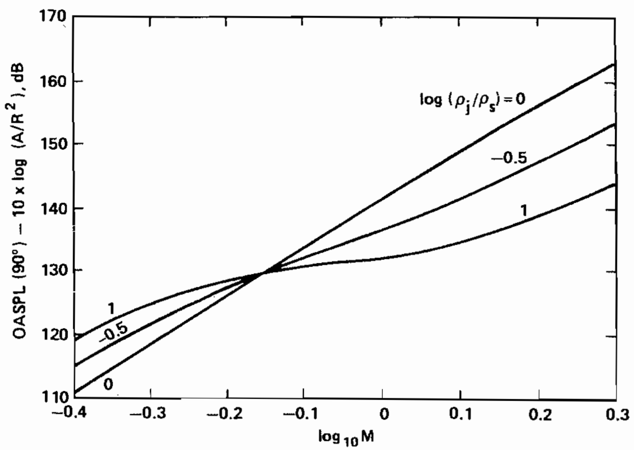

FIGURE 15.6 Overall sound pressure level at $\theta = 90°$.

TABLE 15.1 Values of Strouhal Number and $\Delta(\cdot)$ for Different Values of T_j/T_s[a]

T_j/T_s	$\theta = 50°$	$\theta = 60°$	$\theta = 70°$	$\theta = 80°$	$\theta \geq 90°$
1	0.7 (11 dB)	0.8 (11 dB)	0.8 (11 dB)	1.0	0.9
2	0.5 (10 dB)	0.4 (10 dB)	0.6 (11 dB)	0.5	0.6
3	0.3 (9 dB)	0.4 (10 dB)	0.4 (10 dB)	0.4	0.5

[a]Strouhal number $S = fD_N/U$ at the peak of the one-third-octave-band spectrum of jet mixing noise for $U/c \leq 2.5$ (left columns); Δ = OASPL − $\text{SPL}_{\text{peak}} \cong 11$ dB for all $\theta \geq 80°$ except as indicated in parentheses (right columns).

OASPL − SPL_{peak} between the peak of the one-third-octave-band spectrum and the overall SPL at the same value of θ may be taken to be 11 dB except as indicated in the table.

Figure 15.7 shows a typical relative one-third-octave-band SPL spectrum SPL(f) − OASPL for $\rho_j = \rho_s$ and angles $\theta \geq 90°$. The characteristic shape is the same for all temperatures and angles, although there is significant dependence on temperature and Mach number when θ is smaller than about 50° and $f > f_p$ when refraction of sound by the jet shear layer becomes important. For subsonic jets, the spectrum varies roughly as f^3 at low frequencies and decays like $1/f$ for $f > f_p$.

Figures 15.4–15.7 and Table 15.1, supplemented when necessary by Eqs. (15.8) and (15.9), comprise a general procedure for estimating the SPL, directivity, and spectrum of jet mixing noise.

Example 15.1. Find the total jet mixing noise sound-power- and sound-pressure-level spectrum at 60° from the jet axis and 3 m from the nozzle of a 0.03-m-diameter air jet. The jet exhausts into ambient air (15°C, $p_s = 10.13$ μPa, $\rho_s = 1.225$ kg/m³) at sonic ($U/c = 1$) exit velocity, that is, 340 m/s.

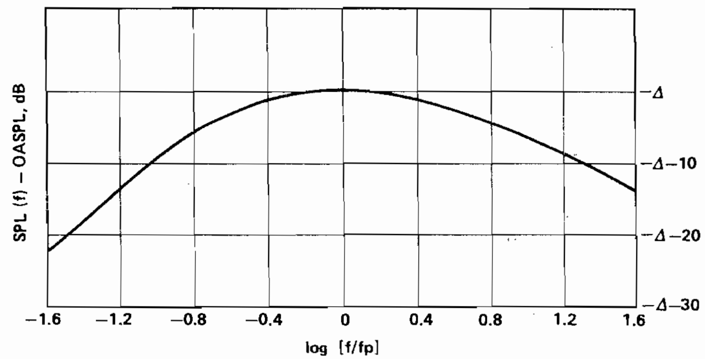

FIGURE 15.7 One-third-octave-band SPL − OASPL (dB) for radiation directions $\theta \geq 90°$ and $\rho_j = \rho_s$.

Solution The mechanical stream power $\frac{1}{2}mU^2$ is 1.70×10^4 W. The ratios ρ_j/ρ_s and U/c are unity. Therefore, from Fig. 15.3 [or Eqs. (15.8) and (15.9)] the ratio of sound power to mechanical stream power is 1.0×10^{-4}. The resulting overall sound power is 1.7 W. From Fig. 15.6 [or Eq. (15.12)] the OASPL at 90° to the jet axis and $R = 3$ m is 98.8 dB re 20 μPa. From Eq. (15.11) the OASPL at 60° to the jet axis and $R = 3$ m is 103.5 dB, and the peak Strouhal number is 0.8. The one-third-octave-band SPL spectrum is found from Fig. 15.6 by adding 103.5 dB to the ordinate with $\Delta = 11$ dB (from Table 15.1).

Realistic jets exhausting from pipes and engine nozzles do not provide smooth, low-turbulence entrainment of flow but rather flow that has been disturbed or spoiled before leaving the nozzle. In this case, the above procedure is not valid unless the jet velocity U exceeds about 100 m/s. Below this speed major portions of the aerodynamically generated noise emanate from internal sources.

Noise of Imperfectly Expanded Jets

Supersonic, underexpanded, or "choked" jets contain shock cells through which the flow repeatedly expands and contracts (see inset to Fig. 15.8). Seven or more distinct cells are often visible extending up to 10 jet diameters downstream of the nozzle. They are responsible for two additional components of jet noise: *screech tones* and broadband *shock-associated noise*. Screech is produced by a feedback mechanism in which a disturbance convected in the shear layer generates sound as it traverses the standing system of shock waves. The sound propagates upstream through the ambient atmosphere and causes the release of a new flow disturbance at the nozzle exit. This is amplified as it convects downstream, and the feedback loop is completed when it encounters the shocks. A notable feature of the screech tones is that the frequencies are independent of the radiation direction, the fundamental occurring at approximately $f = U_c/L(1 + M_c)$, where $M_c = U_c/c$, U_c is the convection velocity of the disturbance in the shear layer, L is the axial length

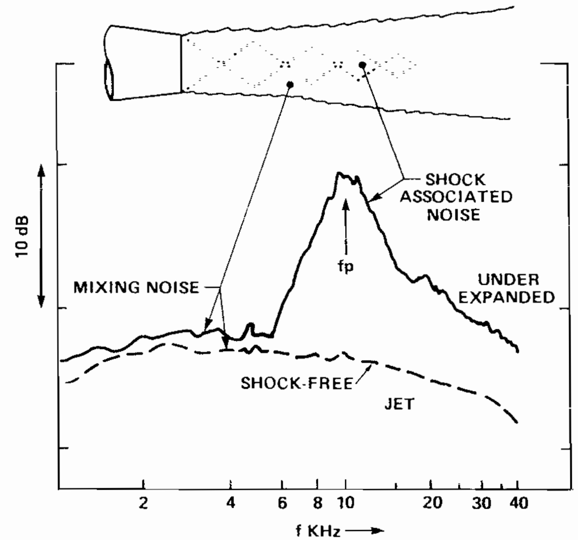

FIGURE 15.8 Jet noise spectra for shock-free and underexpanded jets at $\theta = 90°$, $\beta = 1$.

of the first shock cell, and c is the ambient speed of sound. Although screech is often present in model-scale experiments and can be important for choked jet engines, it is usually easy to eliminate by minor modifications to nozzle design, for example, by notching.

In practice, it is the broadband, shock-associated noise that is important for supersonic jet engines. It can be suppressed by proper nozzle design, but it is always present for a convergent nozzle. The dominant frequencies are usually higher than the screech tones and can range over several octave bands. For predictive purposes it is permissible to estimate separately the respective contributions of mixing noise and shock-associated noise to the overall sound power generated by the jet. The mixing noise predictions are the same as for a shock-free jet.

The overall SPL of shock-associated noise is approximately independent of the radiation direction and may be estimated from

$$\text{OASPL} = C_0 + 10 \times \log \frac{\beta^n A}{R^2}$$

$$C_0 = 156.5 \quad (\text{dB}) \quad n = \begin{cases} 4 & (\beta < 1) \\ 1 & (\beta > 1) \end{cases} \quad \frac{T_j}{T_s} < 1.1 \tag{15.14}$$

$$C_0 = 158.5 \quad (\text{dB}) \quad n = \begin{cases} 4 & (\beta < 1) \\ 2 & (\beta > 1) \end{cases} \quad \frac{T_j}{T_s} > 1.1$$

where T_j = total (reservoir) jet temperature, K
T_s = total ambient temperature, K
$\beta = \sqrt{M_j^2 - 1}$
M_j = fully (ideally) expanded jet Mach number, based on sound speed in jet

The shock-associated noise spectrum exhibits a well-defined peak in the vicinity of

$$f_p = \frac{0.9U_c}{D_N \beta (1 - M_c \cos \theta)} \tag{15.15}$$

where the convection velocity U_c meters per second is equal to $0.7U$ and θ is measured from the jet axis. When $T_j/T_s > 1.1$, the one-third-octave-band SPL (re 20 μPa) is given by

$$\begin{aligned} \text{SPL} = {} & 143.5 + 10 \times \log \frac{\beta^n A}{R^2} - 16.13 \times \log \left(\frac{5.163}{\sigma^{2.55}} + 0.096\sigma^{0.74} \right) \\ & + 10 \times \log \left\{ 1 + \frac{17.27}{N_s} \cdot \sum_{i=0}^{N_s - 1} \left[C(\sigma)^{(i^2)} \right. \right. \\ & \left. \left. \times \sum_{j=1}^{N_s - i - 1} \frac{\cos(\sigma q_{ij}) \sin(0.1158 \sigma q_{ij})}{\sigma q_{ij}} \right] \right\} \end{aligned} \tag{15.16}$$

where $C(\sigma) = 0.8 - 0.2 \times \log_{10}(2.239/\sigma^{0.2146} + 0.0987\sigma^{2.75})$
$\sigma = 6.91 \beta D_N f/c$, dimensionless
c = ambient speed of sound, m/s
N_s = 8 (number of shocks)
$q_{ij} = (1.7ic/U)\{1 + 0.06[j + \frac{1}{2}(i+1)]\}[1 - 0.7(U/c) \cos\theta]$

and n is defined as in (15.14). In the case of a "cold jet," for which $T_j/T_s < 1.1$, the prediction (15.16) should be reduced by 2 dB.

The prediction procedure for shock-associated noise is applicable over all angles θ where shock cell noise is important (say, $\theta > 50°$). When used in conjunction with the prediction procedure for jet mixing noise, the one-third-octave-band sound pressure spectrum for the overall jet noise may be estimated by adding the respective contributions to each frequency band of the mean-square acoustical pressures of the mixing noise and the shock-associated noise. The influence of shock-associated noise is illustrated in Fig. 15.8, which compares the spectrum of the jet mixing noise of a fully expanded, shock-free supersonic jet from a convergent–divergent nozzle at the same pressure ratio. In the latter case the spectral peak occurs at the frequency f_p given by Eq. (15.15).

Flight Effects

The noise generated by a jet engine in flight is modified because of the joint effects of Doppler amplifications (discussed in Section 15.2) and the reduction in mean shear between the jet flow and its environment. From an extensive series of experimental studies[3] empirical formulas have been developed to predict the SPL in flight in terms of the corresponding static levels.

In the Mach number range of $1.1 < M < 1.95$ jet mixing noise $\text{OASPL}(\theta)_{\text{flight}}$ is related to $\text{OASPL}(\theta)_{\text{static}}$ by

$$\text{OASPL}(\theta)_{\text{flight}} = \text{OASPL}(\theta)_{\text{static}} - 10 \times \log\left[\left(\frac{U}{U - V_f}\right)^{m(\theta)} (1 - M_f \cos \Phi)\right]$$

$$m(\theta) = \left[\left(\frac{6959}{|\theta - 125|^{2.5}}\right)^7 + \frac{1}{[31 + 18.5M - (0.41 - 0.37M)\theta]^7}\right]^{-1/7} \tag{15.17}$$

where θ = angle between jet axis and observer at retarded time of emission of sound, degrees
Φ = angle between flight direction and observer direction at retarded time of emission of sound, defined in Fig. 15.2
U = fully expanded jet velocity (relative to nozzle), m/s
V_f = aircraft flight speed, m/s
M_f = flight Mach number relative to sound speed in air, $= V_f/c$

The formula is applicable for $20° < \theta < 160°$. For $M < 1.1$ and $M > 1.95$, the relative velocity exponent $m(\theta)$ should be taken to be given by the above formula at $M = 1.1$, 1.95, respectively.

Estimates of the one-third-octave-band SPL spectrum in flight can be made by using Fig. 15.6 with the OASPL determined by (15.17) and the Strouhal number fD_N/U replaced by that based on the jet velocity: $fD_N/(U - V_f)$.

For shock-associated noise the influence of flight on both the spectrum and the OASPL is approximately given by

$$\text{SPL}_{\text{flight}} = \text{SPL}_{\text{static}} - 40 \log \times (1 - M_f \cos \Phi) \tag{15.18}$$

15.4 COMBUSTION NOISE OF GAS TURBINE ENGINES

Jet mixing noise and shock-associated noise of high-speed jet engines are the result of sources in the flow downstream of the nozzle. Their importance has progressively diminished in recent years with the introduction of large-diameter, high-bypass-ratio turbofan engines with much reduced mass efflux velocities. In consequence, greater attention has been given to noise generated within the engine (termed *core noise*), which tends to be predominant at frequencies less than 1 kHz. Combustion processes are a significant component of core noise, both directly in the form of thermal monopole sources and indirectly through the creation of temperature and density inhomogeneities ("entropy spots"), which behave as dipole sources when accelerated in nonuniform flow.

The noise prediction scheme outlined below is based on an analysis of combustion noise of turbojet, turboshaft, and turbofan engines as well as model-scale data[3]. Annular, can-type, and "hybrid" combusters were all included in the valuation studies.

The overall sound power level (OAPWL, in decibels) is a function of the operating conditions of the combuster and the turbine temperature extraction and may be estimated from the equation

$$\text{OAPWL} = -60.5 + 10 \times \log \frac{mc^2}{\Pi_{\text{ref}}} + 20 \times \log \frac{(\Delta T/T_I)(P_I/p_{\text{ISA}})}{[(\Delta T)_{\text{ref}}/T_s]^2} \tag{15.19}$$

where m = combuster mass flow rate, kg/s
P_I = combuster inlet total pressure, Pa
ΔT = combuster total temperature rise, K
$(\Delta T)_{\text{ref}}$ = reference total temperature extraction by engine turbines at maximum takeoff conditions, K
T_I = inlet total temperature, K
T_s = sea-level atmospheric temperature, 288.15 K
Π_{ref} = reference power, 10^{-12} W
p_{ISA} = sea-level atmospheric pressure, 10.13 kPa = 1.013×10^4 N/m^2
c = sea-level speed of sound, 340.3 m/s

This formula is expected to yield predictions that are accurate to within ±5 dB.

The one-third-octave-band power level spectrum PWL(f) is given in terms of the OAPWL by

$$\text{PWL}(f) = \text{OAPWL} - 16 \times \log[(0.003037f)^{1.8509} + (0.002051f)^{-1.8168}]\,\text{dB} \tag{15.20}$$

where f is frequency (in hertz) and the formula is applicable for 100 Hz $\le f \le$ 2000 Hz. The spectrum is essentially symmetric about a peak at $f = 400$ Hz (Fig. 15.9). In applications where the observed peak frequency f_p differs slightly from this value, the spectrum in the figure should be shifted, retaining its shape, so that the peak coincides with observation. In (15.20), f would be replaced by $400f/f_p$.

The one-third-octave-band sound power pressure spectrum may now be determined from the formula

$$\begin{aligned}\text{SPL} = {} & -10.8 + \text{PWL}(f) - 20 \times \log R \\ & - 2.5 \times \log\left[\frac{1}{(10^{(1.633-0.0567\theta)} + 10^{(19.43-0.233\theta)})^{0.4}} + 10^{(4.333-0.115\theta)}\right]\end{aligned} \tag{15.21}$$

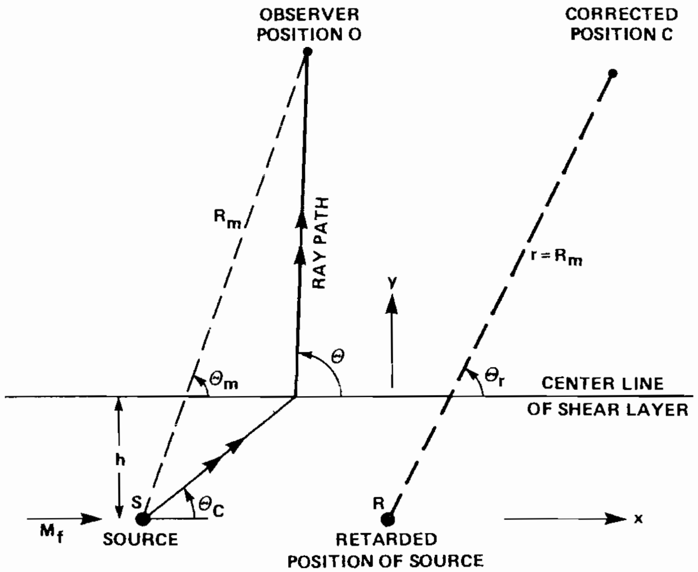

FIGURE 15.9 One-third-octave-band frequency power level spectrum of combuster noise.

where θ = angle from jet exhaust axis, degrees
R = observer distance, m

The peak radiation is predicted by (15.21) to occur at $\theta \approx 60°$, although at very low frequencies ($\leq$200 Hz) the peak may be shifted slightly toward the jet axis.

For an aircraft in flight at speed V_f, the modification of the predicted SPL may be estimated from Eq. (15.18).

15.5 TURBULENT BOUNDARY LAYER NOISE

The intense pressure fluctuations that can occur beneath a turbulent boundary layer are a source of sound and structural vibrations. The sound is produced directly by aerodynamic sources within the flow and indirectly by the *diffraction* at discontinuities in the wall (e.g., corners, ribs, support struts) of structural modes excited by the boundary layer pressures.

The pressure developed beneath a boundary layer on a *hard* wall is called the *blocked pressure* and is twice the pressure that a nominally identical flow would produce if the wall were absent. The rms wall pressure p_{rms} (in pascals) of the turbulent boundary layer can be estimated by[5]

$$\frac{p_{\text{rms}}}{q} \approx \sigma\varepsilon^* = \frac{\sigma}{\frac{1}{2}(1 + T_w/T) + 0.1(\gamma - 1)M^2} \tag{15.22}$$

where σ = 0.006, dimensionless
q = local dynamic pressure, $= \frac{1}{2}\rho U^2$, Pa
ρ = fluid density at outer edge of boundary layer, kg/m^3
U = free-stream velocity at outer edge of boundary layer, m/s
M = free-stream Mach number, $= U/c$, dimensionless
c = speed of sound at outer edge of boundary layer, m/s
T = temperature at outer edge of boundary layer, K
T_w = temperature of the wall, K
γ = ratio of specific heats of gas, dimensionless

The quantity $\sigma \equiv (p_{\text{rms}}/q)_{\text{incompressible}}$, and Eq. (15.22) represents a mapping from an incompressible flow to the compressible state by means of the compressibility factor, ε^*. Recent measurements[6] suggest that the currently accepted value $\sigma = 0.006$ may be too low and that a better approximation is $\sigma = 0.01$.

In many applications wall pressure fluctuations are substantially higher if the flow *separates*. For example, when separation occurs at the compression corner at a ramp or at an expansion corner, the rms wall pressure can typically exceed 2% of the local dynamic pressure q.

The structural response of a flexible wall to forcing by the boundary layer depends on both the temporal and spatial characteristics of the pressure fluctuations. When the wall is locally plane, these can be expressed in terms of the *wall pressure wavenumber–frequency spectrum* $P(\mathbf{k}, \omega)$. This is the two-sided Fourier transform $(1/2\pi)^3 \int_{-\infty}^{\infty} R_{pp}(x_1, x_3, t) \exp[-i(\mathbf{k} \cdot \mathbf{x} - \omega t)]\, dx_1\, dx_3\, dt$ of the space–time correlation function of the wall pressure R_{pp}. By convention, coordinate axes (x_1, x_2, x_3) are taken with x_1, x_3 parallel and transverse to the mean flow, respectively, x_2 measured outward of the wall, and the wavenumber $\mathbf{k} = (k_1, k_3)$ (in reciprocal meters) has components parallel to the x_1, x_3 axes only. The principal properties of the blocked-pressure spectrum $P_0(\mathbf{k}, \omega)$, say, are understood only for low-Mach-number flows ($M \ll 1$).

Wall Pressure Spectrum at Low Mach Number

Here, $P_0(\mathbf{k}, \omega)$ is an even function of ω, and its general features are shown in Fig. 15.10[7] for $\omega > 0$ The strongest pressure fluctuations are produced by eddies in the *convective ridge* of the wavenumber plane that convect along the wall at about 70% of the free-stream velocity. The region $k \equiv |\mathbf{k}| < \omega/c$ (c = speed of sound, in meters per second) is called the acoustical domain, and $k_0 = \omega/c$ is the acoustical wavenumber. The adjacent *subconvective* domain ($k_0 < k \ll \omega/U_c$) is important to determining the structural response of the wall to forcing by the turbulence pressures. In these regions $10 \times \log[P_0(\mathbf{k}, \omega)]$ is typically 30–60 dB below the levels in the convective domain.

Pressure fluctuations in the acoustical domain correspond to sound waves in the fluid. When the wall is smooth and flat, the generation of sound is dominated by quadrupole sources in the flow,[7] and the acoustical pressure frequency spectrum

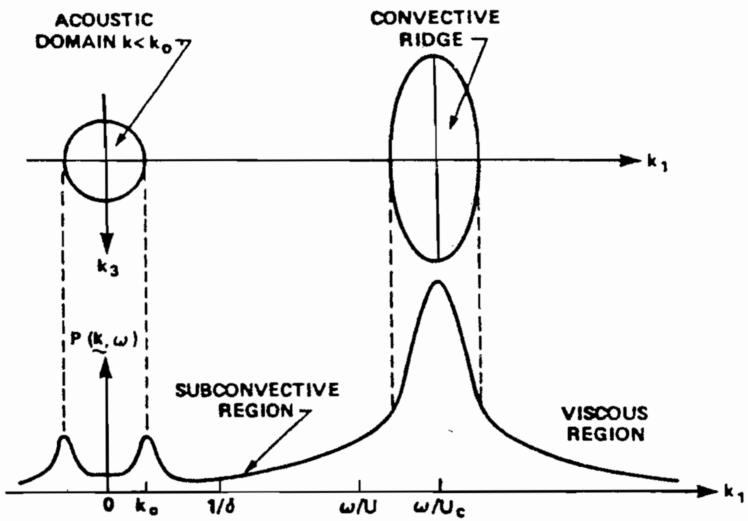

FIGURE 15.10 Turbulent boundary layer wall pressure spectrum at low Mach number for $\omega\delta/U \gg 1$, where δ is the boundary layer thickness (m).

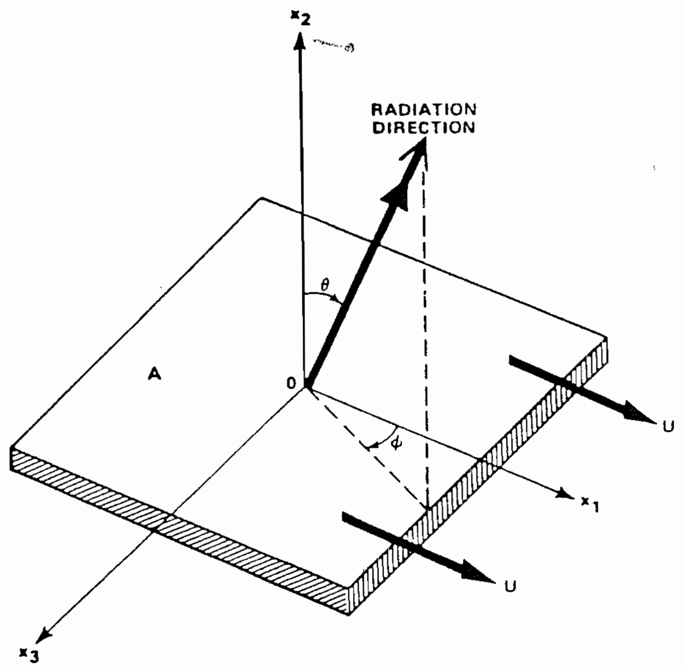

FIGURE 15.11 Coordinates defining the radiation of sound from a region of the wall of area A.

of sound produced by a fixed area of the wall (Fig. 15.11) is

$$\Phi(\omega) = 2\frac{A}{R^2}k_0^2 \cos^2\theta P_0(k_0 \sin\theta \cos\phi, k_0 \sin\theta \sin\phi, \omega) \qquad (15.23)$$

where OASPL $= 10 \times \log\left[\int_0^\infty \Phi(\omega)\, d\omega/(20\ \mu\text{Pa})^2\right]$, dB
A = area of wall region, m^2
R = observer distance from center of A, m
(θ, ϕ) = polar angles of observer defined in Fig. 15.11

Chase[8] has proposed the following representation of the blocked-pressure spectrum that is applicable over the whole range of wavenumbers and is based on an empirical fit to experimental data in the convective and subconvective domains:

$$\frac{P_0(\mathbf{k},\omega)}{\rho^2 v_*^2 \delta^3} = \frac{1}{[(k_+\delta)^2 + 1.78]^{5/2}} \left\{ \frac{0.1553(k_1\delta)^2 k^2}{|k_0^2 - k^2| + \beta^2 k_0^2} + 0.00078 \right.$$
$$\left. \times \frac{(k\delta)^2[(k_+\delta)^2 + 1.78]}{(k\delta)^2 + 1.78} \left(4 + \frac{|k_0^2 - k^2|}{k^2} + \frac{k^2}{|k_0^2 - k^2| + \beta^2 k_0^2} \right) \right\}$$
$$\frac{\omega\delta}{U} > 1 \qquad (15.24)$$

where δ = boundary layer thickness (distance from wall at which mean-flow velocity is equal to $0.99U$), m
ρ = mean fluid density, kg/m^3
v_* = friction velocity, $\approx 0.035U$, m/s
$U_c \approx 0.7U$, m/s
U = mainstream velocity at outer edge of boundary layer, m/s
ω = radian frequency, $= 2\pi f$, rad/s
$k_+ = \sqrt{(\omega - U_c k_1)^2/9v_*^2 + k^2}$, m^{-1}
$\beta \approx 0.1$, dimensionless

The first term in the curly brackets determines the behavior near the convective ridge and the second the low-wavenumber and acoustical domains. The numerical coefficient β controls the height of the spectral peak (Fig. 15.10) at the boundary $k = k_0$ of the acoustical domain and determines the intensity of the sound waves propagating parallel to the plane of the wall.

Example 15.2. Estimate the frequency spectrum $\Psi(\omega)$ of the power dissipated by flexural motion of a plane wall when the wall is excited by a low-Mach-number turbulent flow over a region of area A whose normal impedance $\mathbf{Z}(\mathbf{k}, \omega)$ (kg/m^2 · s) is independent of the orientation of $\mathbf{k}$.

Solution The impedance satisfies $Z(\mathbf{k},\omega) = -p(\mathbf{k},\omega)/v_2(\mathbf{k},\omega)$, where p and v_2, respectively, denote the Fourier components of the pressure and normal velocity on the wall. Let $Z = R - iX$, where R and X are the resistive and reactive components of the impedance, respectively. The total power delivered to the flexural motions is equal to $\int_0^\infty \Psi(\omega)\,d\omega$, where

$$\Psi(\omega) = 2A\int_{k>|k_0|}^{\infty} \frac{R(\mathbf{k},\omega)P_0(\mathbf{k},\omega)\,d^2\mathbf{k}}{R(\mathbf{k},\omega)^2 + [X(\mathbf{k},\omega) + \rho\omega/\sqrt{k^2-k_0^2}]^2}$$

The flexural-mode wavenumbers are the roots $\mathbf{k} = \mathbf{k}_n, n = 1, 2, 3, \ldots,$ of $X(\mathbf{k},\omega) + \rho\omega/\sqrt{k^2 - k_0^2} = 0$. In practice, these usually lie in the low-wavenumber region where $P_0(\mathbf{k},\omega) \equiv P_0(k,\omega)$, so that, when $R \ll X$ and Z is a function of $k \equiv \mathbf{k}$ and ω only,

$$\Psi(\omega) \approx \sum_n \frac{4\pi^2 A k_n P_0(k_n,\omega)}{\left|(\partial/\partial k)\left[X(k,\omega) + \rho\omega\Big/\sqrt{k^2-k_0^2}\right]\right|_{k_n}}$$

When the wall consists of a vacuum-backed, thin elastic plate of bending stiffness B (kg · m^2/s^2), mass density m (kg/m^2) per unit area, and negligible damping $R = 0$, we have $X = -(Bk^4 - m\omega^2)/\omega$, and there is only one flexural mode that occurs at $k = k_* > |k_0|$ such that

$$\Psi(\omega) = \frac{4\pi^2 A\omega(k_*^2 - k_0^2)P_0(k_*,\omega)}{5Bk_*^4 - 4B(k_0k_*)^2 - m\omega^2}$$

where k_* is the positive root of $Bk^4 - m\omega^2 - \rho\omega^2/\sqrt{k^2 - k_0^2} = 0$. Numerical estimates may be made by substituting for $P_0(k_*,\omega)$ from (15.24).

15.6 NOISE FROM FLUID FLOW IN PIPES

Piping system noise typically comes mainly from control valves (see Section 15.11) and high-speeds machines (see Chapter 18). However, under some circumstances the noise induced by flow through milder discontinuities (bends, tees, swags, and other components) may be significant. Here we describe an approximate approach for estimating this type of flow-induced noise.

Pressure fluctuations in the turbulent boundary layer drive the wall of the pipe, causing it to radiate sound. As described in Section 15.5, the structural response of a flexible wall to forcing by the boundary layer depends in a complex manner on both the temporal and spatial characteristics of the pressure fluctuations. Seebold[9] suggested the following approximate method for estimating the noise produced by fluid flow in piping systems. The method estimates the noise that results from boundary layer pressure fluctuations in fully developed turbulent flow in uninterrupted straight pipes[10] and then applies a loss factor correction for local discontinuities. This loss factor correction is based on the notion that the sound power radiated at a discontinuity is approximately proportional to the square of the pressure drop Δp there and can therefore be related to the pressure head loss factor K, where $\Delta p = K(\frac{1}{2}\rho U^2)$.

The sound pressure level at a distance of 1 m from the pipe in the octave band centered on frequency f_c is approximated by

$$\begin{aligned} \text{SPL} = &-3.5 + 40\log U + 20\log\rho + 20\log K \\ &- 10\log\left[\frac{t}{D}\left(1 + \frac{1.83}{D}\right)\right] - 5\log\left[\frac{f_c}{f_r}\left(1 - \frac{f_c}{f_r}\right)\right] + \Delta L(f_c) \end{aligned} \tag{15.25}$$

where U = gas flow velocity, m/s
ρ = fluid density, kg/m^3
t = pipe wall thickness, m
D = inside diameter of pipe, m
f_c = octave-band center frequency, Hz
f_r = ring frequency of pipe, Hz; = $1608/D$ for steel
K = total loss factor per 10-diameter pipe section, dimensionless

The spectral correction $\Delta L(f_c)$ depends on the ratio of the octave-band center frequency f_c to the Strouhal frequency of the pipe flow, $f_p = 0.2U/D$, as[11]

$$\Delta L = \begin{cases} 10.4 + 11.4\log\dfrac{f_c}{f_p} & \text{for } \dfrac{f_c}{f_p} < 0.5 \\ 7 & \text{for } 0.5 \le \dfrac{f_c}{f_p} < 5 \\ 14 - 10\log\dfrac{f_c}{f_p} & \text{for } 5 \le \dfrac{f_c}{f_p} < 12 \\ 41.9 - 36.1\log\dfrac{f_c}{f_p} & \text{for } \dfrac{f_c}{f_p} \ge 0.5 \end{cases} \tag{15.26}$$

When employing (15.25), the piping system should be thought of as being composed of segments 10 diameters in length. The total loss factor K is determined by adding the individual loss factors K_i for the flow fittings and elements present within each 10-diameter segment of pipe. This total loss factor is then entered in Eq. (15.25) to estimate the flow noise emanating from that segment (at a distance of 1 m from the pipe wall). Loss factors for various piping components are provided in Table 15.2. For example, the loss factor for a straight pipe is taken to be 0.12 velocity heads per 10-diameter segment. On the other hand, a 10-diameter-long segment of piping containing an expander (1.5 : 1), an elbow (90°, $R/D = 1.5$), and a tee (flow-through run) would have a total loss factor of approximately 1, $K \approx 0.1 + 0.33 + 0.5 \approx 1$.

15.7 SPOILER NOISE

The term *spoiler noise* is used to characterize the noise produced by an obstacle or other obstruction that spans a duct carrying a mean flow. We shall discuss the case of air flowing in a duct or pipe that may be regarded as "semi-infinite" when

TABLE 15.2 Pressure Head Loss Factors[a] K

Straight pipes (10-diameter-long segment)		0.12				
45° Elbow	Screwed	0.42	Welded, $R/D = 1$	0.29	Welded, $R/D = 1.5$	0.21
90° Elbow	Screwed	0.92	Welded, $R/D = 1$	0.45	Welded, $R/D = 1.5$	0.33
180° Elbow	Screwed	2.00	Welded, $R/D = 1$	0.60	Welded, $R/D = 1.5$	0.43
Tees (screwed)	Thru branch	1.80	Thru run	0.50		
Tees (welded)	Thru branch	1.40	Thru run	0.40		
Reducer	$D_2/D_1 = 0.3$	0.25	$D_2/D_1 = 0.5$	0.17	$D_2/D_1 = 0.7$	0.07
Expander	$D_2/D_1 = 3$	0.80	$D_2/D_1 = 2$	0.56	$D_2/D_1 = 1.25$	0.10
Sudden Contraction	$D_2/D_1 = 0.1$	0.48	$D_2/D_1 = 0.33$	0.41	$D_2/D_1 = 0.8$	0.12
Sudden Expansion	$D_2/D_1 = 10$	0.98	$D_2/D_1 = 3$	0.79	$D_2/D_1 = 1.25$	0.12

[a] After Ref. 9.

it is desired to estimate the acoustical radiation from the open end. A spoiler-noise-generating system is shown schematically in Fig. 15.12. In practice, the spoiler may be a strut, stringer, guide vane, or other flow control device. The nominally steady mean flow exerts unsteady lift and drag forces on the spoiler, which accordingly behaves as an acoustical source of *dipole* type.

The following idealizations will be made:

1. The spoiler can be of arbitrary shape, but its cross-flow dimensions are small relative to the pipe cross section. This ensures that the flow speeds near the spoiler are not significantly greater than the pipe mean flow speed and therefore that turbulence mixing noise (quadrupole) can be neglected. Thus, the case of a valve, which produces a severe throttling of the flow, is excluded (see Section 15.11).
2. The peak frequency of the noise spectrum is below the "cutoff" frequency f_{co} of the pipe, which is given by

$$f_{co} = \begin{Bmatrix} 0.293c/r & \text{Hz (circular pipe)} \\ 0.5c/w & \text{Hz (rectangular pipe)} \end{Bmatrix} \tag{15.27}$$

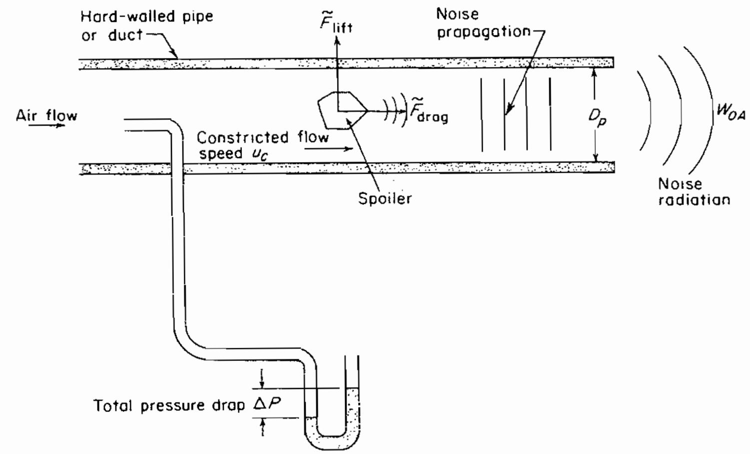

FIGURE 15.12 Flow spoiler system. The sound power is generated by the unsteady drag force on the spoiler and radiated from the open end of the pipe.

where c = sound speed, m/s
r = radius of circular pipe, m
w = largest transverse dimension of rectangular pipe, m

If this condition is not fulfilled, the propagated sound power near and above the peak frequency (which determines most of the overall sound power) will be influenced by transverse modes of the pipe.

3. The pipe wall is acoustically rigid. The fluctuating lift forces on the spoiler are then canceled by images in the wall, and sound is produced solely by the unsteady drag, which corresponds to an acoustical dipole whose axis is parallel to the mean flow. A low-noise spoiler system should therefore use bodies of low drag, such as airfoils, rather than grids or other oddly shaped bodies.

For several elementary flow spoiler configurations, such as the one shown in Fig. 15.12, the *fluctuating drag is directly proportional to the steady-state drag experienced by the body*. This depends on the pressure drop ΔP across the spoiler (as measured by an upstream and a downstream total-pressure probe), and the broadband noise radiated from the open end of the pipe is given by[12]

$$W_{OA} = \frac{k(\Delta P)^3 D_p^3}{\rho^2 c^3} \tag{15.28}$$

where W_{OA} = overall radiated sound power, W
k = constant of proportionality, dimensionless

ΔP = total pressure drop across spoiler, Pa
D_p = pipe diameter, m
ρ = atmospheric density, kg/m^3
c = atmospheric sound speed, m/s

Specific information about spoiler geometry is absent from Eq. (15.28) but is implicit in the pressure drop ΔP. From a variety of experimental spoiler configurations the constant k is found to be about 2.5×10^{-4} for air.

Equation (15.28) determines the broadband sound power. It should strictly be regarded as a lower bound that is applicable only if there are no *discrete-frequency* components of the noise. These are present in certain conditions (e.g., excitation of edge tones) and may well stand out against the broadband levels.[13] When such a mechanism has been identified, the discrete tones can usually be eliminated or controlled by detuning or rounding off sharp corners or edges or cutting feedback paths by treating reflecting surfaces with sound-absorbent materials.

The frequency spectrum measured outside the pipe for the noise generated by the spoiler exhibits a haystack structure (Fig. 15.13) with a peak frequency given by

$$f_p \approx \frac{u_c}{db} \quad \text{Hz} \tag{15.29}$$

where u_c = constricted flow speed, m/s
d = projected width of spoiler, m
b = constant that equals 0.2 for pressure differences ΔP of the order 4000 Pa and 0.5 for ΔP of the order of 40,000 Pa

The constricted flow speed u_c for cold air is given in Table 15.3 as a function of ΔP. Values in between those in the table can be interpolated.

Example 15.3. Find the sound-power-level spectrum of noise produced by a spoiler consisting of a flat plate of width 2 cm stretching across a circular pipe of internal diameter $D_p = 5$ cm. The pressure drop across the spoiler is $\Delta P = 10,000$ Pa.

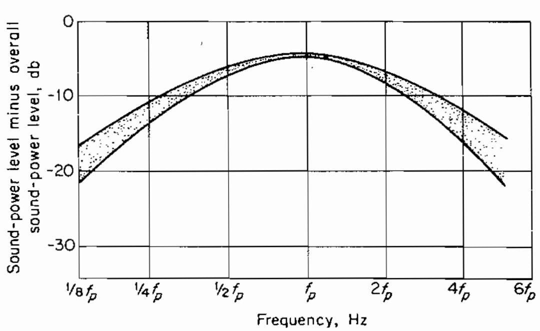

FIGURE 15.13 Generalized octave-band spectrum for in-pipe-generated spoiler noise referenced to the total power radiated from the open end and the peak frequency.

TABLE 15.3 Constricted Flow Speed u_c for Cold Air as Function of Pressure Drop

ΔP, Pa	2500	5000	10,000	20,000	30,000	40,000
u_c, m/s	63	90	124	173	209	238

Solution From Eq. (15.28) the total sound power $L_w \approx 101$ dB re 10^{-12} W. When $\Delta P = 10,000$ Pa, the peak frequency of the spectrum can be expected to be at $f_p \approx 0.35 u_c/d$.

From Table 15.3, we find $u_c = 124$ m/s; hence $f_p \approx 2170$ Hz. The sound power spectrum in octave bands is obtained form Fig. 15.13 with 101 dB added to the ordinate.

15.8 GRID OR GRILLE NOISE

The characteristics of noise produced by flow through grids, grilles, diffusers, guide vanes, or porous plates, which often terminate air conditioning ducts, are similar to those of spoiler-generated sound. The principal differences are that (1) the grid is located at the open end of the duct, (2) the duct cross-sectional area is typically quite large (say, 0.04–1 m^2), and (3) the velocity of the air in the duct is usually small, rarely exceeding 30 m/s. The speed of the "air jets" exhausting from the individual air passages (or orifices) in a diffuser is generally low enough (<100 m/s) that jet mixing noise can be neglected. The dominant sound source is of dipole type and is associated with the interaction of the flow with the diffuser elements (e.g., guide vanes).

When a duct is terminated by a grid of circular rods (Fig. 15.14*a*), periodic shedding of vortices can occur, producing a fluctuating lift force on each rod and an associated *tonal* component of the radiated sound. This source is a dipole (whose axis is parallel to the lift direction) and is in addition to the drag dipole. The frequency of the tone is given approximately by

$$f = \frac{0.2u}{D_R} \tag{15.30}$$

where u = mean flow speed, m/s
D_R = diameter of rods, m

Tonal oscillations produced by a feedback mechanism can also arise when the duct termination consists of a plate perforated with sharp-edged circular cylindrical apertures (Fig. 15.14b).

In general, however, the noise produced by typical air conditioner grids is almost always broadband and of conventional dipole character, with the sound power varying as the sixth power of the velocity. As in the case of spoiler noise, the overall sound power can be related to the pressure drop ΔP across the grid,

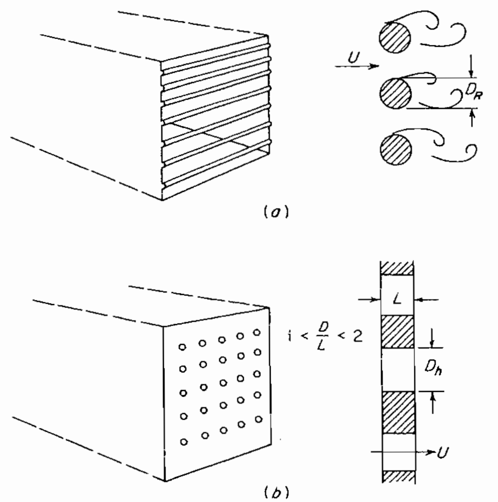

FIGURE 15.14 Special cases of duct terminations: (*a*) circular rods; (*b*) sharp-edge circular cylindrical holes.

independently of the specific grid geometry. To do this, we introduce the pressure drop coefficient

$$\xi = \frac{\Delta P}{\frac{1}{2}\rho u^2} \tag{15.31}$$

where ρ = density of air, kg/m^3
u = mean flow speed in duct prior to grid, m/s

Three typical diffuser configurations together with their pressure drop coefficients ξ are illustrated in Fig. 15.15.[14] The values of ξ for similar diffuser configurations are usually available from the manufacturer. If not, they may be estimated from this figure.

If not given by the manufacturer, the overall sound power level L_w from air conditioning diffusers can be estimated from the empirical formula[14]

$$L_w = 10 + 10 \times \log(S\xi^3 u^6) \quad \text{dB re } 10^{-12}\text{ W} \tag{15.32}$$

where S = area of duct cross section prior to diffuser, m^2
ΔP = pressure drop through diffuser, Pa

The noise spectra of different diffusers do not exhibit identical shapes even when normalized to similar flow speeds and exhaust areas. Construction differences tend to emphasize different frequency regimes, and poorly designed diffusers will radiate discrete-frequency sound. In practical noise control problems, however, a general spectrum shape $L_w - 10 \times \log_{10}(S\xi^3)$ (dB re 10^{-12} W) can be used for each duct velocity u (in meters per second) that fits most diffuser noise spectra to within about ±5 dB, as shown in Fig 15.16.

Configuration	Duct area, m^2	Comment	Pressure drop coefficient ξ
(a)  0.2 m; 0.1 m; 0.035 m	0.020	Parallel louvres	2.9

FIGURE 15.15 Various duct terminations and their pressure drop coefficients $\xi = \Delta P / \frac{1}{2}\rho u^2$. The duct area S is in square meters. (After Ref. 14.)

To estimate the sound power spectrum of the radiation from a given diffuser, first determine the relevant curve from Fig. 15.16 for the particular flow speed. The ordinate in the figure is then increased by $10 \times \log_{10}(S\xi^3)$ decibels to yield the desired one-third-octave-band spectrum with a margin of error of about ±5 dB.

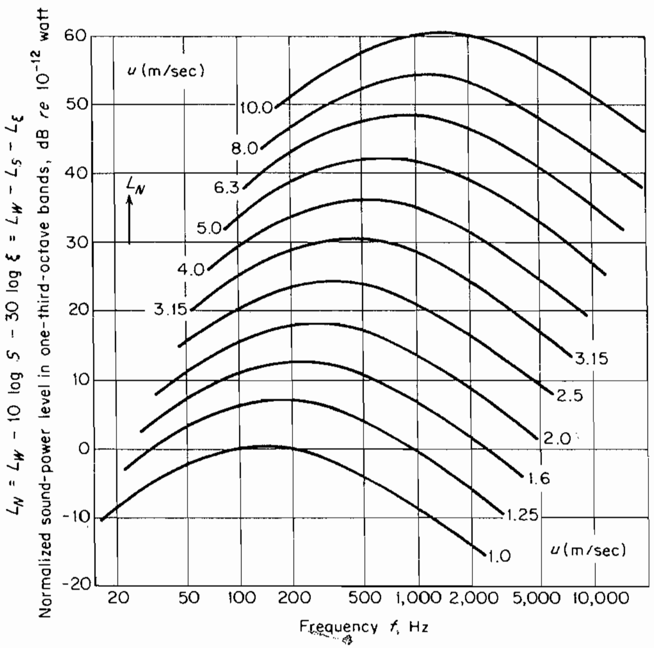

FIGURE 15.16 Normalized one-third-octave-band sound power level spectra for noise radiated from diffusers of various flow velocities. (After Ref. 14.)

15.9 SOUND GENERATION BY AIRFOILS AND STRUTS

Noise of a Strut in a Turbulent Stream

Long struts, airfoils, guide vanes, and so on, which offer negligible drag to a mean flow, frequently experience significant fluctuations in lift when exposed to a turbulent stream and behave as *dipole-type* sources of broadband sound. The strength of the radiation depends on the dimensions of the airfoil and on the turbulence intensity and correlation length of the velocity fluctuations.

A simple description of the radiation can be given when the mean flow is of low Mach number (say, <100 m/s in air) and when the distance to the nearest boundary (e.g., duct wall) is at least of the order of the acoustical wavelength. In these circumstances the *frequency spectral density* of the total radiated sound power $\Pi(\omega)$ is given approximately by

$$\Pi(\omega) = \frac{\pi l a^2 \rho u^2 M^3 (\omega\Lambda/U)^4}{4(1+\pi\omega a/U)[1+(\omega\Lambda/U)^2]^{5/2}[1+(\omega a/3c)^3]^{1/3}} \qquad (15.33)$$

where ω = radian frequency, $= 2\pi f$, f in Hz
a = chord of airfoil, m

l = span of airfoil, m
ρ = density of mean stream, kg/m^3
u = rms turbulence velocity in lift direction, m/s
U = velocity of mean stream, m/s
M = mean flow Mach number, $= U/c$, dimensionless
c = sound speed, m/s
Λ = integral scale of turbulence velocity, m

The total radiated sound power $W = \int_0^\infty \Pi(\omega)\, d\omega$, in watts, can be estimated from

$$W = \frac{1.78(la^2/\Lambda)\rho u^2 U M^3}{(1+10.71a/\Lambda)(1+1.79\, Ma/\Lambda)} \qquad 0 \le M \le 0.3 \qquad (15.34)$$

At low frequencies the acoustical intensity exhibits the characteristic dipole *field shape*, proportional to $\cos^2\theta$, where θ is measured from the direction of the mean lift. At higher frequencies (when the acoustical wavelength is much smaller than the chord of the airfoil but still exceeds the airfoil thickness), the field shape assumes a cardioid form, with a null in the forward direction and peaks close to the direction of the mean flow.

Airfoil Self-Noise

In addition to gust/inflow turbulence-induced noise, an airfoil can also generate *self-noise* when turbulence that arises from the natural instability of the boundary layers on the surface of the airfoil is swept past the trailing edge. This is usually important when the hydrodynamic wavelength of the turbulence eddies is larger than the airfoil thickness at the trailing edge. The mechanism of noise production tends to be weaker than at the leading edge, because the violence of the unsteady motion at the trailing edge is alleviated by vortex shedding into the wake, and to be more prominent at higher frequencies.[15]

The noise may be ascribed to a distribution of lift dipoles near the trailing edge. At low frequencies the acoustical intensity exhibits the characteristic dipole field shape, proportional to $\cos^2\theta$, with a null in the plane of mean motion of the airfoil. At higher frequencies (when the acoustical wavelength is smaller than the chord of the airfoil) the field shape assumes a cardioid form, with a null in the downstream direction and the peak in the forward direction. In either case, when the trailing edge is at right angles to the mean flow, the frequency spectral density of the overall sound power $\Pi(\omega)$ (in watt-seconds) is given approximately by

$$\Pi(\omega) = \frac{\pi l a \omega^2}{24\rho c^3[1+(\omega a/3c)^3]^{1/3}} \int_{-\infty}^{\infty} \frac{P_0(k_1, 0, \omega)}{|k_1|}\, dk_1 \qquad (15.35)$$

where $P_0(\mathbf{k}, \omega)$ = blocked-pressure wavenumber–frequency spectrum on airfoil just upstream of trailing edge (see Section 15.5)
k_1 = wavenumber component parallel to mean flow, m^{-1}

If the flow approaching the trailing edge is turbulent on both sides of the airfoil, $P_0(k_1, 0, \omega)$ in Eq. (15.35) should be replaced by the sum of the wall pressure spectra on the two sides.

When the Chase model [Eq. (15.24)] is used to estimate the integral in Eq. (15.35), the frequency spectral density of the sound power radiated by a section of the airfoil of spanwise length l (in meters) is

$$\Pi(\omega) = \frac{0.08 a l \delta \rho v_*^4 U_c (\omega\delta/U_c)^3}{c^3[1 + (\omega a/3c)^3]^{1/3}[(\omega\delta/U_c)^2 + 1.78]^2} \qquad (15.36)$$

where δ = boundary layer thickness, m
v_* = friction velocity, m/s
$U_c \approx 0.7 \times$ velocity of mean stream, m/s

and other quantities are defined after Eq. (15.35).[16] However, measured levels of $\Pi(\omega)$ frequently exceed predictions of this formula. More detailed empirical formulas are given in the references.[16,17]

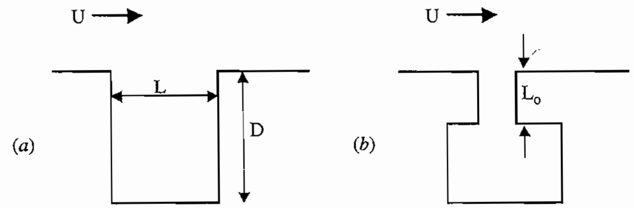
When the frequency is high enough [beyond the range of applicability of Eq. (15.36)] that the *Strouhal number* $\omega h/U \approx 1$, where h is the thickness of the trailing edge of the airfoil, the shedding of discrete vortices from the trailing edge can occur, provided the Reynolds number Ua/ν based on the chord a of the airfoil (dimensionless; ν is kinematic viscosity in square meters per second) does not exceed 10^6–10^7. This produces a distinct contribution to trailing-edge noise, often called "airfoil singing," whose amplitude is not easily predicted.[16]

15.10 FLOWS PAST CAVITIES

Sheared flow passing over a hole or opening in a wall can be the source of intense acoustical tones. Instability of the mean flow over such a wall cavity not only can excite hydrodynamic self-sustained oscillations but also can couple with resonant acoustical modes of the cavity, as in the Helmholtz resonator. Cavity tones are a frequent source of unwanted noise and vibration in branched duct and piping systems, turbomachinery, and exposed openings on automobiles, aircraft, and other high-speed vehicles. In this section we provide relationships for determining when flow over an opening that can be approximated as either a rectangular cavity (Fig. 15.17*a*) or a Helmholtz resonator (Fig. 15.17*b*) might be expected to exhibit strongly resonant behavior.

Flow over Cavities of Uniform Cross Section

For cavities of the type shown in Fig. 15.17*a*, resonant cavity oscillation occurs when the frequency associated with the shedding of vorticity from the upstream edge of the cavity is sufficiently high and the acoustical wavelengths within the cavity are sufficiently short as to allow standing waves inside the cavity. Longitudinal wave resonance is possible when the acoustical wavelength is less



A_o = Orifice Cross-Sectional Area
V_c = Cavity Volume
A_c = Cavity Cross-Sectional Area

FIGURE 15.17 Examples of flows that sustain cavity resonances: (*a*) rectangular cavity of uniform cross section; (*b*) non-axisymmetric Helmholtz resonator.

than twice the cavity length, $c/f \leq 2L$, and depth resonance is observed when the acoustical wavelength is less than four times the cavity depth, $c/f \leq 4D$. For shallow cavities, where cavity length-to-depth ratio is large ($L/D > 1$), the longitudinal standing waves are dominant, while for deep cavities ($L/D < 1$) the depth resonance dominates.

Rossiter[18] derived the following equation for the Strouhal number associated with longitudinal cavity resonance modes:

$$\frac{fL}{U_\infty} = \frac{m - \xi}{M + 1/k_v} \qquad (15.37)$$

where k_v = ratio of shear layer velocity to free-stream velocity, $= U_c/U_\infty \cong 0.57$
m = mode number, $= 1, 2, 3, \ldots$, dimensionless
ξ = empirical constant, = 0.25, dimensionless
L = cavity length, m
M = free-stream Mach number, $= U_\infty/c$, dimensionless

Block[19] developed the following relation for the longitudinal cavity modes that accounts for the dependence of the Strouhal number on the cavity L/D ratio as observed in experimental data for shallow ($L/D > 1$) cavities:

$$\frac{fL}{U_\infty} = \frac{m}{1.75 + M\,(1 + 0.514/(L/D))} \qquad (15.38)$$

The following relation for depthwise modes of cavity oscillation was developed by East[20]:

$$\frac{fL}{U_\infty} = \left(\frac{1}{M}\right)\left(\frac{L}{D}\right)\left(\frac{0.25}{1 + 0.65(L/D)^{0.75}}\right) \qquad (15.39)$$

Lucas,[21] after comparing the ranges of validity of various cavity oscillation models, recommends, for low to moderate Mach number, the use of Block's formula (15.38) for shallow $(L/D > 1)$ cavities. For deep cavities he suggests use of East's formula (15.39) to determine the resonance of the depth mode and Rossiter's formula (15.37) for the longitudinal resonance mode. For such deep cavities the depth resonance will be the dominant mode.

Block[19] combined Eqs. (15.38) and (15.39) so that the frequency for the shallow acoustical waves coincides with the depthwise acoustical modes, providing the following formula for estimating the Mach number at which a cavity begins to oscillate in a given mode m:

$$M = \frac{1.75L/D}{4m[1 + 0.65(L/D)^{0.75}] - [(L/D) + 0.514]} \tag{15.40}$$

Equation (15.40) was shown by Block[19] to give adequate agreement with experimental data for Mach numbers in the range of 0.1–0.5 and for $L/D < 2$.

Flow over a Helmholtz Resonator

The natural frequency f_n of the Helmholtz resonator shown in Fig. 15.17b is given by

$$f_n = \frac{c}{2\pi}\sqrt{\frac{A_o}{V_c L_{\text{eff}}}} \tag{15.41}$$

where c = sound speed, m/s
A_o = orifice cross-sectional area, m^2
V_c = cavity volume, m^3
L_{eff} = effective neck length of orifice, m

The following approximate expression[22] for the effective neck length L_{eff} in the presence of a mean flow over the Helmholtz resonator accounts for an end correction due to the entrained mass of the virtual piston forming the interface between the neck and the exterior space (length ΔL_o):

$$\begin{aligned} L_{\text{eff}} &= L_o + \Delta L_o \\ &= L_o + 0.48\sqrt{A_0} \end{aligned} \tag{15.42}$$

where L_o is the length of the neck length of the orifice in meters.

An experimental study by Panton and Miller[23] indicates a strong response of the Helmholtz resonator excited by a turbulent boundary layer when

$$\frac{2d_o f_n}{U_c} \cong 1 \tag{15.43}$$

where d_o = Helmholtz resonator neck diameter, m
U_c = boundary layer convection velocity, $\approx 0.7U$, m/s
U = mainstream velocity at outer edge of boundary layer, m/s

In Eq. (15.43) f_n is either the Helmholtz resonance frequency in Eq. (15.41) or the fundamental standing-wave (organ pipe) resonance. For the latter, the natural frequency is approximately given by

$$f_n \cong \frac{c}{2L_{\text{eff}}} \tag{15.44}$$

Example 15.4. Many automobiles have a sunroof opening in their roof. Under some conditions the interior volume of the automobile cabin can act in combination with such an opening to create a Helmholtz resonator. If no measures are taken to prevent such an occurrence, at what speed might we expect the automobile's passengers to experience intense pressure fluctuations given a cabin interior volume of approximately 3 m^2, a square opening in the roof 0.4 m on a side, and a combined thickness of the roof and edging surrounding the opening of approximately 10 cm.

Solution Assuming an air temperature of 20°C, the speed of sound $c = 331.5 + 0.58T$ (in °C) = 343.1 m/s. The orifice cross sectional area $A_o = 0.4 \times 0.4 = 0.16$ m^2. The effective length of the opening is given by Eq. (15.42) as $L_{\text{eff}} = 0.1 + 0.48\sqrt{0.16} = 0.29$ m. Applying the above values and the cavity volume of $V_c = 3$ m^2, from Eq. (15.41) we expect the Helmholtz resonance to occur at $f_n = 23.4$ Hz. We take the neck diameter to be given by the length of the opening, $d_o = 0.4$ m. Substituting this value and that of the resonance frequency into Eq. (15.43), we can solve for the convection velocity, $U_c \approx 2 \times 0.4 \times 23.4 = 18.7$ m/s. The corresponding velocity of the mainstream, and thus our estimate of the vehicle speed at which we expect to strongly excite the Helmholtz resonance, is $U = U_c/0.7 = 26.7$ m/s, or 96 kph.

15.11 AERODYNAMIC NOISE OF THROTTLING VALVES

The noise of gas control or throttling valves may generally be associated with two sources: (1) mechanical vibration of the trim and (2) aerodynamic throttling. Noise generation by these mechanisms rarely occurs simultaneously, but when it does, the cure of one is usually the cure of the other.

Aerodynamic Noise

The prediction of the noise radiated from the body of a valve and from the downstream piping connected to it involves the following conceptual steps: (1) prediction of the magnitude and the spatial and spectral distribution of the noise inside the pipe based on the aerodynamic characteristics of the valve and the cross sectional area of the pipe, (2) prediction of the vibration response of the pipe to the internal sound field, (3) prediction of the sound radiation of the vibrating pipe.

In Step 1, the sound power generated by the valve has two components. The first is owing to the dynamic drag and lift forces (dipole) generated by the interaction of the turbulent flow with the valve, which are roughly proportional to the sixth power of the flow velocity. The second is sound power generated by the jet noise component (quadrupole), which is roughly proportional to the eighth power of the jet exit velocity. At very high pressure ratios, when the flow in the valve passage is supersonic, a shock pattern emerges downstream of the valve and generates intense screech noise. The dipole mechanism dominates the internal sound field at low Mach numbers and the quadrupole at high Mach numbers.

Based on the scaling of experimental data,[24] the lowest pipe wall attenuation occurs at $f_0 = (f_R/4)(c_{gas}(T)/c_0)$, where f_R is the ring frequency (Eq.15.58) and $c_{gas}(T)$ and $c_0 = 340$ m/s are the speed of sound of the gas in the pipe at local temperature and the that of air at room temperature respectively.

A fully analytical prediction procedure is too cumbersome. Consequently, the valve industry has adopted a prediction procedure based on both analytical and empirical methods that predicts the sound pressure level of the valve noise at 1 meter from the pipe wall directly from the aerodynamic properties of the valve and the geometric and material properties of the pipe. The rest of this chapter describes this semi-empirical prediction procedure.

Investigations of noise-induced pipe failures[25] have enabled maximum safe sound power levels to be established for given pipe sizes and wall thicknesses, as indicated in Fig. 15.18. The power levels shown in the figure correspond approximately to a sound level of 130 dBA at 1 m from the pipe wall downstream of the valve. Exceeding this level will most probably lead to piping failure, and a limit of 110 dBA at 1 m is recommended for safety and to maintain the structural integrity of valve-mounted accessories.

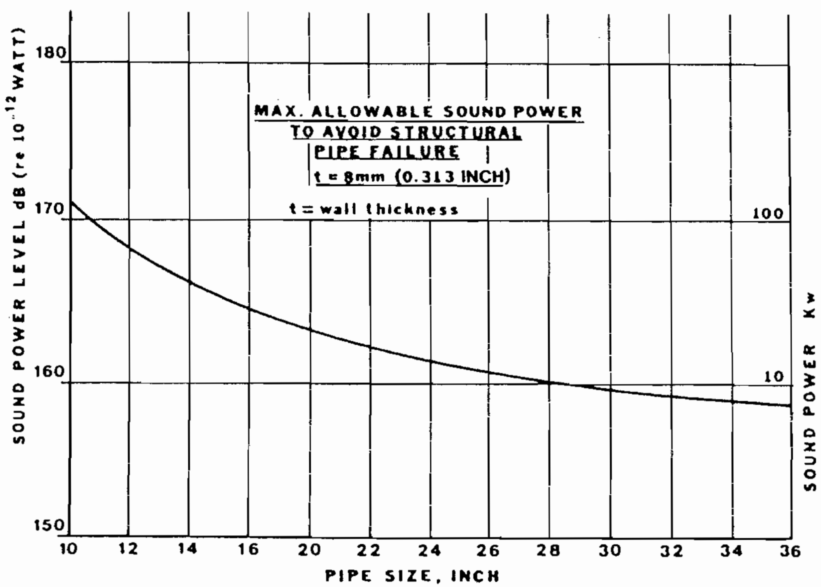


FIGURE 15.18 Suggested sound power level and sound power (Kw) limits inside pipe to avoid structural pipe failure based on actual occurrence.[24]

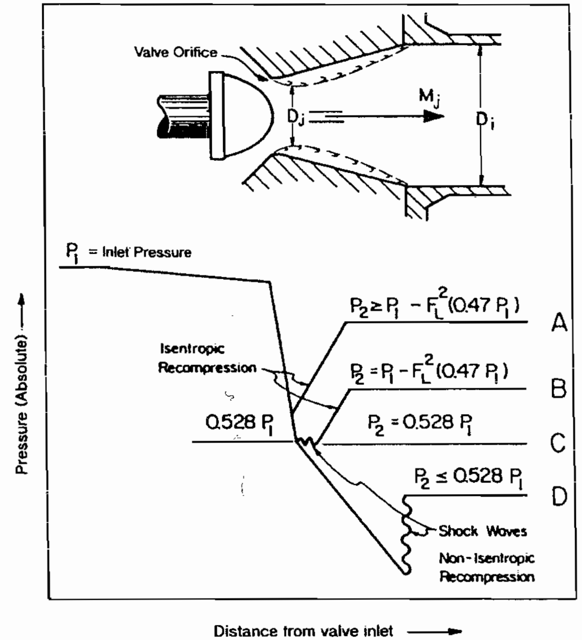

FIGURE 15.19 Schematic flow profile and static pressure diagram of throttling valve for various downstream pressures (P_2).

The aerodynamic noise is determined by the mechanical stream power $W_{\mathrm{mech\ strm}} = \frac{1}{2}mU^2$ (m being the mass flow and U the velocity; see Section 15.3) that is converted from potential energy (inlet pressure) to kinetic energy (velocity head) within the valve and subsequently to thermal energy (corresponding to reduced downstream pressure and an increase in entropy).[26] The pressure reduction (i.e., the conversion of kinetic into thermal energy) occurs via the generation of turbulence or, when the flow is supersonic, through shock waves. The sound power is equal to $\eta W_{\mathrm{mech\ strm}}$, where η is an acoustical efficiency factor. Unlike the case of a jet discharging into the atmosphere, the jet from a valve cannot expand freely, and only a fraction of the kinetic energy is converted by turbulence into thermal energy. This is illustrated in Fig. 15.19, which is a schematic view of a throttling valve and the associated pressure profile for various downstream pressures P_2.* On curve A the flow is subsonic, and turbulence-generated sound is predominantly of dipole type. At the critical pressure ratio ($P_1/P_2 = 1.89$ for air), curve B shows the presence of incipient shock waves followed by subsonic recompression, with both turbulence and shocks as noise sources. At higher pressure ratios recompression tends to be nonisentropic, and sound is produced predominantly by shock waves (curve D).

*In the rest of this chapter all pressures are absolute static pressures (in pascals).

Downstream of the vena contracta (D_j in Fig. 15.19) a portion of the velocity head is always recovered. The fraction lost is equal to F_L^2, where F_L is an experimentally determined pressure recovery coefficient that depends on valve type and size. The pressure drop $P_1 - P_2$ across the valve required to reach sonic velocity in the vena contracta is $F_L^2(P_1 - P_0)$, where P_0 is the static pressure in the vena contracta.[26] In subsonic flow the remaining portion of the jet power is recovered through isentropic recompression and is not converted to sound. If there were no pressure recovery at the valve orifice and assuming sonic flow at speed in c_0 meters per second (curve D in Fig. 15.19),

$$W_{\text{mech strm}} = \tfrac{1}{2} m c_0^2 \tag{15.45}$$

where m is the mass flow in kilograms per second, which also determines the valve flow coefficient C_v [see Eq. (15.50) or Table 15.4] together with the specific gravity G_f of the vapor or gas (relative to air = 1) and the valve inlet pressure P_1 (in pascals) such that

$$W_{\text{mech strm}} = 7.7 \times 10^{-11} C_v F_L c_0^3 P_1 G_f \quad \text{W} \tag{15.46}$$

The total sound power is then

$$W = \eta W_{\text{mech strm}} \quad \text{W} \tag{15.47}$$

$$L_W = 10 \times \log \frac{\eta W}{10^{-12}} \quad \text{dB} \tag{15.48}$$

When the pressure ratio is not sonic, η should be replaced by the acoustical power coefficient η_m determined below and (to simplify the calculations) should be used in conjunction with the sonic mechanical stream power given by Eq. (15.45). The acoustical power coefficient is further used in Eq. (15.53).

It may be remarked that the pressure recovery coefficient F_L can be used to predict the pressure P_0 in the vena contracta and also, to a satisfactory approximation, the area A_v of the vena contracta by

$$P_0 = P_1 - \frac{P_1 - P_2}{F_L^2} \tag{15.49a}$$

$$A_v = \frac{C_v F_L}{5.91 \times 10^4} \quad \text{m}^2 \tag{15.49b}$$

The valve's flow coefficient C_v can be calculated as follows:

$$C_v = \begin{Bmatrix} 2.14 \times 10^7 \dfrac{m}{\sqrt{\Delta P (P_1 + P_2) G_f}} & \Delta P \le \dfrac{1}{2} F_L^2 P_1 \\ 1.95 \times 10^7 \dfrac{m}{F_L P_1 \sqrt{G_f}} & \Delta P \ge \dfrac{1}{2} F_L^2 P_1 \end{Bmatrix} \tag{15.50}$$

Acoustical Efficiency

At Mach 1 a free jet has an acoustical efficiency $\eta \approx 10^{-4}$. If it is assumed that the sources of valve noise are dipoles and quadrupoles of equal magnitude (5×10^{-5}) at the Mach 1 reference point, then their respective efficiencies are represented by curves A and B in Fig. 15.20, and both curves can be combined to yield a subsonic slope C that originates at 1×10^{-4} and varies as $U^{3.6}$. This curve can be modified further to account for the decrease in $W_{\text{mech strm}}$ ($\propto U^3$) with subsonic velocities, leading to the final curve D for the effective efficiency (i.e., acoustical power coefficient) η_m that varies as $U^{6.6}$ or $(P_1/P_0 - 1)^{2.57}$ when $U \propto (P_1/P_0 - 1)^{0.39}$, P_0 being the static pressure in the vena contracta. This approximation gives satisfactory results for $0.38 \le M \le 1$ (i.e., down to $P_1/P_2 = 1.1$).

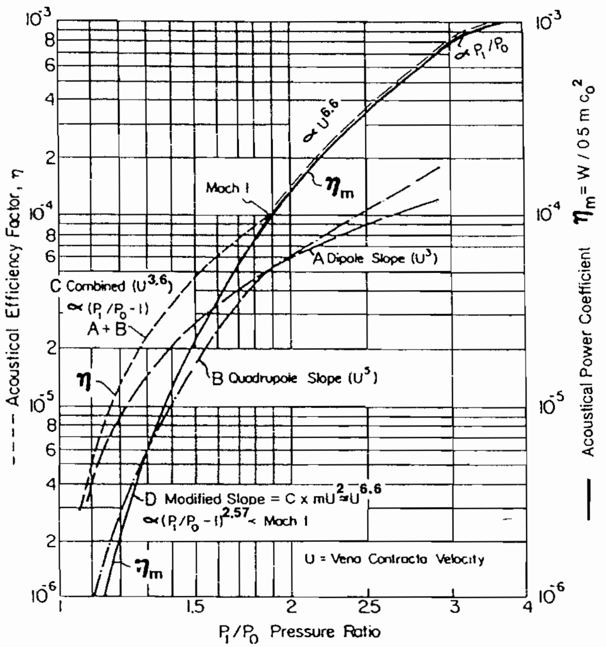

FIGURE 15.20 Slopes of dipole and quadrupole acoustical efficiency curves, assuming each has equal strength at Mach 1; their combined slope and the η_m curve after subtracting the effects of change in mass flow m and orificial velocity U for regions below Mach 1 from the combined curve.

For practical use it is convenient to express η_m in terms of P_1/P_2 = inlet pressure/outlet pressure. The following formulas[28,29] may be used for this purpose:

regime I: $P_1/P_2 < P_1/P_{2\text{critical}}$ (subsonic):

$$\eta_{mI} = 10^{-4} F_L^2 \left(\frac{P_1 - P_2}{P_1 F_L^2 - P_1 + P_2} \right)^{2.6} \tag{15.51a}$$

regimes II and III: $P_1/P_{2\text{critical}} < P_1/P_2 < 3.2\alpha$:

$$\eta_{mII} = 10^{-4} F_L^2 \left(\frac{P_1/P_2}{P_1/P_{2\text{critical}}} \right)^{3.7} \tag{15.51b}$$

regime IV: $3.2\alpha < P_1/P_2 < 22\alpha$ ($M_j > 1.4$):

$$\eta_{mIV} = 1.32 \times 10^{-3} F_L^2 \left(\frac{P_1/P_2}{P_1/P_{2\text{break}}} \right) \tag{15.51c}$$

regime V: $P_1/P_2 > 22\alpha$ (constant efficiency):

$$\eta_{mV} = \text{maximum value from regime IV} \tag{15.51d}$$

where
$\alpha = (P_1/P_{2\text{critical}})/1.89$
$P_1/P_{2\text{break}} = \alpha\gamma^{\gamma/(\gamma-1)}$ at $M = \sqrt{2}$
γ = ratio of specific heat of gas
$P_1/P_{2\text{critical}} = P_1/(P_1 - 0.5 P_1 F_L^2)$

The values of these parameters may be taken from Table 15.5.

When the downstream piping is straight and there are no sudden changes in cross-sectional area, the highest internal $\frac{1}{3}$-octave band sound pressure level L_{pi} (re 2×10^{-5} Pa) downstream of the valve is given by

$$L_{pi} = -61 + 10 \times \log \frac{\eta_m C_v F_L P_1 P_2 c_0^4 G_f^2}{D_i^2} \quad \text{dB} \tag{15.52}$$

where D_i = internal diameter of downstream pipe, m
G_f = specific gravity of gas relative to air at 20°C
$c_0 = \sqrt{\gamma P_0/\rho_0}$, m/s (speed of sound)
γ = ratio of specific heats
ρ_0 = gas density at vena contracta, kg/m³

Pipe Transmission Loss Coefficient

Knowledge of the peak internal sound frequency f_p is crucial for a proper prediction of the pipe transmission loss coefficient T_L. The coefficient T_L does not vary significantly between the first cutoff frequency f_0 [see Eq. (15.58)] and the ring frequency f_R of the pipe (see lower curve in Fig. 15.21), but variations can be large at other frequencies. The slope of T_L is about −6 dB per octave below f_0 and +6 dB per octave above f_r.[28]

For Mach numbers in the pipe less than about 0.3 and for relatively heavy pipes (as found in typical process plants) it may be assumed that the *minimum*

TABLE 15.5 Important Pressure Ratios for Air[a]

F_L	0.5	0.6	0.7	0.8	0.9	1.0
P_1/P_2 critical	1.13	1.20	1.30	1.43	1.61	1.89
P_1/P_2 break	1.95	2.07	2.24	2.40	2.76	3.25
α Ratio	0.60	0.64	0.68	0.76	0.85	1.0
22α	13	14	15	16	19	22

Note: P_1/P_0 critical = 1.89.
[a]May be used for other gases with reasonable accuracy.

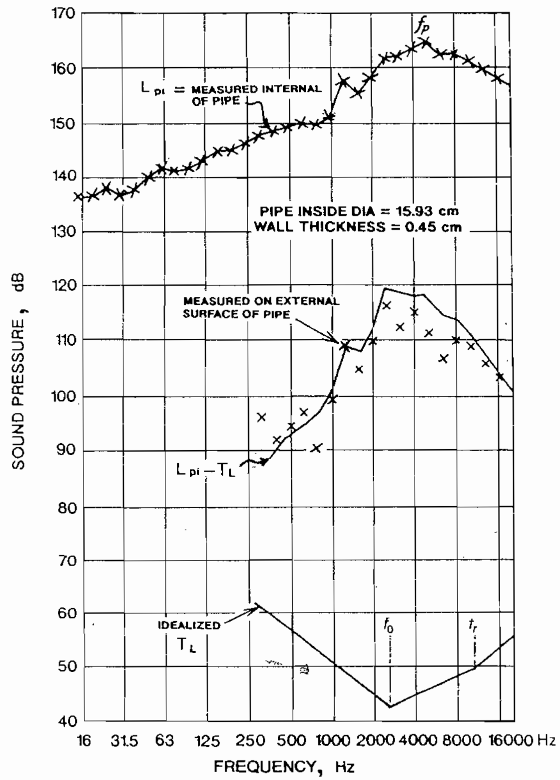

FIGURE 15.21 Test data taken on a 150-mm globe valve showing good agreement using the stated transmission loss equation. Notice the resultant shift in the peak sound frequency (f_p) from ~4.8 kHz inside the pipe to the first cutoff frequency of the pipe (f_0) at 2.5 kHz outside the pipe.

transmission loss occurs at f_0 and is given by[28]

$$T_{Lf_0} = 10 \times \log\left[9 \times 10^6 \frac{r t_p^2}{D_i^3}\left(\frac{P_2}{P_a} + 1\right)\right] \quad \text{dB} \tag{15.53}$$

where r = distance from pipe wall to observer, m
t_p = thickness of pipe wall, m
D_i = internal pipe diameter, m
P_2 = internal static pressure downstream of valve, Pa
P_a = external static pressure at same downstream distance, Pa

Typical values are given in Table 15.6. For fluids with higher sonic velocities and for thinner pipe walls, the minimum value of T_{Lf_0} shifts toward the ring frequency f_R [see Eq. (15.58)].

TABLE 15.6 Minimum Pipe Transmission Loss Coefficient T_{Lf_0}[a]

	Pipe Schedule	
Nominal Pipe Size, m	40	80
0.025	72	76
0.050	65	69
0.080	64	68
0.100	60	64
0.150	57	61
0.200	54	58
0.250	52	57
0.300	51	56
0.400	50	55
0.500	48	53

[a] At 1 m distance from steel pipe (dB) for 200 kPa internal and 100 kPa external air pressure. Pipe schedules per ANSI B36.10.

The total transmission loss coefficient for the valve is now expressed in the form

$$T_L = T_{Lf_0} + \Delta T_{Lf_p} \tag{15.54}$$

where the correction ΔT_{Lf_p} (in decibels) is determined by the peak noise frequency according to

$$\Delta T_{Lf_p} = \begin{cases} 20 \times \log \dfrac{f_0}{f_p} & f_p \le f_0 \\ 13 \times \log \dfrac{f_p}{f_0} & f_p \le 4 f_0 \\ 20 \times \log \dfrac{f_p}{4 f_0} + 7.8 & f_p > 4 f_0 \end{cases} \tag{15.55}$$

The peak frequency is estimated from[29]

$$f_p = \begin{cases} \dfrac{0.2 M_j c_0}{D_j} & M_j < 4 \\ \dfrac{0.28 c_0}{D_j \sqrt{M_j^2 - 1}} & M_j > 4 \end{cases} \tag{15.56}$$

where c_0 = speed of sound at vena contracta, m/s
D_j = jet diameter at valve orifice

and

$$M_j = \left\{\frac{2}{\gamma - 1}\left[\left(\frac{P_1}{\alpha P_2}\right)^{(\gamma-1)/\gamma} - 1\right]\right\}^{1/2} \tag{15.57}$$

$$f_R = \frac{c_L}{\pi D_i} = 4 f_0; \quad \text{for steel pipes and air} \quad f_R \approx \frac{5000}{\pi D_i} \tag{15.58}$$

For a gas other than air f_0 must be multiplied by $c_{0,\text{gas}}/c_{0,\text{air}}$.

The diameter D_j is difficult to determine because of the complex flow geometry in many valves. A reasonable approximation is to use the hydraulic diameter D_H as the jet diameter and make use of a valve-style modifier F_d (see Table 15.4) to obtain

$$D_j \approx 4.6 \times 10^{-3} F_d \sqrt{C_v F_L} \quad \text{m} \tag{15.59}$$

This formula is *not* applicable if jet portions combine downstream (usually at higher pressure ratios). This is common with multiple-hole valve cages,[30] short-stroke parabolic valve plugs in the "flow to close" direction, and butterfly valves at larger openings.

The external sound level (measured at 1 m from the wall) is now given by

$$L_a = 5 + L_{pi} - T_L - L_g \quad \text{dBA} \tag{15.60}$$

where L_g is a correction for fluid velocity in the pipe:

$$L_g = -16 \times \log\left(1 - \frac{1.3 \times 10^{-5} P_1 C_v F_L}{D_i^2 P_2}\right) \tag{15.61}$$

The laboratory test data shown in Fig. 15.21, taken with air on a DN150 globe valve, exhibits good agreement between predicted and measured external valve sound levels using T_L calculated from Eq. (15.54). In the absence of unusual phenomena such as jet "screech," Eq. (15.60) is found to be accurate to within ±3 dB assuming that all the valve coefficients are well established.

Accounting for Additional Noise due to High Velocities in Valve Outlet

Gas expanding in volume due to pressure reduction in a valve can cause high valve outlet velocities. These, in turn, can create secondary noise sources in the downstream pipe or pipe expander.[31,32]

The first step is to estimate the valve's outlet velocity (limited to sonic c_2):

$$U_R = 4 \frac{m}{\pi \rho_2 (d_i^2)} \tag{15.62}$$

where d_i is the valve diameter in meters.

The internal sound pressure level produced by this velocity is

$$L_{piR} = 65 + 10 \log\left(M_R^3 \frac{W_{mR}}{D_i^2}\right) \tag{15.63}$$

Here

$$W_{mR} = \frac{m}{2} U_R^2 \left[\left(1 - \frac{d_i^2}{D_i^2}\right) + 0.2\right] \tag{15.64}$$

and

$$M_R = \frac{U_R}{c_2} \tag{15.65}$$

Use Eq. (15.60) to calculate the external sound level L_R, substituting L_{piR} for L_{pi}, and using Eq. (15.54) to calculate TL, here substituting f_{pR} for f_p, where

$$f_{pR} = 0.2 \frac{U_R}{d_i} \tag{15.66}$$

The combined estimated external sound level at 1 m from the pipe from both the valve and the downstream piping now is

$$L_{ps} = 10 \log(10^{L_a/10} + 10^{L_R/10}) \tag{15.67}$$

The reader in encouraged to review reference 24, which illustrates the use of the prediction procedure in numerous examples.

Methods of Valve Noise Reduction

The two basic variables controlling the valve noise are the jet Mach number M_j and the internal peak frequency f_p. In subsonic flows lower jet velocities can be achieved by use of a valve trim that is less streamlined ($F_L \geq 0.9$, say).

At higher pressure ratios the only remedy is to use orifices or resistance paths in series, so that each operates subsonically. Such a "zig-zag" path valve is shown in Fig. 15.22. For example, for natural gas with an inlet pressure of 10,000 kPa that is to be throttled down to 5000 kPa and assuming a valve pressure recovery factor $F_L = 0.9$, the internal pressure ratio P_1/P_0 for a single-stage reduction would be $P_1/P_2\alpha = 2.35 : 1$. However, using the trim from Fig. 15.22 with 10 reduction steps, the orificial pressure ratio for each step is now only 1.603 : 1 with an acoustical power coefficient of only 1.1×10^{-7}. Ignoring the partial addition of 10 separate power sources, this represents a noise reduction of about 30 dB.

A less costly way to reduce "audible" valve noise is to increase the peak frequency by using multiorifice trim, as shown in Fig. 15.23. The throttling is still single stage, but the jets are divided into a number of parallel ports. This reduces the value of the valve style modifier $F_d \approx 1/\sqrt{n_o}$, where n_o is the number of equally sized parallel ports. Since F_d is proportional to jet diameter D_j, f_p can be shifted to higher levels. Thus if $n_o = 16$, as in Fig. 15.23, $F_d = 0.25$ and f_p is four times higher than for a single orifice ($F_d = 1$) with the same total flow area. If the peak frequency occurs in the mass-controlled region, an overall reduction in the external (audible) sound level of $\Delta T_{Lf_p} = 20 \times \log(f_{p1}/f_{p0}) = 20 \times \log(1/0.25) \approx 12$ dB is achieved.

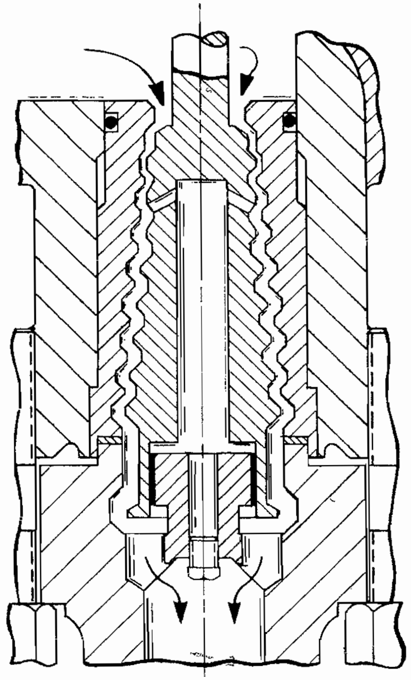

FIGURE 15.22 High-pressure reducing valve using multiple-step trim with a single flow path. Ideally each step will have subsonic orifice velocity.

The beneficial effects of a reduction in velocity combined with higher transmission loss caused by increased frequency are obtained with the elaborate arrangement shown in Fig. 15.24. This combines the multistep and multipath approach by use of a layer of disks having individually cast or etched channels.

A more economical solution is to couple a static downstream pressure-reducing device, such as a multihole restrictor, with a throttling valve with a fluted disk as indicated in Fig. 15.25. The fluted disk generates multiple jets with increased noise frequencies, although most of the energy is converted by the static pressure plate. At maximum design flow the valve is sized to have a low pressure ratio of 1.1 or 1.15 and the remainder of the pressure reduction occurs across the static plate having inherent low-noise throttling due to multistage, multihole design.

The most advanced and most compact form of a low noise valve trim is shown in Fig. 15.26. It consists of identical stamped or cut plates and constitutes a two-stage device, hence the narrow envelope. The device combines a supersonic first stage with a subsonic second stage for lowest overall acoustic efficiency, while retaining the final high frequency peak outlet sound level for high transmission losses.

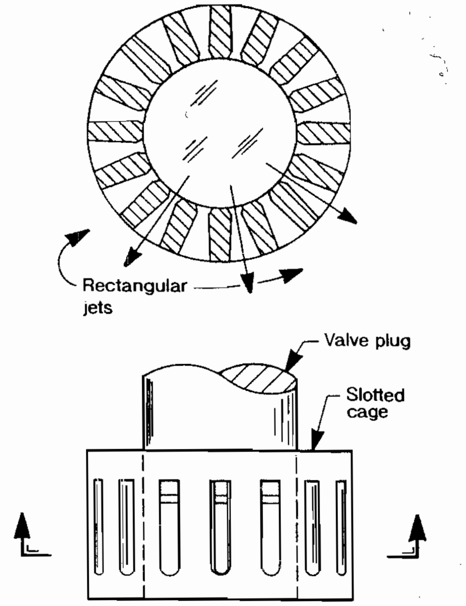

FIGURE 15.23 Slotted valve cage subdivides single-step flow path in 16 separate openings ($F_d = 0.25$) to increase peak frequency and thereby transmission loss.

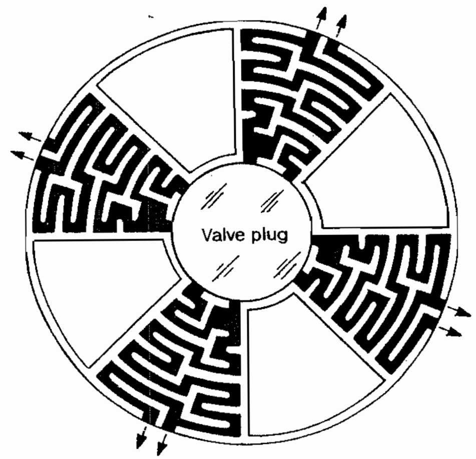

FIGURE 15.24 Labyrinth-type flow path cast or machined into each of a stack of metal plates surrounding a valve plug to provide a combination of multistep and multichannel flow paths in order to reduce throttling velocity and increase peak frequency.

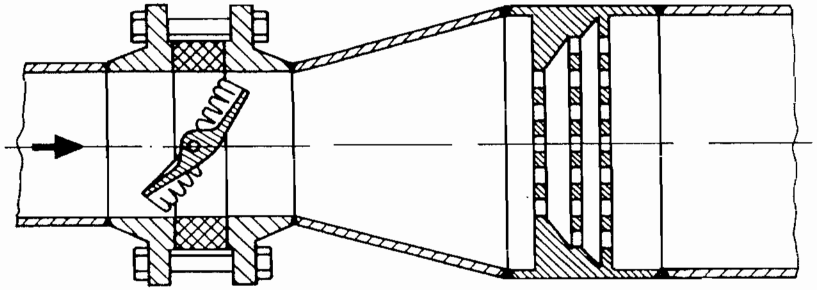

FIGURE 15.25 Modulating fluted butterfly valve cooperates with triple-stage static resistance plate for purposes of pressure reduction. Static plates see 90% of pressure drop at maximum design flow. Balance is handled by the valve.

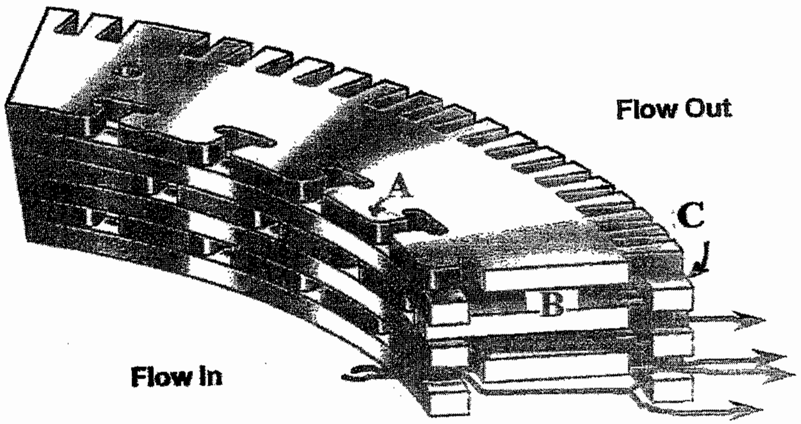

FIGURE 15.26 A stacked trim made from identical plates offers most advanced noise reduction. Here gas enters inlet orifices (A) configured as supersonic diffusers. These orifices convert about 95% of the stream power of the gas through a mechanism of shock waves; the gas then expands into sound-absorbing settling chambers (B) and finally exits the trim through a series of small subsonic passages (C).

Placing a silencer downstream of a valve is not cost effective because a good portion of the sound power travels upstream or radiates through the valve body and actuator, yielding noise reductions that typically do not exceed about 10 dB. Similar remarks apply to acoustical insulation of the pipe wall, where attenuations are limited to about 15 dB. The effectiveness of various abatement procedures is summarized below:

1. One-inch-thick pipe insulation: 5–10-dB reduction
2. Doubling thickness of pipe wall: 6-dB reduction

3. Silencer downstream: 10-dB reduction
4. Silencers upstream and downstream: 20-dB reduction
5. Multiport resistance plate downstream of valve: 15–20-dB reduction (use only 5–10% of valve inlet pressure as valve ΔP at maximum flow)
6. Special low-noise valve: 15–30-dB reduction

ACKNOWLEDGMENT

The authors wish to acknowledge the contribution of Dr. M. H. Howe for the portions of this chapter that have been retained from previous editions of this book.

CHAPTER 16

Prediction of Machinery Noise

ERIC W. WOOD AND JAMES D. BARNES

Acentech, Inc.
Cambridge, Massachusetts

Engineering information and prediction procedures are presented describing the sound power emission characteristics of various industrial machinery. The types of equipment addressed in this chapter include air compressors, boilers, coal-handling equipment, cooling towers, air-cooled condensers, diesel-engine-powered equipment, fans, feed pumps, gas turbines, steam turbines, steam vents, transformers, and wind turbines. The information has been extracted from consulting project files and the results of field measurement programs. The machinery noise prediction procedures are based on studies of empirical field data sponsored by numerous clients, including the Edison Electric Institute and the Empire State Electric Energy Research Corporation, for whom references 1–3 were prepared with the authors' colleagues: Robert M. Hoover, Laymon N. Miller, Susan L. Patterson, Anthony R. Thompson, and István L. Vér.

Characteristics identified and described for the noise produced by the machines discussed in this chapter include the estimated overall, A-weighted, and octave-band sound power levels (L_w) in dB re 1 pW, general directivity and tonal characteristics observed in the far field of the source, and temporal characteristics associated with the source operation. In addition, noise abatement concepts that have proven to be useful to the authors during previous consulting projects are described briefly. Successful noise control treatments often require a detailed understanding of site-specific operating and maintenance requirements as well as pertinent acoustical conditions at the site. We suggest that acoustical design handbooks or experienced acoustical engineering professionals be consulted when guidance is needed for specific design applications.

The information and procedures presented here can be used for numerous engineering applications requiring predictions of the approximate acoustical characteristics of new machinery installations and estimates of the noise attenuation that may be needed to meet local requirements. The prediction procedures are expected to provide A-weighted sound-power-level estimates that are generally accurate to within about ±3 dB. Individual octave-band sound-power-level estimates will necessarily be somewhat less accurate than A-weighted

CHAPTER 16

Prediction of Machinery Noise

ERIC W. WOOD AND JAMES D. BARNES

Acentech, Inc.
Cambridge, Massachusetts

Engineering information and prediction procedures are presented describing the sound power emission characteristics of various industrial machinery. The types of equipment addressed in this chapter include air compressors, boilers, coal-handling equipment, cooling towers, air-cooled condensers, diesel-engine-powered equipment, fans, feed pumps, gas turbines, steam turbines, steam vents, transformers, and wind turbines. The information has been extracted from consulting project files and the results of field measurement programs. The machinery noise prediction procedures are based on studies of empirical field data sponsored by numerous clients, including the Edison Electric Institute and the Empire State Electric Energy Research Corporation, for whom references 1–3 were prepared with the authors' colleagues: Robert M. Hoover, Laymon N. Miller, Susan L. Patterson, Anthony R. Thompson, and István L. Vér.

Characteristics identified and described for the noise produced by the machines discussed in this chapter include the estimated overall, A-weighted, and octave-band sound power levels (L_w) in dB re 1 pW, general directivity and tonal characteristics observed in the far field of the source, and temporal characteristics associated with the source operation. In addition, noise abatement concepts that have proven to be useful to the authors during previous consulting projects are described briefly. Successful noise control treatments often require a detailed understanding of site-specific operating and maintenance requirements as well as pertinent acoustical conditions at the site. We suggest that acoustical design handbooks or experienced acoustical engineering professionals be consulted when guidance is needed for specific design applications.

The information and procedures presented here can be used for numerous engineering applications requiring predictions of the approximate acoustical characteristics of new machinery installations and estimates of the noise attenuation that may be needed to meet local requirements. The prediction procedures are expected to provide A-weighted sound-power-level estimates that are generally accurate to within about ±3 dB. Individual octave-band sound-power-level estimates will necessarily be somewhat less accurate than A-weighted sound-power-level estimates. The prediction procedures estimate the equivalent (energy average) L_{eq} sound power level during operation of one machine. For equipment with intermittent operating cycles, the estimated sound power levels may be reduced by 10 log (operating cycle) if long-term equivalent values are required. When several identical machines are operating simultaneously, the sound power levels can be increased by 10 log (number of machines). When equipment is located within a large plant, other nearby large equipment may provide some shielding that will reduce the noise radiated to distant neighbors in shielded directions (see Chapter 7). When equipment is located within an enclosed plant, a portion of the acoustical energy will be dissipated inside the plant, leading to further reductions in the far-field noise. One should note that doors, windows, and ventilation openings can substantially diminish the acoustical performance (composite sound transmission loss) of building exterior walls (see Chapter 12).

The reader should try to obtain actual field data and/or manufacturers' information whenever possible for machines being studied. Information about the noise produced by gas flows and fans in buildings is presented in Chapters 15 and 17. Noise abatement information is provided in several other chapters. Indoor sound field characteristics are described in Chapters 6 and 7, and outdoor sound propagation is discussed in Chapter 5. The noise emission information provided in this chapter is representative of equipment presently available in the United States. Equipment in use in other countries may produce noise levels that are somewhat different than presented here. Prediction formulas for the overall sound power level are provided in the text of this chapter. Adjustments to predict the A-weighted and octave-band sound power levels are provided in Table 16.1.
